Papillomaviruses are tumor viruses that cause both cancerous and benign lesions in a host. Replication of papillomaviral DNA within a host cell requires the multifunctional 605-residue viral *E1* protein. Monomers of E1 assemble at a replication origin on DNA and form a pair of hexamers that wrap around a single strand of DNA. These assemblies are helicases that operate bidirectionally in the replication of viral DNA. The N-terminal half of the E1 protein includes a regulatory domain and a sequence-specific DNA-binding domain, whereas the helicase activity is located in the C-terminal half of the protein. The C-terminal helicase domain (Figure 16.21) includes a segment involved in oligomer formation (residues 300 to 378) and an AAA+ domain (residues 379 to 605).

AAA+ domains are found in proteins of many functions, including motor activity by dyneins (see Section 16.3) and helicases, protein degradation by proteasomes (see Chapter 31), and disassembly of SNARE complexes (see Chapter 9). This ubiquitous module consists of two subdomains: an N-terminal nucleotide-binding segment known as an α/β **Rossmann fold**, and a C-terminal α -helical domain (Figure 16.22). The Rossmann fold is wedge-shaped and has a β -sheet of parallel strands in a $\beta 5$ - $\beta 1$ - $\beta 4$ - $\beta 3$ - $\beta 2$ pattern. Key features of this fold include a Lys residue in the Walker A motif, an Asp–Asp or Asp–Glu pair in the Walker B motif, and a crucial Arg residue in a structure called an **arginine finger**. These three motifs are essential for ATP binding and hydrolysis. In an AAA+ hexamer, the ATP-binding sites lie at the interface between any two subunits, involving the arginine finger of any given subunit and the Walker A and Walker B motifs of the adjacent subunit.

The structure of a large fragment (residues 306 to 577) of the papillomavirus E1 protein bound to a segment of ssDNA (Figure 16.23) reveals the remarkable mechanism by which this helicase traverses a DNA chain. The oligomerization domains form a symmetric hexamer, but the six AAA+ domains each display a unique conformation. The DNA strand is bound in the center pore of the AAA+ hexamer, with six nucleotides of the DNA chain each bound to residues from each of the protein subunits. The crucial nucleotide-binding residues include Lys⁵⁰⁶ and His⁵⁰⁷ on a hairpin loop and Phe⁴⁶⁴, all of which face the center pore of the protein (Figure 16.24). Lys⁵⁰⁶ interacts with one DNA phosphate oxygen, and His⁵⁰⁷ forms a hydrogen bond with the phosphate of an adjacent

Figure 16.21 Structure of the papillomavirus E1 helicase. (a) The papillomavirus E1 protein is a 605-residue monomer that forms hexameric assemblies at specific sites on single-stranded DNA (PDB id = 2V9P). (b) The C-terminal helicase domain shown here includes an oligomerization domain (magenta) and the AAA+ domain (blue).

Figure 16.22 The AAA+ domain is composed of an N-terminal, wedge-shaped Rossmann fold and a C-terminal α -helical domain (upper left). The P-loop (red), the Walker B motif (yellow), and the arginine finger (blue) are shown. The ATP-binding sites lie between subunits of the hexamer. Each ATP site includes the arginine finger of one subunit and the Walker A and Walker B motifs of the adjacent subunit (PDB id = 1D2N).

Figure 16.23 A view of the E1 helicase along the ssDNA axis, showing the DNA-binding hairpin loops from each monomer (*colored*) interacting with the phosphates of DNA. DNA is shown as a ball-and-stick model in the center of the structure (PDB id = 2GXA).

Figure 16.24 The hairpin loops of each subunit in the E1 helicase interact with two adjacent nucleotides in the DNA chain. Interactions include an ionic bond between Lys⁵⁰⁶ (*yellow*) and a DNA phosphate oxygen, a hydrogen bond between His⁵⁰⁷ and the phosphate of an adjacent nucleotide, and van der Waals interactions between the aromatic rings of Phe⁴⁶⁴ (*purple*) and His⁵⁰⁷ (*olive*) and the aliphatic chain of Lys⁵⁰⁶, with the sugar linking the two phosphates (PDB id = 2GXA).

nucleotide in the DNA chain. The aliphatic portion of Lys⁵⁰⁶ and the aromatic groups of Phe⁴⁶⁴ and His⁵⁰⁷ share van der Waals interactions with the DNA sugar moiety linking these two phosphates. The hairpin loops of the six protein subunits form a spiral staircase, following the ssDNA as it threads through the central pore of the hexamer (Figure 16.25).

A central hairpin loop from one of the AAA+ subunits coordinates each DNA nucleotide as it enters the helicase pore. Then, as each AAA+ domain proceeds through the intermediate states of ATP binding and hydrolysis, its hairpin loop steps down through the six conformations of the staircase, maintaining continuous contact with its nucleotide, as it escorts it through the pore, finally releasing the nucleotide as it exits the pore. Following release, the hairpin moves back to the top of the staircase, picks up the next available nucleotide, and begins another journey down the staircase. For one full cycle of the hexamer, each subunit hydrolyzes one ATP, releases one ADP, and translocates one nucleotide through the central pore. A full cycle thus translocates six nucleotides with associated hydrolysis of six ATPs and release of six ADPs.

Figure 16.25 The hairpin loops of the E1 helicase hexamer are arranged in a spiral staircase that winds around the DNA strand. **(a)** Axial view (PDB id = 2GXA) and **(b)** the coordinated escort mechanism for DNA translocation by sequential ATP hydrolysis. As the helicase moves along the strand, the hairpin loop of one protein monomer binds each nucleotide as it enters the central cavity of the helicase. The loop adopts six conformations as the helicase moves along the DNA, preserving the loop–nucleotide interaction until the nucleotide exits the cavity. The released protein loop then returns to the other end of the cavity to bind a new, incoming nucleotide. Every sixth nucleotide of DNA is colored *black* and is escorted by the purple *hairpin*. 16.5 | How Do Bacterial Flagella Use a Proton Gradient to Drive Rotation?

Bacterial cells swim and move by rotating their flagella using a family of motor proteins that are very different from those already described in this chapter. The flagella of *E. coli* are helical filaments up to 15,000 nm (15 μm) in length and 15 nm in diameter. The direction of rotation of these filaments affects the movements of the cell. When the half-dozen flagella on the surface of the bacterial cell rotate in a counter-clockwise (CCW) direction, they twist and bundle together in a left-handed helical structure and rotate in a concerted fashion, propelling the cell through the medium. Every few seconds, the flagellar motor reverses, the helical bundle of filaments (now turning clockwise, or CW) unwinds into a jumble, and the bacterium somersaults or

tumbles. Alternating between CCW and CW rotations, the bacterium can move toward food sources, such as amino acids and sugars.

The rotations of bacterial flagellar filaments are the result of the rotation of motor protein complexes in the bacterial plasma membrane.

16.5a The Flagellar Rotor Is a Complex Structure

The flagellum is built from at least 25 proteins and comprises three parts: a rotary motor anchored in the bacterial inner membrane, a long filament that serves as a helical propeller, and a hook that functions as a universal joint that connects the motor with the filament (Figure 16.26). The long filament is composed of many copies of a globular protein called **flagellin**. The rotary motor includes several rings of protein subunits, including the C ring, the MS ring, the P ring, and the L ring. The MS ring is built from 26 copies of the protein FliF. The C ring is attached to the MS ring and includes three *rotor* proteins—FliG, FliM, and FliN—involved in rotation of the motor. The C ring includes 26 copies of FliG, 34 copies of FliM, and $34 \times 4 = 136$ copies of FliN. The stationary portion of the motor—the *stator*—is formed from the proteins motA and motB. Eight motA₄–motB₂ complexes are embedded in the bacterial inner membrane around the MS ring.

16.5b Gradients of H⁺ and Na⁺ Drive Flagellar Rotors

What energy source drives the flagellar motor? Gradients of protons and Na⁺ ions exist across bacterial inner membranes, typically with more H⁺ and Na⁺ outside the cell. In *E. coli*, spontaneous inward flow of protons through the motA–motB complexes drives the rotation of the motor (Figure 16.27). In *Vibrio cholerae*, inward Na⁺ ion flow powers the motor. Flagellar motors are thus energy conversion devices. In *E. coli*, each motA–motB complex passes 70 H⁺ per revolution of the motor. With a full complement of eight motA–motB complexes, a motor conducts about 560 protons per revolution. The H⁺-driven flagellar rotors reach top rotational speeds of about 360 Hz (corresponding to 21,600 rpm). Thus, the overall rate of proton flow for the motor is approximately 200,000 H⁺/sec! Flagellar motors driven by Na⁺ ions are even faster, with rotational rates of 1700 Hz (100,000 rpm) observed in *V. cholerae*.

The motA–motB complexes work with FliG in the C ring to transfer protons across the membrane. FliG contains 335 residues, and most of the FliG protein structure (residues 104 to 335) consists of two compact domains joined by an α -helix (Figure 16.27). A ridge on the C-terminal domain contains five charged residues that interact with motA and are important for motor rotation. Asp³² of motB is essential for rotation of the motor and is probably involved in proton transfer. Two membrane channels from the transmembrane segments of the motA₄–motB₂ complex also participate in proton movement. Each encounter of a motA–motB complex with a FliG subunit as the motor turns results in movement of one proton through each of these channels. The passage of about 70 H⁺ through each motA–motB complex in one revolution of the motor (which would involve encounters with 34 FliG subunits) is consistent with this suggestion ($70/34 \approx 2$).

16.5c The Flagellar Rotor Self-Assembles in a Spontaneous Process

Flagellar rotors are true masterpieces of biological self-assembly. The ring of FliF subunits, within the MS ring, is the first to assemble in the plasma membrane. Other proteins then attach to this ring one after another, from the base to the tip, to construct the motor structure. Once the motor has formed, the flexible hook and the flagellar filament are assembled. Precise recognition of the existing template structure allows this highly ordered self-assembly process to proceed without error. The flagellar filament is made from 20,000 to 30,000 copies of flagellin polymerized into a hollow

helical tube structure. Each turn of the helical filament contains about 5000 flagellin subunits and is about 2300 nm long. A complete flagellum can have up to six full helical turns. Flagellin molecules are transported through the long, narrow, central channel of the motor and flagellum from the cell interior to the far end of the flagellum, where they self-assemble with the help of a pentameric complex of *FliD*, a capping protein (see Figure 16.26). The *FliD* complex has a plate and five leg domains. It rotates in a stepping fashion at the end of the filament, exposing one binding site at a time and guiding the binding of newly arriving flagellin molecules in a helical pattern.

16.5d Flagellar Filaments Are Composed of Protofilaments of Flagellin

Each cylindrical flagellar filament is composed of 11 fibrils or **protofilaments** (component filaments) that form the cylinder, with each fibril lying at a slight tilt to the cylinder axis (Figure 16.28a). An end-on view of the filament shows 11 subunits, each representing the end of a protofilament (Figure 16.28b). The flagellin protein of *Salmonella typhimurium* contains 494 residues and consists of four domains, denoted D0 through D3 (Figure 16.28c). D0 and D1 are composed of α -helices, whereas D2 and D3 consist primarily of β -strands. The N-terminus of the peptide chain lies at the base of D0. The peptide runs from D0 to D3 and then reverses and returns to D0, where the N- and C-termini are juxtaposed. The structure resembles a Greek capital gamma (Γ), with a height of 140 Å and a width of 110 Å. Each flagellin protein is arranged with D0 inside the filament and D3 facing the outside. The central pore, 20 Å in diameter, is lined by the α -helices of D0.

16.5e Motor Reversal Involves Conformation Switching of Motor and Filament Proteins

The flagellar motor reverses direction every few seconds so that the bacterium can change its swimming direction to seek better environments. Motor reversal involves conformation changes both in motor proteins and also in the filament itself. In the motor structure, the rotor proteins *FliG*, *FliM*, and *FliN* work together to control direction changes of the motor, and they are known collectively as the **switch complex**. *FliN* appears to lie at the base of the C ring, *FliG* lies at the top of the C ring, and *FliM* resides in the middle, contacting both *FliN* and *FliG* (see Figure 16.26).

Reversal of the flagellar motor causes the long filament to switch from a left-handed (L) helical structure to a right-handed (R) helical form. This makes the bundle of flagella fall apart, causing the bacterium to tumble. This left-to-right switch in the filament is caused by a conformational change that occurs in the flagellin subunits in some protofilaments. Interestingly, the driving force for these conformation changes is probably the torque applied to D0 and D1 of flagellin subunits along the filament when the motor itself reverses.

Figure 16.26 A model of the *E. coli* flagellar motor. The motor is anchored by interactions of stationary *motA* and *motB* proteins in the M and S rings with the inner membrane. Spontaneous flow of protons through the *motA*–*motB* complexes and into the cell drives the rotation of the motor. Flow rates of 200,000 protons per second drive the motor at speeds approaching 22,000 rpm. (Adapted from Thomas, D. R., Morgan, D. G., Francis, N. R., and DeRosier, D. J., 2007. Bit by bit The structure of the complete flagellar hook/basal body complex. *Microscopy and Microanalysis* 13:34–35. Image provided by David J. DeRosier, Brandeis University.)

Figure 16.27 Interactions between the stationary motA-motB complexes and the rotating FliG ring drive the flagellar motor. Proton flow through the motA-motB complexes is presumably coupled to conformation changes that alter ionic interactions between charged residues at the motA-motB and FliG interface, driving rotation of the FliG ring. Other conserved features include a hydrophobic patch (light green), a Gly-Gly motif (purple), and a EHPQR motif (blue, in the middle domain (PDB id = 1LKV).

Figure 16.28 The *E. coli* flagellum is composed of 11 protofilaments that run the length of the flagellar filament. The filament is shown in (a) cross section and (b) perpendicular to the filament. The protofilaments are long polymers of the flagellin protein (c), which consists of two α -helical domains (D0 and D1) that lie at a slight tilt to the filament axis and two β -sheet domains (D2 and D3) that extend outward from the filament. Flagellin is shown in two conformation forms, R (left; PDB id = 1UCU) and L (right; PDB id = 3A5X). (Parts (a) and (b) courtesy of Keiichi Namba, Osaka University, Japan.)

Foundational Biochemistry Things You Should Know after Reading Chapter 16.

- Molecular motors convert the chemical energy of ATP to the mechanical energy of motion.
- Linear motors crawl or creep along a polymer lattice.
- Rotating motors consist of a rotating element (the rotor) and a stationary element (the stator).
- The cells of skeletal muscle are long and multinucleate and are referred to as muscle fibers.
- Release of Ca^{2+} ions from the sarcoplasmic reticulum triggers muscle contraction.
- The thin filaments of skeletal muscle are composed of actin monomers associated in long polymers.
- The thick filaments of skeletal muscle are composed primarily of myosin.
- The heavy chain of myosin is comprised of a large globular head and a long tail. The tails of two heavy chains intertwine to form a coiled coil.
- The P-loop NTPases harness the energy of ATP to accomplish a variety of cellular functions including those of molecular motors.
- The shortening of sarcomeres involves sliding motions in opposing directions at the two ends of a myosin thick filament.
- ATP lowers the viscosity of solutions of myosin and actin, indicating that ATP decreases the affinity of myosin for actin.
- ATP hydrolysis drives conformation changes in the myosin heads that mediate muscle contraction.
- The cytoskeleton is a dynamic, three-dimensional structure that establishes cell shape, provides mechanical strength, facilitates cell movement, supports intracellular transport and guides chromosome separation during mitosis and meiosis.
- The cytoskeleton is comprised of microfilaments of actin, microtubules of tubulin, and intermediate filaments.
- Tubulin is an $\alpha\beta$ dimeric protein that polymerizes to form microtubules.
- Microtubules in vitro undergo treadmilling, adding $\alpha\beta$ dimers on the plus end and removing dimers on the minus end.
- Myosins, kinesins, and dyneins are the motor proteins that transport cellular cargo.
- Kinesin 1 (conventional kinesin) is a tetramer consisting of two heavy chains and two light chains.
- Cytoplasmic dynein consists of two heavy chains and several light chains.
- Dyneins move organelles in a plus-to-minus direction, from the cell periphery to the centrosome.
- Kinesins move organelles in a minus-to-plus direction, resulting in outward movement of organelles and vesicles.
- Cytoskeletal motors are highly processive.
- ATP binding and hydrolysis drives hand-over-hand movement of kinesin.
- ATP hydrolysis drives conformation changes that facilitate movement of the dynein stalk along microtubules.
- Helicases are translocases that unwind DNA and RNA duplex substrates, either $3' \rightarrow 5'$ or $5' \rightarrow 3'$.
- Negative cooperativity facilitates hand-over-hand movement of Rep helicase along DNA.
- The hairpin loops of papillomavirus are arranged in a spiral staircase that winds around a DNA strand.
- Rotation of flagellar rotors of many bacteria are driven by spontaneous proton flow across the membrane.
- Flow rates of 200,000 protons per second drive the flagellar motor at speeds approaching 22,000 rpm. Reversal of the flagellar motor causes the long filament to switch from a left-handed helical structure to a right-handed helical form.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Assessing the Performance Consequences of Skeletal Muscle Anatomy** The cheetah is generally regarded as nature's fastest mammal, but another amazing athlete in the animal kingdom (and almost as fast as the cheetah) is the pronghorn antelope, which roams the plains of Wyoming. Whereas the cheetah can maintain its top speed of 70 mph for only a few seconds, the pronghorn antelope can run at 60 mph for about an hour! (It is thought to have evolved to do so in order to elude now-extinct ancestral cheetahs that lived in North America.) What differences would you expect in the muscle structure and anatomy of pronghorn antelopes that could account for their remarkable speed and endurance?
- Analyzing the Action of a Muscle Contraction Inhibitor** An ATP analog, β,γ -methylene-ATP, in which a $-\text{CH}_2-$ group replaces the oxygen atom between the β - and γ -phosphorus atoms, is a potent inhibitor of muscle contraction. At which step in the contraction cycle would you expect β,γ -methylene-ATP to block contraction?
- Understanding the Role of Phosphocreatine** ATP stores in muscle are augmented or supplemented by stores of phosphocreatine. During periods of contraction, phosphocreatine is hydrolyzed to drive the synthesis of needed ATP in the creatine kinase reaction:

Muscle cells contain two different isozymes of creatine kinase, one in the mitochondria and one in the sarcoplasm. Explain.

- Understanding the Biochemistry of Rigor Mortis** *Rigor* is a muscle condition in which muscle fibers, depleted of ATP and phosphocreatine, develop a state of extreme rigidity and cannot be easily extended. (In death, this state is called *rigor mortis*, the rigor of death.) From what you have learned about muscle contraction, explain the state of rigor in molecular terms.
- Assessing the Contraction Potential of Human Muscle** Skeletal muscle can generate approximately 3 to 4 kg of tension or force per square centimeter of cross-sectional area. This number is roughly the same for all mammals. Because many human muscles have large cross-sectional areas, the force that these muscles can (and must) generate is prodigious. The gluteus maximus (on which you are probably sitting as you read this) can generate a tension of 1200 kg! Estimate the cross-sectional area of all of the muscles in your body and the total force that your skeletal muscles could generate if they all contracted at once.
- Understanding the Structure of Tubulin** Calculate a diameter for a tubulin monomer, assuming that the monomer MW is 55,000, that the monomer is spherical, and that the density of the protein monomer is 1.3 g/mL. How does the number that you calculate compare to the dimension portrayed in Figure 16.12?

7. **Structure of Tubulin** Considering the function of tubulin inside cells, suggest an explanation for why it is built from two different subunits, α and β (see Figure 16.12), and not from one type of subunit or from three or more different subunits.
8. **Assessing the Tubulin Content of a Liver Cell** Use the number you obtained in problem 6 to calculate how many tubulin monomers would be found in a microtubule that stretched across the length of a liver cell. (See Table 1.1 for the diameter of a liver cell.)
9. **Understanding Axonal Vesicle Transport** The giant axon of the squid may be up to 4 inches in length. Use the value cited in this chapter for the rate of movement of vesicles and organelles across axons to determine the time required for a vesicle to traverse the length of this axon.
10. **Axonal Vesicle Transport** If an axon is 3.5 inches long, how much time will it take for a vesicle to be transported down its entire length? If a typical tubulin dimer has a length of 80 Å, how many dimers are needed to cover this axonal length?
11. **Understanding the Molecular Structure of Myosin** As noted in this chapter, the myosin molecules in thick filaments of muscle are offset by approximately 14 nm. How many residues of a coiled-coil structure are needed to span 14 nm?
12. **Structure of Myosin** Revisit Figure 16.5a for a model of myosin. What is the function of LC 1?
13. **Myosin's Coiled Coils** Consider the peptide segments shown. Which sequence best fits the requirements for the coiled coil structure of myosin? Explain your answer.
 - a) V E D W G R Q
 - b) A D K V T E F
 - c) D R E A C H W
 - d) A R E V N Y I
14. **Assessing the Energetics of Sarcoplasmic Reticulum Calcium Transport** Use the equations of Chapter 9 to determine the free energy difference represented by a Ca^{2+} gradient across the sarcoplasmic reticulum membrane if the luminal (inside) concentration of Ca^{2+} is 1 mM and the concentration of Ca^{2+} in the solution bathing the muscle fibers is 1 μM .
15. **Understanding the Energetic Driving Force of the Ca-ATPase** Use the equations of Chapter 3 to determine the free energy of hydrolysis of ATP by the sarcoplasmic reticulum Ca-ATPase if the concentration of ATP is 3 mM, the concentration of ADP is 1 mM, and the concentration of P_i is 2 mM.
16. **Energetics of ATPase Activity** (Integrates with Chapter 3) Make a graph relating the free energy (ΔG in kJ/mol) for the hydrolysis of ATP at differing ratios of [ADP] to [ATP] (ranging from 0.01 to 10) if the concentration of phosphate [P_i] is constant at 20 mM and ΔG^0 for the hydrolysis is -35.7 kJ/mol (see Table 3.1).
17. **Understanding the Stoichiometry of Sarcoplasmic Reticulum Calcium Transport** Under the conditions described in problems 15 and 16. What is the maximum number of Ca^{2+} ions that could be transported per ATP hydrolyzed by the Ca-ATPase?
18. **Understanding the Energetics of Motor Proteins** For each of the motor proteins in Table 16.2, calculate the force exerted over the step size given, assuming that the free energy of hydrolysis of ATP under cellular conditions is -50 kJ/mol.
19. **Relating Myosin Function and Stoichiometry to Weight Lifting** When you go to the gym to work out, you not only exercise many muscles but also involve many myosins (and actins) in any given exercise activity. Suppose you lift a 10 kg weight a total distance of 0.4 m. Using the data in Table 16.2 for myosin, calculate the minimum number of myosin heads required to lift this weight and the number of sliding steps these myosins must make along their associated actin filaments.
20. **Understanding Human Smooth Muscle** In which of the following tissues would you expect to find smooth muscle?
 - a. arteries
 - b. stomach
 - c. urinary bladder
 - d. diaphragm
 - e. uterus
 - f. The gums in your mouth.
21. **Analyzing the Mechanism of Muscle Contraction** When an action potential (nerve impulse) arrives at a muscle membrane (sarcolemma), in what order do the following events occur?
 - a. Release of Ca^{2+} ions from the sarcoplasmic reticulum.
 - b. Hydrolysis of ATP, with release of energy.
 - c. Detachment of myosin from actin.
 - d. Sliding of myosin along actin filament.
 - e. Opening of switch 1 and switch 2 on myosin head.
22. **Essay Question on the Functional Relevance of Molecular Motors** (Essay question.) You are invited by the National Science Foundation to attend a scientific meeting to set the agenda for funding of basic research related to molecular motors for the next 10 years. Only basic research will be funded, ruling out studies on human subjects. You are asked to suggest the research area most worthy of scientific research. Your presentation must include (1) a brief background on what we currently know about the subject; (2) identification of a key research topic about which more needs to be known; and (3) a justification of why additional knowledge in this area is critical for advancing the field (that is, why investigations in this area are especially important). You are not being asked to provide the methods or experiments that might be used to address the problem—only the concept. Base your presentation on what you have learned in this chapter (you may consult and include references from the Further Reading section), and limit your presentation to 300 words.
23. **Movement of Kinesin** Consult Figure 16.16 and use the data in problem 9 to determine how many steps a kinesin motor must take to traverse the length of the squid giant axon.
24. **Biochemistry of Muscle Cramps** When athletes overexert themselves on hot days, they often suffer immobility from painful muscle cramps. Which of the following is a reasonable hypothesis to explain such cramps?
 - a. Muscle cells do not have enough ATP for normal muscle relaxation.
 - b. Excessive sweating has affected the salt balance within the muscles.
 - c. Prolonged contractions have temporarily interrupted blood flow to parts of the muscle.
 - d. All of the above.
25. **Genetics of Duchenne Muscular Dystrophy** Duchenne muscular dystrophy is a sex-linked recessive disorder associated with severe deterioration of muscle tissue. The gene for the disease:
 - a. is inherited by males from their mothers.
 - b. should be more common in females than in males.
 - c. both a and b.
 - d. neither a nor b.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

26. Examine the PSAFE model for myosin II, and explain the function of each subunit.

27. Using the PSAFE model for the kinesin protein K1F1A, identify the function of switch 1, and explain why K1F1A cannot move cargo when switch 1 is bound to AMPPNP.
28. Using the PSAFE model for E1 helicase, describe the features of AAA+ domains.

Think-Pair-Share Question

Motor Proteins on Polysaccharides This chapter discussed the movement of motor proteins over protein- or DNA-based rails. Imagine the possibility that polysaccharides could be used as rails for motor proteins. What should be the chemical and physical requirements for such polysaccharides and for the motor proteins that could bind to them? Suggest at least three different properties. (Revisit the discussions of Chapter 7 for the structure and properties of polysaccharides.)

Metabolism: An Overview

17

Part III Metabolism and Its Regulation

Gray Harde/Corbis

*All is flux, nothing stays still.
Nothing endures but change.*

Heraclitus (c. 540–c. 480 B.C.)

◀ Anise swallowtail butterfly (*Papilio zelicanus*) with its pupal case. Metamorphosis of butterflies is a dramatic example of metabolic change.

Essential Question

The word *metabolism* derives from the Greek word for “change.” **Metabolism** represents the sum of the chemical changes that convert **nutrients**, the “raw materials” necessary to nourish living organisms, into energy and the chemically complex finished products of cells. **What are the chemical reactions that collectively constitute the metabolism of the cell?**

Metabolism consists of thousands of enzymatic reactions organized into discrete pathways. These pathways proceed in a stepwise fashion, transforming substrates into end products through many specific chemical intermediates, called **metabolites**. Metabolism is sometimes referred to as intermediary metabolism to reflect this aspect of the process.

17.1 | Is Metabolism Similar in Different Organisms?

One of the great unifying principles of modern biology is that organisms show marked similarity in their major pathways of metabolism. Given the almost unlimited possibilities within organic chemistry, this generality would seem unlikely. Yet it's true, and it provides strong evidence that all life has descended from a common ancestral form. All forms of nutrition and almost all metabolic pathways evolved in early prokaryotes prior to the appearance of eukaryotes 1 billion years ago. For example, **glycolysis**, the metabolic pathway by which energy is released from glucose and captured in the form of ATP under anaerobic conditions, is common to almost every cell. It is believed to be the most ancient of metabolic pathways, having arisen prior to the appearance of oxygen in abundance in the atmosphere. All organisms, even those that can synthesize their own glucose, are capable of glucose degradation and ATP synthesis via glycolysis. Other prominent pathways are also virtually ubiquitous among organisms.

Key Questions

- 17.1 Is Metabolism Similar in Different Organisms?

- 17.6 What Food Substances Form the Basis of Human Nutrition?

Classification	Carbon Source	Energy Source	Electron Donors	Examples
<i>Photoautotrophs</i>	CO ₂	Light	H ₂ O, H ₂ S, S, other inorganic compounds	Green plants, algae, cyanobacteria, photosynthetic bacteria
<i>Photoheterotrophs</i>	Organic compounds	Light	Organic compounds	Nonsulfur purple bacteria
<i>Chemoautotrophs</i>	CO ₂	Oxidation–reduction reactions	Inorganic compounds: H ₂ , H ₂ S, NH ₄ ⁺ , NO ₂ [−] , Fe ²⁺ , Mn ²⁺	Nitrifying bacteria; hydrogen, sulfur, and iron bacteria
<i>Chemoheterotrophs</i>	Organic compounds	Oxidation–reduction reactions	Organic compounds (e.g., glucose)	All animals, most microorganisms, nonphotosynthetic plant tissue such as roots, photosynthetic cells in the dark

17.1a Living Things Vary in Their Carbon and Energy Requirements

Although most cells have the same core set of central metabolic pathways, different cells (and, by extension, different organisms) are characterized by the alternative pathways they might express. These pathways offer a wide diversity of metabolic possibilities. For instance, organisms are often classified according to the major metabolic pathways they exploit to obtain carbon or energy. Classification based on carbon requirements defines two major groups: autotrophs and heterotrophs. **Autotrophs** are organisms that can use carbon dioxide as their only source of carbon. **Heterotrophs** require an organic form of carbon, such as glucose, in order to synthesize other essential carbon compounds.

Classification based on energy sources also gives two groups: phototrophs and chemotrophs. **Phototrophs** are *photosynthetic organisms*, which use light as a source of energy. **Chemotrophs** use organic compounds such as glucose or, in some instances, oxidizable inorganic substances such as Fe²⁺, NO₂[−], NH₄⁺, or elemental sulfur as sole sources of energy. Typically, the energy is extracted through oxidation–reduction reactions. Based on these characteristics, every organism falls into one of four categories (Table 17.1).

Metabolic Diversity Varies Across Life’s Five Kingdoms Prokaryotes (the kingdom Monera, which consists of archaea and bacteria) show a greater metabolic diversity than all the four eukaryotic kingdoms (Protista, Fungi, Plants, and Animals) put together. Prokaryotes are variously chemoheterotrophic, photoautotrophic, photoheterotrophic, or chemoautotrophic. No protists are chemoautotrophs; fungi and animals are exclusively chemoheterotrophs; and plants are characteristically photoautotrophs, although some are heterotrophic in their mode of carbon acquisition.

17.1b Oxygen Is Essential to Life for Aerobes

A further metabolic distinction among organisms is whether or not they can use oxygen as an electron acceptor in energy-producing pathways. Those that can are called **aerobes** or *aerobic organisms*; others, termed **anaerobes**, can subsist without O₂. Organisms for which O₂ is obligatory for life are called **obligate aerobes**; humans are an example. Some species, the so-called **facultative anaerobes**, can adapt to anaerobic conditions by substituting other electron acceptors for O₂ in their energy-producing pathways; *Escherichia coli* is an example. Yet others cannot use oxygen at all and are even poisoned by it; these are the **obligate anaerobes**. *Clostridium botulinum*, the bacterium that produces botulin toxin, is such an organism.

17.1c The Flow of Energy in the Biosphere and the Carbon and Oxygen Cycles Are Intimately Related

The primary source of energy for life is the sun. Photoautotrophs use light energy to drive the synthesis of organic molecules, such as carbohydrates, from atmospheric CO₂ and water (Figure 17.1). Molecular oxygen (O₂) is a by-product of this process. Heterotrophic cells then use these organic products of photosynthetic cells both as

Figure 17.1 The flow of energy in the biosphere is coupled primarily to the carbon and oxygen cycles.

A Deeper Look

Calcium Carbonate—A Biological Sink for CO₂

Carbon dioxide accumulation in the atmosphere is a major driver of global warming. A significant CO₂ sequestration site that is often overlooked is the calcium carbonate shells of corals, molluscs, and crustacea. These invertebrate animals deposit CaCO₃ in the form of protective exoskeletons. In some invertebrates, such as the *scleractinians* (hard corals) of tropical seas, photosynthetic dinoflagellates

(marine eukaryotic algae) live within the animal cells as **endosymbionts** called *zooxanthellae*. These phototrophic cells use light to drive the resynthesis of organic molecules from CO₂ released (as bicarbonate ion) by the animal's metabolic activity. In the presence of Ca²⁺, the photosynthetic CO₂ fixation pulls the deposition of CaCO₃, as summarized in the following coupled reactions:

fuels and as building blocks, or precursors, for the biosynthesis of their own unique complement of biomolecules. O₂ is reduced to water as a consequence of energy-releasing electron-transfer reactions that underlie the use of these organic fuels. Ultimately, CO₂ is the end product of heterotrophic carbon metabolism, and CO₂ is returned to the atmosphere for reuse by the photoautotrophs. In effect, solar energy is converted to the chemical energy of organic molecules by photoautotrophs, and heterotrophs recover this energy by oxidizing the organic substances. The flow of energy in the biosphere is thus conveyed within the carbon and oxygen cycles, and the force driving these cycles is light energy.

17.2 | What Can Be Learned from Metabolic Maps?

Metabolic maps (Figure 17.2) portray the principal reactions of the intermediary metabolism of carbohydrates, lipids, amino acids, nucleotides, and their derivatives. These maps are confusing at first glance and seem difficult to decipher. For now, view this map as an overview of the complexity of intermediary metabolism. Despite their appearance, these maps become easy to follow once the major metabolic routes are known and their functions are understood. The underlying order of metabolism and the important interrelationships between the various pathways then appear as simple patterns against the seemingly complicated background. An interactive version of the IUBMB-Sigma-Nicholson Metabolic Pathways chart is available online. In addition, both an atlas of human metabolism and a virtual metabolic human are available online. These tools allow users to model metabolic pathways and explore relationships between human health, disease, and nutrition.

17.2a The Metabolic Map Can Be Viewed as a Set of Dots and Lines

One interesting transformation of the intermediary metabolism map is to represent each intermediate as a black dot and each enzyme as a line (Figure 17.3). Then, the more than 1000 different enzymes and substrates depicted in Figure 17.2 are represented by just two symbols. This map has about 520 dots (metabolites or intermediates). This simplified map reveals the network nature of metabolism, where some intermediates (dots) have a variety of fates, depending upon which enzyme (line) might act on them. Table 17.2 lists the numbers of dots that have one or two or more lines (enzymes) associated with them. Thus, this table classifies intermediates by the number of enzymes that act upon them. A dot connected to just a single line must be either a nutrient, a storage form, an end product, or an excretory product of metabolism. Also, because many pathways tend to proceed in only one direction (that is, they are essentially irreversible under physiological conditions), a dot connected to just two lines is probably an intermediate in only one pathway and has only one fate in metabolism. If three lines are connected to a dot, that intermediate has at least two

Table 17.2 Number of Dots (Intermediates) in the Metabolic Map of Figure 17.2, and the Number of Lines Associated with Them	
Lines	Dots
1 or 2	410
3	71
4	20
5	11
6 or more	8

Figure 17.2 A metabolic map, indicating the reactions of intermediary metabolism and the enzymes that catalyze them. More than 500 different chemical intermediates, or metabolites, and a greater number of enzymes are represented here. (Source: From Donald Nicholson, Map #22, © International Union of Biochemistry and Molecular Biology.)

Figure 17.3 The metabolic map as a set of dots and lines. The heavy dots and lines trace the central energy-releasing pathways known as glycolysis and the citric acid cycle. (Adapted from Alberts, B., et al., *Molecular Biology of the Cell*, 2nd ed. New York: Garland Publishing Co., 1989.)

possible metabolic fates; four lines, three fates; and so on. Note that about 80% of the intermediates connect to only one or two lines and thus have only a single role in the cell. However, intermediates at branch points are subject to a variety of fates. In such instances, the pathway followed is an important regulatory choice. Indeed, whether any substrate is routed down a particular metabolic pathway is the consequence of a regulatory decision made in response to the cell's (or organism's) momentary requirements for energy or nutrition.

17.2b Alternative Metabolic Pathway Models Can Provide New Insights into Pathways

Alternative mappings of metabolic reactions have been proposed for several reasons. First the sheer complexity of pathways has prompted biochemists to seek simpler portrayals of an organism's chemistry. Second, traditional metabolite-focused maps (such as Figures 17.1 and 17.4a) do not provide insight into the essential role of enzymes

in metabolism. Even more significantly, the rise of **genomics** (the study of the whole genomes of organisms), **transcriptomics** (the study of global messenger RNA expression), and **proteomics** (the study of the totality of proteins) has provoked fresh interpretations of biological order and function. For example, Juliet Gerrard has proposed that metabolic maps be recast in *protein-centric* presentations (Figure 17.4b). In such maps, the metabolites and the enzymes that interconvert them are transposed, revealing a new emphasis—the metabolites are signals in a cellular network of proteins.

Protein-centric maps may be condensed and simplified by realizing that some pathway enzymes are clustered in *multienzyme complexes* and that metabolites are literally passed from enzyme to enzyme within such clusters (Figure 17.4c). The result is a simplified representation of metabolic networks, containing only the essential signaling information. Metabolic maps are representations of large amounts of information. Conceptualizing them in different formats enables biochemists to analyze vast amounts of information in new and insightful ways.

17.2c Metabolism Is a Network

The architecture of metabolism is typically presented as a collection of enzymes arranged in linear or cyclic pathways. These pathways are interconnected into a network consisting of thousands of metabolites and enzymes. In a metabolic network, intermediates can be described as nodes linked by the reactions that produce and consume them, as shown in Figure 17.2 and Table 17.1. A recent detailed study of metabolism in *E. coli* revealed a median connectivity of two nodes, but the average was 5.8.

Figure 17.4 Three different representations of a metabolic pathway. (a) The traditional view of a metabolic pathway is metabolite-centric. Metabolites are indicated by capital letters in blue circles; enzymes are indicated above the arrows by the letter E, with subscript numbers indicating different reactions. (b) The protein- (or enzyme-) centric view of Gerrard is more informative for some purposes. Here and in (c), metabolites are indicated by capital letters above the arrows; enzymes are indicated within yellow circles or boxes, with subscript numbers indicating different reactions. (c) A simplified version of the protein-centric view where proteins in the pathway form multifunctional complexes.

The average is skewed because P_i , ADP, and ATP (the three most connected metabolites) participate in more than a thousand different reactions. Of the more than 800 known metabolites in *E. coli*, roughly 500 participate in only a few reactions. Because metabolism shows such a high degree of connectivity, mathematical models are required to analyze it effectively. The scientific discipline in which computational and mathematical modeling is used to study biological systems is called **systems biology**.

17.2d Metabolic Pathways with Multiple Enzymes May Take Different Forms

Every metabolic pathway consists of sequential enzymatic steps (Figure 17.5). Several types of organization are possible. The enzymes of some multienzyme systems may exist as physically separate, soluble entities, with diffusing intermediates (Figure 17.5a). In other instances, the enzymes of a pathway are collected to form a discrete multienzyme complex, and the substrate is sequentially modified as it is passed along from enzyme to enzyme (Figure 17.5b). This type of organization has the advantage that intermediates are not lost or diluted by diffusion. In a third pattern of organization, the enzymes common to a pathway reside together as a *membrane-bound system* (Figure 17.5c). In this case, the enzyme participants (and perhaps the substrates as well) must diffuse in just the two dimensions of the membrane to interact with their neighbors.

As research reveals the ultrastructural organization of the cell in ever greater detail, more and more of the so-called soluble enzyme systems are found to be physically united into functional complexes. Thus, in many (perhaps all) metabolic pathways, the consecutively acting enzymes interact with one another to form stable aggregations that are sometimes referred to as **metabolons**, a word meaning “units of metabolism.” Further, in more highly evolved organisms such as birds and mammals, evolutionary processes have led to the fusion of genes encoding enzymes for several sequential steps in a metabolic pathway. Expression of the fused gene produces a single **multifunctional polypeptide** capable of catalyzing a series of steps in a pathway.

Figure 17.5 Schematic representation of types of multienzyme systems carrying out a metabolic pathway: **(a)** Physically separate, soluble enzymes with diffusing intermediates. **(b)** A multienzyme complex. Substrate enters the complex and becomes bound and then sequentially modified by enzymes E₁ to E₅ before product is released. No intermediates are free to diffuse away. **(c)** A membrane-bound multienzyme system.

Chemistry in History

Dr. Marie Maynard Daly

Dr. Marie Maynard Daly (1921–2003) contended with the twin adversities of sexism and segregation during her hard-fought climb through academia where she earned multiple degrees in chemistry. She earned her bachelor's degree from Queens College, her master's from New York University, and her PhD from Columbia University. This dedication led to her distinction as the first black woman in the United States to earn a chemistry PhD.

Dr. Daly is responsible for some of the earliest research on the relationship between diet, blood cholesterol levels, and cardiac health. She was also a major contributor to some of the foundational research in the structure and function of DNA. When Dr. Daly retired, she created a scholarship fund at Queens College to help African-American science students pursue their education.

17.3 How Do Anabolic and Catabolic Processes Form the Core of Metabolic Pathways?

Metabolism serves two fundamentally different purposes: the generation of energy to drive vital functions and the synthesis of biological molecules. To achieve these ends, metabolism consists largely of two contrasting processes: catabolism and anabolism. *Catabolic pathways are characteristically energy yielding, whereas anabolic pathways are energy requiring.* **Catabolism** involves the oxidative degradation of complex nutrient molecules (carbohydrates, lipids, and proteins) obtained either from the environment or from cellular reserves. The breakdown of these molecules by catabolism leads to the formation of simpler molecules such as lactic acid, ethanol, carbon dioxide, urea, or ammonia. Catabolic reactions are usually exergonic, and often the chemical energy released is captured in the form of ATP (see Chapter 3). Because catabolism is oxidative for the most part, part of the chemical energy may be conserved as energy-rich electrons transferred to the coenzymes NAD^+ (nicotinamide adenine dinucleotide) and NADP^+ (nicotinamide adenine dinucleotide phosphate). These two reduced coenzymes have very different metabolic roles: NAD^+ reduction is part of catabolism; NADPH oxidation is an important aspect of anabolism. The energy released upon oxidation of NADH is coupled to the phosphorylation of ADP in aerobic cells, and so NADH oxidation back to NAD^+ serves to generate more ATP. The coupled process by which NADH oxidation leads to ATP synthesis is called **oxidative phosphorylation**. Most of the ATP produced in aerobic cells arises via oxidative phosphorylation. In contrast, NADPH is the source of the reducing power needed to drive reductive biosynthetic reactions.

Thermodynamic considerations demand that the energy necessary for biosynthesis of any substance exceed the energy available from its catabolism. Otherwise, organisms could achieve the status of perpetual motion machines: A few molecules of substrate whose catabolism yielded more ATP than required for its resynthesis would allow the cell to cycle this substance and harvest an endless supply of energy.

17.3a Anabolism Is Biosynthesis

Anabolism is a biosynthetic process in which the varied and complex biomolecules (proteins, nucleic acids, polysaccharides, and lipids) are assembled from simpler precursors. Such biosynthesis involves the formation of new covalent bonds, and an input of chemical energy is necessary to drive these endergonic processes. The ATP generated by catabolism provides this energy. Furthermore, NADPH is an excellent donor of high-energy electrons for the reductive reactions of anabolism. Despite their divergent roles, anabolism and catabolism are interrelated in that the products of one provide the substrates of the other (Figure 17.6). Many metabolic intermediates are shared between the two processes, and the precursors needed by anabolic pathways are found among the products of catabolism.

17.3b Anabolism and Catabolism Are Not Mutually Exclusive

Interestingly, anabolism and catabolism occur simultaneously in the cell. The conflicting demands of concomitant catabolism and anabolism are managed by cells in two ways. First, the cell maintains tight and separate regulation of both catabolism

Figure 17.6 Energy relationships between the pathways of catabolism and anabolism. Oxidative, exergonic pathways of catabolism release free energy and reducing power that are captured in the form of ATP and NADPH, respectively. Anabolic processes are endergonic, consuming chemical energy in the form of ATP and using NADPH as a source of high-energy electrons for reductive purposes.

and anabolism, so metabolic needs are served in an immediate and orderly fashion. Second, competing metabolic pathways are often localized within different cellular compartments. Isolating opposing activities within distinct compartments, such as separate organelles, avoids interference between them. For example, the enzymes responsible for catabolism of fatty acids, the *fatty acid oxidation pathway*, are localized within mitochondria. In contrast, *fatty acid biosynthesis* takes place in the cytosol.

17.3c The Pathways of Catabolism Converge to a Few End Products

The catabolism of the principal energy-yielding nutrients (carbohydrates, lipids, and proteins) in a typical heterotrophic cell involves a succession of enzymatic reactions. In the presence of oxygen (*aerobic catabolism*), these molecules are degraded ultimately to carbon dioxide, water, and ammonia. Aerobic catabolism consists of three distinct stages. In **stage 1**, the nutrient macromolecules are broken down into their respective building blocks. Despite the great diversity of macromolecules, these building blocks represent a rather limited number of products. Proteins yield up their 20 component amino acids, polysaccharides give rise to carbohydrate units that are convertible to glucose, and lipids are broken down into glycerol and fatty acids (Figure 17.7).

In **stage 2**, the collection of product building blocks generated in stage 1 is further degraded to yield an even more limited set of simpler metabolic intermediates. The deamination of amino acids leaves α -keto acid carbon skeletons. Several of these α -keto acids are citric acid cycle intermediates and are fed directly into stage 3 catabolism via this cycle. Others are converted either to the three-carbon α -keto acid *pyruvate* or to the acetyl groups of *acetyl-coenzyme A* (acetyl-CoA). Glucose and the glycerol from lipids also generate pyruvate, whereas the fatty acids are broken into two-carbon units that appear as *acetyl-CoA*. Because pyruvate also gives rise to acetyl-CoA, we see that the degradation of macromolecular nutrients converges to a common end product, acetyl-CoA (Figure 17.7).

Stage 3 of catabolism involves the combustion of acetyl-CoA units in the citric acid cycle, an oxidative process that is coupled to NAD^+ reduction, so NADH is formed. CO_2 is a by-product. NADH oxidation through electron transfer to O_2 is coupled to ATP synthesis (*oxidative phosphorylation*), with H_2O as the by-product of O_2 reduction. Thus, CO_2 and H_2O are the ultimate waste products of aerobic catabolism. Stage 3 metabolism generates most of the energy produced by the cell.

17.3d Anabolic Pathways Diverge, Synthesizing an Astounding Variety of Biomolecules from a Limited Set of Building Blocks

A rather limited collection of simple precursor molecules is sufficient to provide for the biosynthesis of virtually any cellular constituent, be it protein, nucleic acid, lipid, or polysaccharide. All of these substances are constructed from appropriate building

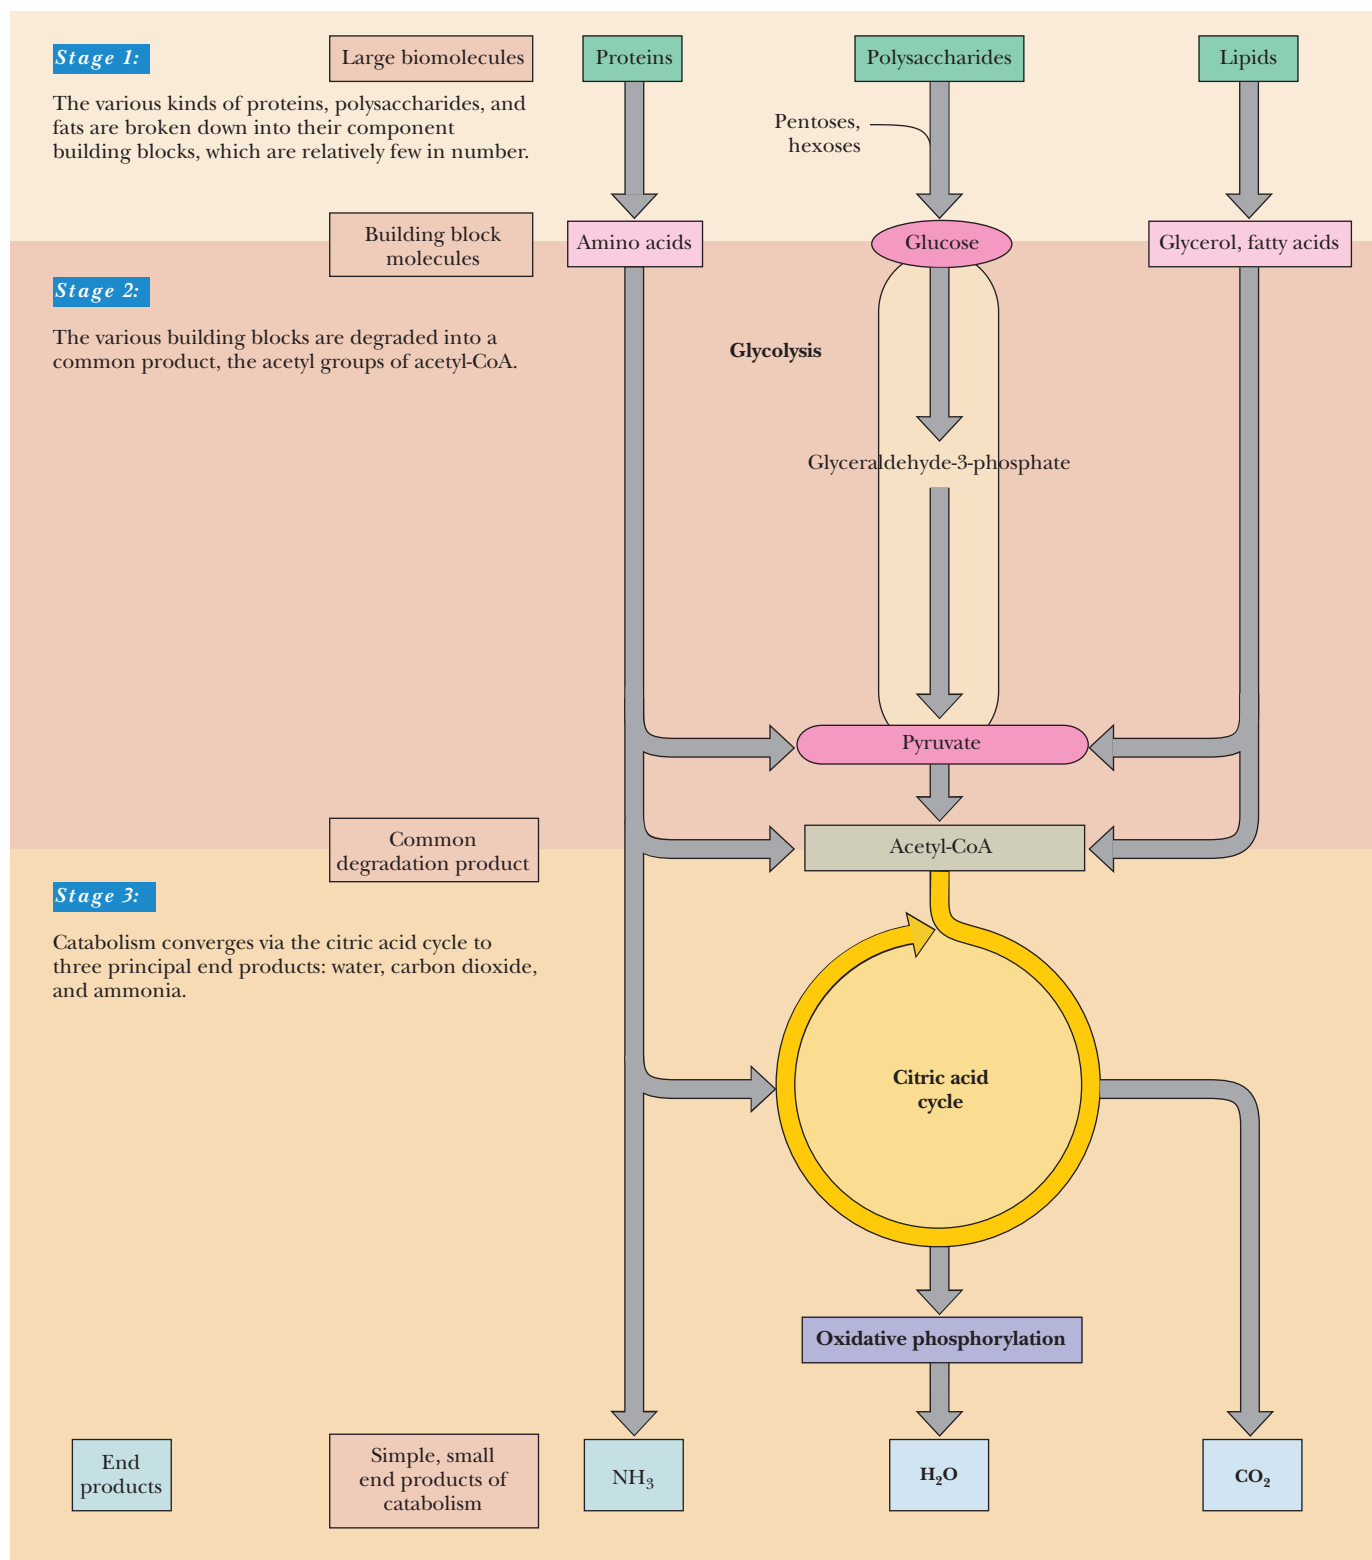

Figure 17.7 The three stages of catabolism. **Stage 1:** Proteins, polysaccharides, and lipids are broken down into their component building blocks, which are relatively few in number. **Stage 2:** The various building blocks are degraded into the common product, the acetyl groups of acetyl-CoA. **Stage 3:** Catabolism converges to three principal end products: water, carbon dioxide, and ammonia.

blocks via the pathways of anabolism. In turn, the building blocks (amino acids, nucleotides, sugars, and fatty acids) can be generated from metabolites in the cell. For example, amino acids can be formed by amination of the corresponding α -keto acid carbon skeletons, and pyruvate can be converted to hexoses for polysaccharide biosynthesis.

17.3e Amphibolic Intermediates Play Dual Roles

Certain central pathways of intermediary metabolism, such as the citric acid cycle, and many metabolites of other pathways have dual purposes—they serve in both catabolism and anabolism. For example, oxaloacetate, an intermediate in the citric acid cycle, is the precursor for synthesis of the amino acid aspartate. This dual nature is reflected in the designation of such pathways as **amphibolic** rather than solely catabolic or anabolic. In any event, in contrast to catabolism—which converges to the common intermediate, acetyl-CoA—the pathways of anabolism diverge from a small group of simple metabolic intermediates to yield a spectacular variety of cellular constituents.

17.3f Corresponding Pathways of Catabolism and Anabolism Differ in Important Ways

The anabolic pathway for synthesis of a given end product usually does not match precisely the pathway used for catabolism of the same substance. Some of the intermediates may be common to steps in both pathways, but different enzymatic reactions and unique metabolites characterize other steps. A good example of these differences is found in a comparison of the catabolism of glucose to pyruvic acid by the pathway of glycolysis and the biosynthesis of glucose from pyruvate by the pathway called *gluconeogenesis*. The glycolytic pathway from glucose to pyruvate consists of 10 enzymes. Although it may seem efficient for glucose synthesis from pyruvate to proceed by a reversal of all 10 steps, gluconeogenesis uses only seven of the glycolytic enzymes in reverse, replacing those remaining with four enzymes specific to glucose biosynthesis. In similar fashion, the pathway responsible for degrading proteins to amino acids differs from the protein synthesis system, and the oxidative degradation of fatty acids to two-carbon acetyl-CoA groups does not follow the same reaction path as the biosynthesis of fatty acids from acetyl-CoA.

17.3g Metabolic Regulation Requires Different Pathways for Oppositely Directed Metabolic Sequences

The main reason for different pathways serving in opposite metabolic directions is that such pathways must be independently regulated. If catabolism and anabolism passed along the same set of metabolic tracks, equilibrium considerations would dictate that slowing the traffic in one direction by inhibiting a particular enzymatic reaction would also slow traffic in the opposite direction. Independent regulation of anabolism and catabolism can be accomplished only if these two contrasting processes move along different routes or, in the case of shared pathways, the rate-limiting steps serving as the points of regulation are catalyzed by enzymes that are unique to each opposing sequence (Figure 17.8). Note that opposing pathways are reciprocally regulated: Activation of one is accompanied by inhibition of the other. Reciprocal regulation means that the opposing metabolic sequences function in only one direction at any moment in time. The direction in which they operate is determined by allosteric effectors acting on key steps in the opposing pathways.

17.3h ATP Is Produced and Consumed in a Cellular Energy Cycle

We saw in Chapter 3 that ATP is the energy currency of cells. In phototrophs, ATP is one of the two energy-rich primary products resulting from the transformation of light energy into chemical energy. (The other is NADPH; see the following discussion.) In heterotrophs, the pathways of catabolism have as their major purpose the release of free energy that can be captured in the form of energy-rich phosphoric anhydride bonds in ATP. In turn, ATP provides the energy that drives the manifold

Activation of one mode is accompanied by reciprocal inhibition of the other mode.

Figure 17.8 Parallel pathways of catabolism and anabolism must differ in at least one metabolic step to be regulated independently. Shown here are two possible arrangements of opposing catabolic and anabolic sequences between A and P. **(a)** The parallel sequences proceed via independent routes. **(b)** Only one reaction has two different enzymes, a catabolic one (E_3) and its anabolic counterpart (E_6). These provide sites for regulation.

Figure 17.9 The ATP cycle in cells. ATP is formed via photosynthesis in phototrophic cells or catabolism in heterotrophic cells. Energy-requiring cellular activities are powered by ATP hydrolysis, liberating ADP and P_i .

activities of all living cells—the synthesis of complex biomolecules, the work involved in transporting substances into cells, the work of cell motility, and the work of muscle contraction. These diverse activities are all powered by energy released in the hydrolysis of ATP to ADP and P_i . Thus, there is an energy cycle in cells where ATP serves as the vessel carrying energy from photosynthesis or catabolism to the energy-requiring processes unique to living cells (Figure 17.9).

17.3i NAD^+ Collects Electrons Released in Catabolism

The substrates of catabolism—proteins, carbohydrates, and lipids—are good sources of chemical energy because the carbon atoms in these molecules are in a relatively reduced state (Figure 17.10). In the oxidative reactions of catabolism, reducing equivalents are released from these substrates, often in the form of **hydride ions** (a proton coupled with two electrons, H^-). These hydride ions are transferred in enzymatic *dehydrogenase* reactions from the substrates to NAD^+ molecules, reducing them to NADH. A second proton accompanies these reactions, appearing in the overall equation as H^+ (Figure 17.11).

Figure 17.10 Comparison of the state of reduction of carbon atoms in biomolecules: $-\text{CH}_2-$ (fats) $>$ $-\text{CHOH}-$ (carbohydrates) $>$ $\text{C}=\text{O}$ (carbonyls) $>$ $-\text{COOH}$ (carboxyls) $>$ CO_2 (carbon dioxide, the final product of catabolism).

Figure 17.11 Hydrogen and electrons released in the course of oxidative catabolism are transferred as hydride ions to the pyridine nucleotide, NAD^+ , to form $\text{NADH} + \text{H}^+$ in dehydrogenase reactions of the type

The reaction shown is catalyzed by alcohol dehydrogenase.

In turn, NADH is oxidized back to NAD^+ when it transfers its reducing equivalents to electron acceptor systems that are part of the metabolic apparatus of the mitochondria. The ultimate oxidizing agent (e^- acceptor) is O_2 , becoming reduced to H_2O .

Oxidation reactions are exergonic, and the energy released is coupled with the formation of ATP in the process called oxidative phosphorylation. The NAD^+/NADH system can be viewed as a *shuttle* that carries the electrons released from catabolic substrates to the mitochondria, where they are transferred to O_2 , the ultimate electron acceptor in catabolism. In the process, the free energy released upon NADH oxidation by O_2 is trapped through phosphorylation of ADP to form ATP. The NADH cycle is an important player in the transformation of the chemical energy of carbon compounds into the chemical energy of phosphoric anhydride bonds. Such transformations of energy from one form to another are referred to as **energy transduction**. Oxidative phosphorylation is one cellular mechanism for energy transduction. Also, relative NAD^+ levels are an important indicator of the metabolic status of cells, with a high NAD^+/NADH ratio indicating energy limitation, as in starvation.

17.3j NADPH Provides the Reducing Power for Anabolic Processes

Whereas catabolism is fundamentally an oxidative process, anabolism is, by its contrasting nature, reductive. The biosynthesis of the complex constituents of the cell begins at the level of intermediates derived from the degradative pathways of catabolism; or, at the most basic level, biosynthesis begins with oxidized substances available in the inanimate environment, such as carbon dioxide. When the hydrocarbon chains of fatty acids are assembled from acetyl-CoA units, activated hydrogens are needed to reduce the carbonyl ($\text{C}=\text{O}$) carbon of acetyl-CoA into a $-\text{CH}_2-$ at every other position along the chain. When glucose is synthesized from CO_2 during photosynthesis in plants, reducing power is required. These reducing equivalents are provided by NADPH , the usual source of high-energy hydrogens for reductive biosynthesis. NADPH is generated when NADP^+ is reduced with electrons in the form of hydride ions. In heterotrophic organisms, these electrons are removed from fuel molecules by NADP^+ -specific dehydrogenases. In these organisms,

Figure 17.12 Transfer of reducing equivalents from catabolism to anabolism via the NADPH cycle.

NADPH can be viewed as the carrier of electrons from catabolic reactions to anabolic reactions (Figure 17.12). In photosynthetic organisms, the energy of light is used to pull electrons from water and transfer them to NADP^+ ; O_2 is a by-product of this process.

17.3k Coenzymes and Vitamins Provide Unique Chemistry and Essential Nutrients to Pathways

In addition to NAD^+ and NADPH, a variety of other small molecules are essential to metabolism. Some of these essential nutrients are **vitamins**.

Vitamins are required in the diet, usually in trace amounts, because they cannot be synthesized by the organism itself. The requirement for any given vitamin depends on the organism. Not all vitamins are required by all organisms. Vitamins required in the human diet are listed in Table 17.3. These important substances are traditionally distinguished as being either water soluble or fat soluble.

Except for vitamin C (ascorbic acid), the water-soluble vitamins are all components or precursors of important biological substances known as **coenzymes**. These are low-molecular-weight molecules that bring unique chemical functionality to certain enzyme reactions. The side chains of the common amino acids provide only a limited range of chemical reactivities and carrier properties. Coenzymes, acting in concert with appropriate enzymes, provide a broader range of catalytic properties for the reactions of metabolism. Coenzymes are typically modified by these

Table 17.3 Vitamins and Coenzymes

Vitamin	Coenzyme Form	Function
<i>Water-Soluble</i>		
Thiamine (vitamin B ₁)	Thiamine pyrophosphate	Decarboxylation of α -keto acids and formation and cleavage of α -hydroxyketones
Niacin (vitamin B ₃ , nicotinic acid)	Nicotinamide adenine dinucleotide (NAD^+)	Hydride transfer
	Nicotinamide adenine dinucleotide phosphate (NADP^+)	Hydride transfer
Riboflavin (vitamin B ₂)	Flavin adenine dinucleotide (FAD)	One- and two-electron transfer
	Flavin mononucleotide (FMN)	One- and two-electron transfer
Pantothenic acid (vitamin B ₅)	Coenzyme A	Activation of acyl groups for transfer by nucleophilic attack, and activation of the α -hydrogen of the acyl group for abstraction as a proton
Pyridoxal, pyridoxine, pyridoxamine (vitamin B ₆)	Pyridoxal phosphate	Formation of stable Schiff base (aldimine) adducts with α -amino groups of amino acids; serving as an electron sink to stabilize reaction intermediates
Cobalamin (vitamin B ₁₂)	5'-Deoxyadenosylcobalamin	Intramolecular rearrangement, reduction of ribonucleotides to deoxyribonucleotides, and methyl group transfer
	Methylcobalamin	
Biotin (vitamin B ₇)	Biotin–lysine complexes (biocytin)	Carrier of carboxyl groups in carboxylation reactions
Folic acid (vitamin B ₉)	Tetrahydrofolate	Acceptor and donor of 1-C units for all oxidation levels of carbon except that of CO_2
<i>Fat-Soluble</i>		
Retinol (vitamin A)		
Retinal (vitamin A)		
Retinoic acid (vitamin A)		
Ergocalciferol (vitamin D ₂)		
Cholecalciferol (vitamin D ₃)		
α -Tocopherol (vitamin E)		
Menaquinone (vitamin K)		

reactions and are then converted back to their original forms by other enzymes, so small amounts of these substances can be used repeatedly. Coenzymes may also act as *carriers* of specific functional groups, such as methyl groups and acyl groups. The coenzymes derived from the water-soluble vitamins are listed in Table 17.3. The fat-soluble vitamins are not directly related to coenzymes, but they play essential roles in a variety of critical biological processes, including vision, maintenance of bone structure, and blood coagulation. The mechanisms of action of fat-soluble vitamins are not as well understood as their water-soluble counterparts, but modern research efforts are gradually closing this gap.

17.4 What Experiments Can Be Used to Elucidate Metabolic Pathways?

Research into the chemistry of metabolism and its organization into pathways can be traced back to the end of the nineteenth century. A major intellectual advance took place then when Eduard Buchner showed that the fermentation of glucose to yield ethanol and carbon dioxide can occur in extracts of broken yeast cells. Until this discovery, many thought that metabolism was a vital property, unique to intact cells; even the eminent microbiologist Louis Pasteur, who contributed so much to our understanding of fermentation, was a *vitalist*, one of those who believed that the processes of living substance transcend the laws of chemistry and physics. After Buchner's revelation, biochemists searched for intermediates in the transformation of glucose and soon learned that inorganic phosphate was essential to glucose breakdown. This observation gradually led to the discovery of a variety of phosphorylated organic compounds that serve as intermediates along the fermentative pathway.

17.4a Enzyme Inhibitors Can Be Used to Reveal Individual Metabolic Reactions

An important tool for elucidating the steps in the pathway was the use of *metabolic inhibitors*. Adding an enzyme inhibitor to a cell-free extract caused an accumulation of intermediates in the pathway prior to the point of inhibition (Figure 17.13). Each inhibitor was specific for a particular site in the sequence of metabolic events. As the arsenal of inhibitors was expanded, the individual steps in metabolism were revealed.

Figure 17.13 The use of inhibitors to reveal the sequence of reactions in a metabolic pathway.

(a) Control: Under normal conditions, the steady-state concentrations of a series of intermediates will be determined by the relative activities of the enzymes in the pathway. **(b) Plus inhibitor:** In the presence of an inhibitor (in this case, an inhibitor of *enzyme 4*), intermediates upstream of the metabolic block (B, C, and D) accumulate, revealing themselves as intermediates in the pathway. The concentration of intermediates lying downstream (E and F) will fall.

17.4b Mutations Create Specific Metabolic Blocks

Genetics provides an approach to the identification of intermediate steps in metabolism that is somewhat analogous to inhibition. Mutation in a gene encoding an enzyme often results in an inability to synthesize the enzyme in an active form. Such a defect leads to a block in the metabolic pathway at the point where the enzyme acts, and the enzyme's substrate accumulates. Such genetic disorders are lethal if the end product of the pathway is essential or if the accumulated intermediates have toxic effects. In microorganisms, however, it is often possible to manipulate the growth medium so that essential end products are provided. Then the biochemical consequences of the mutation can be investigated. Studies on mutations in genes of the filamentous fungus *Neurospora crassa* led G. W. Beadle and E. L. Tatum to hypothesize in 1941 that genes are units of heredity that encode enzymes (a principle referred to as the one gene–one enzyme hypothesis).

17.4c Isotopic Tracers Can Be Used as Metabolic Probes

Another widely used approach to the elucidation of metabolic sequences is to feed cells a substrate or metabolic intermediate labeled with a particular isotopic form of an element that can be traced. Two sorts of isotopes are useful in this regard: radioactive isotopes, such as ^{14}C , and stable *heavy* isotopes, such as ^{18}O or ^{15}N . Because the chemical behavior of isotopically labeled compounds is rarely distinguishable from that of their unlabeled counterparts, isotopes provide reliable tags for observing metabolic changes. The metabolic fate of a radioactively labeled substance can be traced by determining which atoms in intermediates derived from the labeled compound are radioactive (Figure 17.14).

Heavy isotopes endow the compounds in which they appear with slightly greater masses than their unlabeled counterparts. These compounds can be separated and quantitated by mass spectrometry (or density gradient centrifugation, if they are macromolecules). For example, ^{18}O was used in separate experiments as a tracer of the fate of the oxygen atoms in water and carbon dioxide to determine whether the atmospheric oxygen produced in photosynthesis arose from H_2O , CO_2 , or both:

If ^{18}O -labeled CO_2 was presented to a green plant carrying out photosynthesis, none of the ^{18}O was found in O_2 . Curiously, it was recovered as H_2^{18}O . In contrast, when

Figure 17.14 One of the earliest experiments using a radioactive isotope as a metabolic tracer. Cells of *Chlorella* (a green alga) synthesizing carbohydrate from carbon dioxide were exposed briefly (5 s) to ^{14}C -labeled CO_2 . The products of CO_2 incorporation were then quickly isolated from the cells, separated by two-dimensional paper chromatography, and observed via autoradiographic exposure of the chromatogram. Such experiments identified radioactive 3-phosphoglycerate (PGA) as the primary product of CO_2 fixation. The 3-phosphoglycerate was labeled in the 1-position (in its carboxyl group). Radioactive compounds arising from the conversion of 3-phosphoglycerate to other metabolic intermediates included phosphoenolpyruvate (PEP), malic acid, triose phosphate, alanine, as well as sugar phosphates and diphosphates.

Courtesy of Professor Melvin Calvin, Lawrence Berkeley Laboratory, University of California, Berkeley

plants fixing CO_2 were equilibrated with H_2^{18}O , $^{18}\text{O}_2$ was evolved. These latter labeling experiments established that photosynthesis is best described by the equation

That is, in the process of photosynthesis, the two oxygen atoms in O_2 come from two H_2O molecules. One O is lost from CO_2 and appears in H_2O , and the other O of CO_2 is retained in the carbohydrate product. Two of the four H atoms are accounted for in (CH_2O) , and two reduce the O lost from CO_2 to H_2O .

17.4d NMR Spectroscopy Is a Noninvasive Metabolic Probe

A technology analogous to isotopic tracers is provided by **nuclear magnetic resonance (NMR) spectroscopy**. The atomic nuclei of certain isotopes, such as ^1H and ^{31}P , have *magnetic moments*. The resonance frequency of a magnetic moment depends on the local chemical environment. That is, the NMR signal of the nucleus is influenced in an identifiable way by the chemical nature of its neighboring atoms in the compound. Such variation in an atom's nuclear magnetic resonance frequency as a function of the electronic environment in its neighborhood is called **chemical shift**. Chemical shifts reveal a great deal of structural information about the environment around the atom and thus the nature of the compound containing the atom. Transformations of substrates and metabolic intermediates labeled with magnetic nuclei can be traced by following changes in NMR spectra. Furthermore, NMR spectroscopy is a noninvasive procedure. Whole-body NMR spectrometers are being used today in hospitals to directly observe the metabolism (and clinical condition) of living subjects (Figure 17.15). NMR is a useful tool for clinical diagnosis and for the investigation of metabolism in situ (literally “in site,” meaning in this case “where and as it happens”).

17.4e Cell Fractionation Reveals Which Compartment Contains a Metabolic Pathway

Although the interior of a prokaryotic cell is not subdivided into compartments by internal membranes, the cell still shows some spatial segregation of metabolism. For example, certain metabolic pathways, such as phospholipid synthesis and oxidative phosphorylation, are localized in the plasma membrane. Protein biosynthesis is carried out on ribosomes.

In contrast, eukaryotic cells are extensively compartmentalized by an endomembrane system. Each of these cells has a true nucleus bounded by a double membrane

Figure 17.15 With NMR spectroscopy, one can observe the metabolism of a living subject in real time. These NMR spectra show the changes in ATP, creatine-P (phosphocreatine), and P_i levels in the forearm muscle of a human subject before (a) and after (b) 19 minutes of exercise. Note that the three P atoms of ATP (α , β , and γ) have different chemical shifts, reflecting their different chemical environments.

called the *nuclear envelope*. The nuclear envelope is continuous with the endomembrane system, which is composed of differentiated regions: the endoplasmic reticulum; the Golgi complex; various membrane-bounded vesicles such as lysosomes, vacuoles, and microbodies; and, ultimately, the plasma membrane itself. Eukaryotic cells also possess mitochondria and, if they are photosynthetic, chloroplasts. Disruption of the cell membrane and fractionation of the cell contents into the component organelles have allowed an analysis of their respective functions (Figure 17.16). Each compartment is dedicated

Figure 17.16 Fractionation of a cell extract by differential centrifugation. Cells in a tissue are ruptured during homogenization, releasing their contents. It is possible to separate organelles and subcellular particles in a centrifuge because their inherent size and density differences give them different rates of sedimentation in an applied centrifugal field. Nuclei are pelleted in relatively weak centrifugal fields and mitochondria in somewhat stronger fields, whereas very strong centrifugal fields are necessary to pellet ribosomes and fragments of the endomembrane system.

to specialized metabolic functions, and the enzymes appropriate to these specialized functions are confined together within the organelle. In many instances, the enzymes of a metabolic sequence occur together within the organellar membrane. Thus, the flow of metabolic intermediates in the cell is spatially as well as chemically segregated. For example, the 10 enzymes of glycolysis are found in the cytosol, but pyruvate, the product of glycolysis, is fed into the mitochondria. These organelles contain the citric acid cycle enzymes, which oxidize pyruvate to CO_2 . The great amount of energy released in the process is captured by the oxidative phosphorylation system of mitochondrial membranes and used to drive the formation of ATP (Figure 17.17).

17.4f Metabolic Pathways Are Also Time-Dependent

The spatial compartmentalization of metabolic pathways within cells provides important advantages, one of which is isolating competing pathways from one another. Cells and organisms also exhibit temporal compartmentalization of their metabolic pathways. That is, metabolic pathways may be turned on and off in a time-dependent and/or cyclic fashion. For example, the metabolism of many organisms—microbes, animals, and plants—is regulated in synchrony with the 24-hour cycle of day and night, a pattern called **circadian rhythmicity** and often referred to as the **biological clock**. Why? Because light and/or varying nutrient availability represent key signals regarding the transitory nature of the environment, and organisms have evolved and adapted to exploit the information in such signals. Photosynthesis and carbon dioxide fixation in plants typically is active during daylight hours and down-regulated during the dark. Significantly, recent studies have demonstrated that mammalian genes involved in lipid metabolism, glycolysis, gluconeogenesis, electron transport, mitochondrial ATP synthesis, and other metabolic pathways show a circadian pattern of regulated expression. In particular, the genes encoding the rate-limiting enzymes in many of these pathways are under circadian regulation. Feeding time (nutrient availability) is an important external cue that sets the phase of these metabolic gene expression cycles. In the liver, gluconeogenesis and glycogen breakdown are active during the sleep/fasting phase of the circadian rhythm, apparently to maintain blood glucose levels. On the other hand, glycolysis and cholesterol synthesis are active during the wake/feeding phase when substrates become available. Notably, disruptions of the circadian clock result in elevated fat accumulation

Figure 17.17 Compartmentalization of glycolysis, the citric acid cycle, and oxidative phosphorylation.

and other metabolic abnormalities. Yeast cells (*Saccharomyces cerevisiae*) maintained under continuous nutrient-limited conditions adopt a 4- to 5-hour cycle of respiratory activity, as demonstrated by oscillations in O₂ consumption. Over half of the genes in the yeast genome are expressed rhythmically during this yeast metabolic cycle, with genes encoding proteins of similar metabolic function showing synchronous oscillations in expression. Those genes involved with energy metabolism show particularly robust metabolic cycles.

17.5 What Can the Metabolome Tell Us about a Biological System?

Metabolomics is a newly emerged field in biochemistry and an obvious next step in the -omics series of genomics, transcriptomics, and proteomics. The **metabolome** is the complete set of low-molecular-weight substances involved in metabolism or produced by a cell or organism under specified physiological conditions. Metabolomics is the systematic identification and quantitation of all of these substances. Moving from the genome, which specifies all the genetic information available to an organism as encoded in its DNA, to the metabolome takes one from the **genotype** of the organism (its complete genetic potential) to its **phenotype** (the observed traits of an organism achieved through expression of its genes and the interaction of those gene products with the environment). As the ultimate expression of an organism's genetic possibilities and its responses to its environment, the metabolome is the best predictor of an organism's phenotype. As such, metabolomics is occupying a prominent position in the rise of systems biology, where comprehensive information about the genome, the transcriptome, the proteome, and the metabolome combine to provide insightful descriptions of the behavior of cells and organisms, as well as detailed understanding of many diseases (Figure 17.18).

Metabolomic analyses present daunting challenges, even for simple organisms. More than 500 metabolites are represented in the metabolic map shown in Figure 17.2, but far more exist in a typical cell. For example, the 40 or so fatty acids occurring in a cell can alone account for more than a thousand phosphatidic acids. (Phosphatidic acids, with two fatty acids esterified to *sn*-glycerol-3-phosphate create $40 \times 40 = 1600$ species by themselves!) The Human Metabolomics Database (www.hmdb.ca) provides data on more than 115,000 metabolites in cells and fluids (blood, urine, and so on) of the human

Figure 17.18 The -omics of contemporary biochemistry and molecular biology, as it relates to metabolism. The different kinds and relative abundances of the various cellular metabolites are the best indicator of the phenotype of the cell, where phenotype connotes the sum total of all of the cell's (or organism's) characteristics at a given moment in time. Any change in these metabolites indicates that a biochemical perturbation (a phenotypic change) has occurred. In human health, such perturbations may be useful clinical clues. (Adapted from Figure 2a in Patti, G. J., Yanes, O., and Siuzdak, G., 2012. Metabolomics: the apogee of the omics trilogy. *Nature Reviews Molecular Cell Biology* 13:263–269.)

body. The metabolomes of plants are even more complex, with estimates suggesting hundreds of thousands of different metabolites across the plant kingdom. Metabolomic assays must be able to resolve and discriminate this extraordinary array of small molecules. Moreover, concentrations of metabolites in a cell vary widely, from less than 10^{-12} M (for many hormones) to 0.1 M (for Na^+ ions).

The principal tools of metabolomics are NMR spectroscopy and mass spectrometry. Mass spectrometry (Chapter 5) offers unmatched sensitivity for detection of metabolites at low concentrations and NMR spectroscopy can provide exceptional resolution and discrimination of metabolites in complex mixtures (Figure 17.20). Coupling these techniques with a variety of chromatographic separation protocols makes it possible to rapidly analyze thousands of metabolites in biological samples at low cost.

Metabolomic studies take two forms: **Targeted metabolomics** is the scrutiny of a particular metabolic pathway or class of metabolites (for example, lipids or amino acids). Because the metabolites of interest are known, standard compounds can be used to predict the chromatographic, magnetic resonance, or mass spectrometric behavior of the molecules of interest. Figure 17.20 shows the results of a targeted metabolomic analysis. **Untargeted** or **discovery metabolomics** has a more global aim—to identify and quantify *all* of the metabolites present in a biological sample.

Discovery Metabolomics Mass spectrometry (MS) is the key tool in discovery metabolomics, though in some cases, liquid chromatographic (or for hydrophobic substances, gas chromatographic) separation of metabolites into classes (*e.g.*, hydrophobic, hydrophilic) precedes MS (LC/MS analyses). Tandem MS (MS/MS) for fragmentation of molecules and subsequent analysis (as in protein sequencing, see Section 5.4) is also

Figure 17.19 Mass spectrometry offers remarkable sensitivity for metabolomic analyses. Shown here are desorption electrospray ionization mass spectra for urine samples from individuals with inborn errors of metabolism. PKU = phenylketonuria; HCY = homocystinuria; MSUD = maple syrup urine disease. (Adapted from Pan, Z., et al., 2007. used. Technological innovations allow direct MS analysis of single bacterial colonies (Figure 17.21) or very small tissues through microscope interfaces. For example, metabolomic analysis has been carried out on the developing mouse embryonic spinal cord. A significant challenge is that data sets from discovery metabolomics analyses are extraordinarily complex. Software programs are available to collate the MS information and create networks of structural similarities that lead to unambiguous identification of individual metabolites through comparisons with established MS databases. These databases include the Human Metabolome Database and METLIN. METLIN is a metabolite and tandem MS database and data management system maintained by the Scripps Center for Metabolomics. METLIN is the world's largest tandem MS database, containing hundreds of thousands of molecular standards.

Small molecules modulate all steps in the flow of information from genotype to phenotype. Metabolites are the substrates and products of enzymes whose actions determine the phenotype. Metabolites influence gene expression through interactions with DNA-binding proteins that activate or repress transcription. Metabolites serve as allosteric effectors, not just for enzymes, but also for hormone receptors that have broad influences on a cell's expression of its metabolic possibilities. A select set of small

Figure 17.21 A direct and highly sensitive analysis of metabolites by nanospray desorption electrospray ionization mass spectroscopy (NanoDESI MS).

(a) Almost any surface, such as a bacterial colony, plant leaf, or animal skin, can be analyzed by this method. (b) Solvent is delivered by a capillary and then pumped from the sample surface and directly sprayed into an ESI-tandem mass spectrometer. Ions generated from the individual metabolites drawn from the surface are fragmented and analyzed by tandem MS. (c) Spectral networking: The masses of metabolites are collated, based on MS/MS spectral similarity, and displayed as nodes within a network. Individual nodes represent metabolites that can be identified through comparison with the MS profiles of entries in metabolomic databases. (Adapted from Figure 1 in Traxler, M. F., and Kolter, R., 2012. A massively spectacular view of the chemical lives of microbes. *Proceedings of the National Academy of Sciences, USA* **109**:10128–10129.)

molecules, such as phosphate and acetyl-CoA, are used in the regulation of protein function through post-translational modification. Metabolites determine the possibilities of epigenetic modifications. In humans, metabolomic changes due to external factors—diet, lifestyle, the gut microbiome, age, drugs, and sex—generate consequences across all the -omes. In short, metabolomics is key to understanding an organism's biology. Placing metabolomics at the center of information flow to the -omics not only highlights its direct influence on the other -omics, but also emphasizes its importance as the master regulator. Small molecules are at the center of life (Figure 17.22).

Fluxomics Determining the true phenotype of a cell depends not only on knowledge of all the metabolites in a cell at any given moment, but also on information about the flow of metabolites through its metabolic networks. The quantitative study of metabolite flow, or **flux**, is termed **fluxomics**. The fluxome is defined by all of the metabolic fluxes in a metabolic network, and thus represents systems-level information on those cellular processes defined by the metabolic network. As such, the fluxome depends on the metabolome and the proteome, with the proteome representing those enzymes that mediate the reactions comprising the metabolic network. Thus, the fluxome is a dynamic view of the metabolic processes in a cell or organism.

The direct measurement of intracellular metabolic flux is a daunting challenge. Instead, attempts are made to model the fluxome. Such models require detailed knowledge about the metabolome, the prevailing concentrations of enzymes in the metabolic networks, and the kinetic constants for these enzymes under intracellular conditions. When such models become predictive, the effects of disease states or pharmacological interventions can be more productively addressed.

Figure 17.22 Small molecules are at the center of life. The flux of biological information is centered on metabolomics. Metabolic intermediates drive all the other –omics. In humans, external factors such as diet, lifestyle, the gut microbiome, age, drug, and sex directly affect the metabolome, and through it, all the other –omes. (Adapted from Figure 1 in Costa dos Santos, Jr., G. C., Renovato-Martins, M., and Mesquita de Brito, N., 2021. The remodel of the “central dogma”: a metabolomics interaction perspective. *Metabolomics* 17:48, DOI: 10.1007/s11306-021-01800-8

17.6 What Food Substances Form the Basis of Human Nutrition?

The use of foods by organisms is termed **nutrition**. The ability of an organism to use a particular food material depends upon its chemical composition and digestibility. In addition to indigestible fiber, food includes the macronutrients—protein, carbohydrate, and lipid—and the micronutrients—including vitamins and minerals.

17.6a Humans Require Protein

Humans must consume protein to make new proteins. Dietary protein is a rich source of nitrogen, and certain amino acids—the so-called **essential amino acids**—cannot be synthesized by humans (and various animals) and can be obtained only in the diet. The average adult in the United States consumes far more protein than required for synthesis of essential proteins. Excess dietary protein is then merely a source of metabolic energy. Some of the amino acids (termed **glucogenic**) can be converted into glucose, whereas others, the **ketogenic** amino acids, can be converted to fatty acids and/or keto acids. If fat and carbohydrate are already adequate for the energy needs of the individual, then both kinds of amino acids will be converted to triacylglycerol and stored in adipose tissue.

An individual's protein undergoes a constant process of degradation and resynthesis, a cycle known as **protein turnover**. Together with dietary protein, this recycled protein material participates in a nitrogen equilibrium. For most adults, the amount of protein synthesis is equaled by the amount of protein degradation, and the dietary amount of protein is equaled by the amount of nitrogen excreted in the urine (as urea), in the feces, and in sweat. Persons whose nitrogen intake is balanced by their nitrogen excretion are in **zero nitrogen balance**. A positive nitrogen balance occurs whenever there is a net increase in the organism's protein content, such as during periods of growth. Nitrogen balance is positive in healthy individuals from birth through adolescence, in pregnant women, and in people recovering from illness or protein insufficiency. A negative nitrogen balance exists when dietary intake of nitrogen is insufficient to meet the demands for new protein synthesis, as in people who are starving or who need to replace tissue due to illness or injury.

17.6b Carbohydrates Provide Metabolic Energy

The principal purpose of carbohydrate in the diet is production of metabolic energy. Simple sugars are metabolized in the glycolytic pathway. Complex carbohydrates are degraded into simple sugars, which then can enter the glycolytic pathway. Carbohydrates are also essential components of nucleotides, nucleic acids, glycoproteins, and glycolipids. Human metabolism can adapt to a wide range of dietary carbohydrate levels, but the brain depends on glucose for fuel. When dietary carbohydrate consumption exceeds the energy needs of the individual, excess carbohydrate is converted to triacylglycerols and glycogen for long-term energy storage. On the other hand, when dietary carbohydrate intake is low, **ketone bodies** are formed from acetate units to provide metabolic fuel for the brain and other organs.

17.6c Lipids Are Essential, but in Moderation

Fatty acids and triacylglycerols can be used as fuel by many tissues in the human body, and phospholipids are essential components of all biological membranes. Even though the human body can tolerate a wide range of fat intake levels, there are disadvantages in either extreme. Excess dietary fat is stored as triacylglycerols in adipose tissue, but high levels of dietary fat can also increase the risk of atherosclerosis and heart disease. Moreover, high dietary fat levels are also correlated with increased risk for colon, breast, and prostate cancers. When dietary fat consumption is low, there is a risk of **essential fatty acid** deficiencies. The human body cannot synthesize linoleic and linolenic acids, so these must be acquired in the diet. In addition, arachidonic acid can be synthesized in humans only from linoleic acid, so it too is classified as essential. The essential fatty acids are key components of biological membranes, and arachidonic acid is the precursor to prostaglandins, which mediate a variety of processes in the body.

Foundational Biochemistry Things You Should Know after Reading Chapter 17.

- Organisms show marked similarity in their metabolic pathways.
- Living things exhibit metabolic diversity.
- Autotrophs are organisms that can subsist on carbon dioxide as the only source of carbon; heterotrophs require an organic form of carbon.
- Phototrophs are photosynthetic organisms; chemotrophs use organic or inorganic compounds as a source of energy.
- Prokaryotes show greater metabolic diversity than found in all the eukaryotic organisms.
- Oxygen is essential for aerobic organisms.
- The flow of energy in the biosphere is intimately related to the carbon and oxygen cycles.
- Metabolic maps portray the principal reactions comprising the intermediary metabolism of carbohydrates, lipids, amino acids, nucleotides, and their derivatives.
- Traditional metabolic maps emphasize metabolites, but alternative models focused on the enzymes or enzyme complexes can provide new insights.
- Multienzyme systems may take several different forms.
- Multifunctional polypeptides are proteins that can catalyze several of the reactions in a metabolic pathway.
- Catabolic pathways are characteristically energy yielding, whereas anabolic pathways are energy requiring.
- Catabolism involves the oxidative degradation of complex nutrient molecules, such as carbohydrates, lipids, and proteins.
- The energy released in catabolic reactions is often captured in ATP.
- During catabolism, energy-rich electrons are transferred to the coenzymes NAD^+ and NADP^+ .
- Energy released upon oxidation of NADH is coupled to ATP synthesis.
- The ADP/ATP and NAD^+/NADH ratios are key indicators of the energy status of cells.
- NADPH is the source of reducing potential to drive reductive biosynthetic reactions.
- Anabolism is biosynthesis; as such, it is endergonic.
- Anabolism and catabolism are not mutually exclusive.
- The pathways of catabolism converge to a few end products, such as lactate, ethanol, CO_2 , H_2O , and NH_4^+ .
- Anabolic pathways diverge, synthesizing an astounding variety of biomolecules from a limited set of metabolic intermediates that serve as building blocks.
- Amphibolic intermediates play dual roles, serving roles in both catabolic and anabolic pathways.
- Corresponding pathways of catabolism and anabolism, such as glycolysis and gluconeogenesis or fatty acid oxidation and fatty acid biosynthesis, differ in important ways.
- Metabolic regulation requires different pathways for oppositely directed metabolic sequences.
- Opposing metabolic pathways are reciprocally regulated.
- ATP serves in a cellular energy cycle, being produced in catabolism (or photosynthesis) and consumed in biosynthesis, osmotic work, or motility.
- NAD^+ collects electrons released in catabolism.
- The energy released in NADH oxidation is coupled with the formation of ATP; the coupled process is called oxidative phosphorylation.

- Transformation of the energy released in an oxidation–reduction reaction into the chemical energy of a phosphoric anhydride bond is a form of energy transduction.
- Coenzymes provide unique chemistry to metabolic pathways.
- Water-soluble vitamins are precursors for coenzyme synthesis.
- Metabolic pathways have been elucidated by a variety of experimental approaches.
- Metabolic inhibitors block pathways at their site of inhibition.
- Mutations create specific metabolic blocks.
- Either radioactive isotopes or stable heavy isotopes can be used to trace the course of metabolic reactions.
- NMR spectroscopy is a noninvasive metabolic probe.
- Metabolic pathways are compartmentalized with cells.
- Cells and organisms also exhibit temporal compartmentalization of their metabolic pathways.
- The metabolism of many organisms shows circadian rhythmicity.
- The metabolome is the complete set of metabolites involved in metabolism or produced by a cell or organism under specified physiological conditions.
- The metabolome is an excellent predictor of a cell or organism's phenotype.
- The metabolome is an important aspect of systems biology.
- NMR spectroscopy and mass spectrometry are the principal tools of metabolomic analyses.
- Fluxomics is the quantitative study of metabolic flux.
- Small molecules are at the center of life: The flow of biological information is centered on metabolomics.
- Human nutrition depends on carbohydrates, lipids, and proteins for energy and replenishment of metabolic building blocks.
- Vitamins and minerals are also essential to human nutrition.
- Proteins undergo a continuous cycle of synthesis and degradation termed protein turnover.
- Most adults excrete as much nitrogen as they consume and thus are in zero nitrogen balance.
- Carbohydrates and triglycerides are important sources of nutritional energy.
- Essential fatty acids cannot be synthesized by humans and must be obtained in the diet.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. Global Carbon Dioxide Cycling Expressed as Human Equivalents

If 3×10^{14} kg of CO_2 are cycled through the biosphere annually, how many human equivalents (70 kg people composed of 18% carbon by weight) could be produced each year from this amount of CO_2 ?

2. The Different Modes of Carbon and Energy Metabolism

Define the differences in carbon and energy metabolism between *photoautotrophs* and *photoheterotrophs* as well as between *chemoautotrophs* and *chemoheterotrophs*.

3. Metabolic Strategies in Plants

Why can plants be considered both photoautotrophic and chemoheterotrophic?

4. Where Do the O Atoms in Organisms Come From?

Name three principal inorganic sources of oxygen atoms that are commonly available in the inanimate environment and readily accessible to the biosphere.

5. How Do Catabolism and Anabolism Differ?

What are the features that generally distinguish pathways of catabolism from pathways of anabolism?

6. Anabolic vs Catabolic Pathways

How do anabolic and catabolic pathways differ in terms of the thermodynamic parameters enthalpy (H) and entropy (S)?

7. Oxidation States of Carbon

A main feature of catabolism is the oxidation of carbon atoms in organic molecules from a reduced state ($-\text{CH}_3$ or $-\text{CH}_2-$) to the fully oxidized state of CO_2 . An atom is oxidized when it loses electrons (as in $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$). In its oxidized form, carbon is still surrounded by four valence electrons making four chemical bonds. How does carbon lose electrons when oxidized from $-\text{CH}_3$ or $-\text{CH}_2-$ to CO_2 ? (Hint: The electronegativity value of H is 2.1, of C is 2.5, and of O is 3.5.)

8. How Are the Enzymes of Metabolic Pathways Organized?

Name the four principal modes of enzyme organization in metabolic pathways.

9. Why Do Anabolic and Catabolic Pathways Differ?

Why is the pathway for the biosynthesis of a biomolecule at least partially different from the pathway for its catabolism? Why is the pathway for the biosynthesis of a biomolecule inherently more complex than the pathway for its degradation?

10. What Are Primary Metabolic Roles of the Three Principal Nucleotides?

(Integrates with Chapters 1 and 3.) What are the metabolic roles of ATP, NAD^+ , and NADPH?

11. NAD^+ vs. NADP^+

The structure shown is NADP^+ . Compare this to the structure of NAD^+ shown in Figure 17.11. What is the difference between these two structures and why is this difference so important?

- 12. How Is Metabolism Regulated?** (Integrates with Chapter 15.) Metabolic regulation is achieved via regulating enzyme activity in three prominent ways: allosteric regulation, covalent modification, and enzyme synthesis and degradation. Which of these three modes of regulation is likely to be the quickest; which the slowest? For each of these general enzyme regulatory mechanisms, cite conditions in which cells might employ that mode in preference to either of the other two.
- 13. What Are the Advantages of Metabolic Compartmentalization?** What are the advantages of compartmentalizing particular metabolic pathways within specific organelles?
- 14. Why Are Metabolomic Analyses Challenging?** Name and discuss four challenges associated with metabolomic measurements in biological systems.
- 15. Which Is Better: NMR or MS?** Compare and contrast mass spectrometry and NMR in terms of their potential advantages and disadvantages for metabolomic analysis.
- 16. How Do Vitamin-Derived Coenzymes Aid Metabolism?** What chemical functionality is provided to enzyme reactions by pyridoxal phosphate (see Chapter 13)? By coenzyme A (see Chapter 19)? By vitamin B₁₂ (see Chapter 23)? By thiamine pyrophosphate (see Chapter 19)?
- 17. What Are the Features of the Series of -omes?** Define the following terms:
- genome
 - transcriptome
 - proteome
 - metabolome
 - fluxome
- 18. What Is the Alcohol Dehydrogenase Enzyme Mechanism?** The alcohol dehydrogenase reaction, described in Figure 17.11, interconverts ethyl alcohol and acetaldehyde and involves hydride transfer to and from NAD⁺ and NADH, respectively. Write a reasonable mechanism for the conversion of ethanol to acetaldehyde by alcohol dehydrogenase.
- 19. Where Are Various Metabolic Pathways Localized and What Are Their Inputs?** For each of the following metabolic pathways, describe where in the cell it occurs and identify the starting material and end product(s):
- citric acid cycle
 - glycolysis
 - oxidative phosphorylation
 - fatty acid synthesis
- 20. A Possible Solution to Global Warming** Many solutions to the problem of global warming have been proposed. One of these involves strategies for carbon sequestration—the removal of CO₂ from the earth's atmosphere by various means. From your reading of this chapter, suggest and evaluate a strategy for carbon sequestration in the ocean.
- 21. Radioactive Isotopes as Metabolic Tracers** Both ³²P and ³⁵S are radioactive isotopes that decay to stable isotopes of other elements by emission of an electron (β^- decay). Consult the Periodic Table to determine the elemental products (daughter isotopes) of ³²P and of ³⁵S decay. Given the half-life of ³²P as 14.3 days and that of ³⁵S as

87.4 days, calculate what percentage of each would remain from a sample that contained both and decayed for 100 days.

- 22. Nitrogen Balance** Section 17.6 discusses the importance of the nitrogen balance. List classes of biomolecules other than proteins that depend on a well-regulated nitrogen balance.
- 23. Organisms and Their Source of Energy** What three categories of organisms are described below?
- Lives in an environment where there is no sunlight. Derives energy from redox reactions initiated by inorganic compounds. Capable of fixing CO₂.
 - Lives in an environment where there is plenty of sunlight. Derives energy from redox reactions involving inorganic compounds but driven by visible light. Capable of fixing CO₂.
 - Lives in an environment where there may or may not be sunlight. Derives energy from redox reactions initiated by organic compounds. Capable of fixing CO₂.

The Metabolism of Obligate Anaerobes

- 24. Obligate Anaerobes** Which statement is most likely to be true concerning obligate anaerobes?
- These organisms can use oxygen if it is present in their environment.
 - These organisms cannot use oxygen as their final electron acceptor.
 - These organisms carry out fermentation for at least 50% of their ATP production.
 - Most of these organisms are vegetative fungi.

Methods to Study a Cell's Metabolism

- 25. Methods to Assess Metabolism** Which of the following experimental approaches is likely to give the most complete picture of a particular cell's metabolism: NMR spectroscopy, metabolic inhibitors, mass spectroscopy, or isotopic tracers? Explain.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

- 26.** Examine the ActiveModel for alcohol dehydrogenase and identify the amino acid side chains involved in binding the NAD coenzyme.

Think-Pair-Share Question

Section 17.2 discusses different ways metabolic pathway diagrams can be organized (metabolite- or protein-centric). Consider alternative ways to organize metabolic pathways similar as shown in Figure 17.4 but focusing on the chemical changes that occur within the biomolecules. Try to apply any of these alternatives to the pathway shown at the top of the next page. Provide pathways for a carbon-centric scheme focused on the increase or decrease in the number of carbon-carbon bonds in the molecules and an electron-centric scheme focused on changes in the oxidation number of carbon within the molecules (revisit Figure 17.10 for the oxidation states of carbon). Provide at least one other possible metabolic pathway organization.

Food Passionates/Corbis

Living organisms, like machines, conform to the law of conservation of energy, and must pay for all their activities in the currency of catabolism.

Ernest Baldwin
Dynamic Aspects of Biochemistry (1952)

◀ Louis Pasteur's scientific investigations into fermentation of grape sugar were pioneering studies of glycolysis.

Essential Question

Nearly every living cell carries out a catabolic process known as **glycolysis**—the stepwise degradation of glucose (and other simple sugars). Glycolysis is a paradigm of metabolic pathways. Carried out in the cytosol of cells, it is basically an anaerobic process; its principal steps occur with no requirement for oxygen. **What are the chemical basis and logic for this central pathway of metabolism; that is, how does glycolysis work?**

Living things first appeared in an environment lacking O_2 , and glycolysis was an early and important pathway for extracting energy from nutrient molecules. It played a central role in anaerobic metabolic processes during the first 2 billion years of biological evolution on earth. Contemporary organisms still employ glycolysis to provide precursor molecules for aerobic catabolic pathways (such as the tricarboxylic acid cycle) and as a short-term energy source when oxygen is limiting. A complex array of molecular signals fine-tune and adapt glycolysis to a variety of metabolic needs.

18.1 | What Are the Essential Features of Glycolysis?

In the glycolysis pathway (Figure 18.1), which will be explained in detail below, a molecule of glucose is converted by 10 enzyme-catalyzed steps into two molecules of 3-carbon pyruvate. Most of the details of this pathway (the first metabolic pathway to be elucidated) were worked out in the first half of the twentieth century by the German biochemists Otto Warburg, Gustav Embden, and Otto Fritz Meyerhof. In fact, the sequence of reactions in Figure 18.1 is often referred to as the **Embden–Meyerhof pathway**.

Why is glycolysis so important to organisms? There are several reasons. For some tissues (such as brain, kidney medulla, and rapidly contracting skeletal muscles) and for some cells (such as erythrocytes and sperm cells), glucose is the only source of metabolic energy. In addition, the product of glycolysis—pyruvate—is a versatile

Key Questions

- 18.1 What Are the Essential Features of Glycolysis?
- 18.2 Why Are Coupled Reactions Important in Glycolysis?
- 18.3 What Are the Chemical Principles and Features of the First Phase of Glycolysis?
- 18.4 What Are the Chemical Principles and Features of the Second Phase of Glycolysis?
- 18.5 What Are the Metabolic Fates of NADH and Pyruvate Produced in Glycolysis?
- 18.6 How Do Cells Regulate Glycolysis?
- 18.7 Are Substrates Other Than Glucose Used in Glycolysis?
- 18.8 How Do Cells Respond to Hypoxic Stress?

Phase 1

Phosphorylation of glucose and conversion to 2 molecules of glyceraldehyde-3-phosphate; 2 ATPs are used to prime these reactions.

**Phase 2**

Conversion of glyceraldehyde-3-phosphate to pyruvate and coupled formation of 4 ATP and 2 NADH.

Figure 18.1 The glycolytic pathway. The numbered steps are indicated in blue circles.

metabolite that can be used in several ways. In most tissues, when oxygen is plentiful (aerobic conditions), pyruvate is oxidized (with loss of the carboxyl group as CO_2), and the remaining two-carbon unit becomes the acetyl group of acetyl-coenzyme A (acetyl-CoA) (Figure 18.2). This acetyl group is metabolized in the tricarboxylic acid (TCA) cycle (and fully oxidized) to yield CO_2 .

Alternatively, in the absence of oxygen (anaerobic conditions), pyruvate can be reduced to lactate through oxidation of NADH to NAD^+ —a process termed **lactic acid fermentation**. In microorganisms such as brewer's yeast and in certain plant tissues, pyruvate can be reduced to ethanol, again with oxidation of NADH to NAD^+ . Most students will recognize this process as **alcoholic fermentation**.

Figure 18.2 Pyruvate produced in glycolysis can be used by cells in several ways. In animals, pyruvate is normally converted to acetyl-coenzyme A, which is then oxidized in the TCA cycle to produce CO₂. When oxygen is limiting, pyruvate can be converted to lactate. Alcoholic fermentation in yeast converts pyruvate to ethanol and CO₂.

Glycolysis consists of two phases. In the first phase, a series of five reactions, glucose is broken down into two molecules of glyceraldehyde-3-phosphate. In the second phase, five subsequent reactions convert these two molecules of glyceraldehyde-3-phosphate into two molecules of pyruvate. Phase 1 consumes two molecules of ATP (Figure 18.1). The later stages of glycolysis result in the production of four molecules of ATP. The net is $4 - 2 = 2$ molecules of ATP produced per molecule of glucose. Microorganisms, plants, and animals (including humans) carry out the 10 reactions of glycolysis in more or less similar fashion, although the rates of the individual reactions and the means by which they are regulated differ from species to species.

18.2 | Why Are Coupled Reactions Important in Glycolysis?

The process of glycolysis converts some, but not all, of the metabolic energy of the glucose molecule into ATP. The free energy change for the conversion of glucose into two molecules of lactate (the anaerobic route in contracting muscle) is -183.6 kJ/mol:

This process occurs with no net oxidation or reduction. Although several individual steps in the pathway involve oxidation or reduction, these steps compensate each other exactly. Thus, the conversion of a molecule of glucose into two molecules of lactate involves a rearrangement of bonds, with no net loss or gain of electrons. The energy made available through this rearrangement is a relatively small part of the total energy obtainable from glucose (see Figure 1.17).

The production of two molecules of ATP in glycolysis is an energy-requiring process:

Glycolysis couples these two reactions:

Careers in Chemistry

Neem J. Patel

Neem J. Patel is a Ph.D. candidate at the University of California studying soil recovery after forest fires. She completed her undergraduate studies at Georgia State University with a B.S. in Biology and a minor in Chemistry. She was so intrigued with her biochemistry courses that she took more than her degree required. During these years, Patel directly applied that knowledge to study petroleum-contaminated sediments from the DeepWater Horizon Spill.

She later became an assistant research scientist at New York University while she earned her M.S. with a focus on the meiotic regulation of brewer's yeast. Patel credits the molecular and biochemical methods honed through her education for preparing her for such rigorous laboratory research. From amplicon sequencing to western blotting, Patel's love for biochemistry has given her the tools to pursue her passion.

Thus, under standard-state conditions, $(61/183.6) \times 100\%$, or 33%, of the free energy released is preserved in the form of ATP in these reactions. However, as discussed in Section 3.2, solution conditions, such as pH, concentration, ionic strength, and presence of metal ions, can substantially alter the free energy change for such reactions. Under cellular conditions, the free energy change for the synthesis of ATP (Equation 18.2) is much larger, and approximately 50% of the available free energy is converted into ATP. Clearly, then, more than enough free energy is available in the conversion of glucose into lactate to drive the synthesis of two molecules of ATP.

18.3 What Are the Chemical Principles and Features of the First Phase of Glycolysis?

In the first phase of glycolysis, glucose is phosphorylated at C-1 and C-6, and the six-carbon skeleton of glucose is cleaved to yield two three-carbon molecules of glyceraldehyde-3-phosphate. Phosphorylation and cleavage reorganize the glucose molecule so that molecules of ATP can be produced in the second phase of glycolysis.

18.3a Reaction 1: Glucose Is Phosphorylated by Hexokinase or Glucokinase—The First Priming Reaction

The initial reaction of the glycolysis pathway involves phosphorylation of glucose at carbon atom 6 by either hexokinase or glucokinase. (Recall that kinases are enzymes that transfer the γ -phosphate of ATP to nucleophilic acceptors.) Phosphorylation activates glucose for the subsequent reactions in the pathway. However, the formation of such a phosphoester is thermodynamically unfavorable and requires energy input to operate in the forward direction (see Section 3.4). The energy comes from ATP, a requirement that at first seems counterproductive. Glycolysis is designed to *make* ATP, not consume it. However, the hexokinase or glucokinase reaction (Figure 18.1, Step 1) is one of two **priming reactions** in the pathway. Just as old-fashioned, hand-operated water pumps (Figure 18.3) have to be primed with a small amount of water to deliver more water to the thirsty pumper, the glycolysis pathway requires two priming ATP molecules to start the sequence of reactions and delivers four molecules of ATP in the end.

The complete reaction for the first step in glycolysis is

The hydrolysis of ATP makes 30.5 kJ/mol available in this reaction, and the phosphorylation of glucose costs 13.8 kJ/mol (Table 18.1). Thus, the reaction liberates 16.7 kJ/mol under standard-state conditions (1 M concentrations), and the equilibrium of the reaction lies far to the right ($K_{\text{eq}} = 850$ at 25°C; see Table 18.1). Under cellular conditions (Table 18.2), this first reaction of glycolysis is more favorable than at standard state, with a ΔG of -33.9 kJ/mol (see Table 18.1).

©Charles D. Winters

Figure 18.3 Just as a water pump must be primed with water to get more water out, the glycolytic pathway is primed with ATP in steps 1 and 3 in order to achieve net production of ATP in the second phase of the pathway.

The Cellular Advantages of Phosphorylating Glucose The incorporation of a phosphate into glucose in this energetically favorable reaction is important for several reasons. First, phosphorylation keeps the substrate in the cell. Glucose is a neutral molecule and could diffuse across the cell membrane, but phosphorylation confers a negative charge on glucose and the plasma membrane is essentially impermeable to glucose-6-phosphate (Figure 18.4). Moreover, rapid conversion of glucose to glucose-6-phosphate keeps the *intracellular* concentration of glucose low, favoring facilitated diffusion of glucose *into* the cell. In addition, because regulatory control can be imposed only on reactions not at equilibrium, the favorable thermodynamics of this first reaction makes it an important site for regulation.

The Isozymes of Hexokinase In most animal, plant, and microbial cells, the enzyme that phosphorylates glucose is **hexokinase**. Magnesium ion (Mg^{2+}) is required for this reaction, as for the other kinase enzymes in the glycolytic pathway. The true substrate for the hexokinase reaction is MgATP^{2-} . There are four isozymes of

Figure 18.4 Phosphorylation of glucose to glucose-6-phosphate by ATP creates a charged molecule that cannot easily cross the plasma membrane.

Table 18.2 Steady-State Concentrations of Glycolytic Metabolites in Erythrocytes

Metabolite	mM

Figure 18.5 Glucose-6-phosphate is the branch point for several metabolic pathways.

hexokinase in most animal tissues. Hexokinase I is the principal form in the brain. Hexokinase in skeletal muscle is a mixture of types I (70% to 75%) and II (25% to 30%). The K_m for glucose is 0.03 mM for type I and 0.3 mM for type II; thus, hexokinase operates efficiently at normal blood glucose levels of 4 mM or so. The animal isozymes are allosterically inhibited by the product, glucose-6-phosphate. High levels of glucose-6-phosphate inhibit hexokinase activity until consumption by glycolysis lowers its concentration. The hexokinase reaction is one of three points in the glycolysis pathway that are *regulated*. As the generic name implies, hexokinase can phosphorylate a variety of hexose sugars, including glucose, mannose, and fructose.

The type IV isozyme of hexokinase, called **glucokinase**, is found predominantly in the liver and pancreas. Compared to the other isozymes, type IV requires 5 mM glucose to reach 0.5 V_{max} and is relatively unaffected by glucose-6-P. Thus, glucokinase becomes important metabolically only when liver glucose levels are high (for example, when the individual has consumed large amounts of carbohydrates). When glucose levels are low, hexokinase is primarily responsible for phosphorylating glucose. However, when glucose levels are high, glucose is converted by glucokinase to glucose-6-phosphate and is eventually stored in the liver as glycogen. Glucokinase is an *inducible* enzyme—the amount present in the liver is controlled by *insulin* (secreted by the pancreas). (In patients with type 2 diabetes, glucokinase expression is dramatically reduced. These individuals cannot tolerate high levels of blood glucose and produce little liver glycogen.) Because glucose-6-phosphate is common to several metabolic pathways (Figure 18.5), it occupies a branch point in glucose metabolism.

Hexokinase Binds Glucose and ATP with an Induced Fit In most organisms, hexokinase occurs in a single form: a two-lobed 50 kDa monomer that resembles a clamp, with a large groove in one side (Figure 18.6; see also Figure 13.24). As predicted by Daniel Koshland (Section 13.6), hexokinase undergoes an induced fit, closing around the substrates ATP and glucose when they are bound (Figure 18.6).

The human hexokinase isozymes I, II, and III are twice as big as those of lower organisms. They are composed of two separate domains, each similar to the yeast enzyme, and connected head to tail by a long α -helix (Figure 18.7). The sequence and structure similarity apparently arose from the duplication and fusion of a primordial hexokinase gene. Interestingly, both halves of hexokinase II support catalysis, but only the C-terminal half of isozymes I and III performs phosphorylation of glucose. The N-terminal half, on the other hand, has apparently evolved into a form that allosterically regulates the activity of the C-terminal half! Type IV hexokinase (glucokinase) is similar in structure to the yeast enzyme, with a single clamp domain, a single active site, and a mass of 50 kDa (Figure 18.7).

A Deeper Look

Glucokinase—An Enzyme with Different Roles in Different Cells

Glucokinase has historically received less attention than its hexokinase type I–III cousins, even though they share the distinction of catalyzing the first step of glycolysis—the phosphorylation of glucose. Interestingly, however, glucokinase plays quite different roles in different cell types. In liver, glucokinase is important for synthesis and storage of glycogen in the post-prandial state (following a meal, when glucose levels are high). On the other hand, in the β -cells of the pancreas, glucokinase is the *glucose sensor* that recognizes glucose and initiates a signaling pathway that results in glucose-induced insulin secretion.

When blood glucose increases following a meal, glucose uptake by glucose transporters in the β -cell plasma membrane elevates the intracellular glucose concentration to millimolar levels. Under these conditions, glucokinase is the dominant initiator of glycolysis, since hexokinase is inhibited by glucose-6-P (figure). Glucokinase-driven glycolysis leads to an increased ATP/ADP ratio, which results in K^+ channel closure and subsequent opening of Ca^{2+} channels. Increased intracellular Ca^{2+} triggers secretion of insulin by the β -cells. In this way, the action of glucokinase in the β -cells results in glucose uptake (and energy gain) by insulin-sensitive organs throughout the body.

Glucokinase facilitates glucose-induced insulin secretion in β -cells of the pancreas.

18.3b Reaction 2: Phosphoglucoisomerase Catalyzes the Isomerization of Glucose-6-Phosphate

The second step in glycolysis is a common type of metabolic reaction: the isomerization of a sugar. In this particular case, the carbonyl oxygen of glucose-6-phosphate is shifted from C-1 to C-2. This amounts to isomerization of an aldose (glucose-6-phosphate) to a ketose (fructose-6-phosphate) as shown in Figure 18.8. The reaction

Figure 18.8 The phosphoglucose isomerase mechanism involves (1) opening of the pyranose ring, (2) proton abstraction leading to enediol formation, and (3) proton addition to the double bond followed by ring closure.

Phosphoglucose isomerase, with fructose-6-P (blue) bound (PDB id = 1HOX).

is necessary for two reasons. First, the next step in glycolysis is phosphorylation at C-1, and the hemiacetal —OH of glucose would be more difficult to phosphorylate than a simple primary hydroxyl. Second, the isomerization to fructose (with a carbonyl group at position 2 in the linear form) activates C-3, facilitating C-C bond cleavage in the fourth step of glycolysis. The enzyme responsible for this isomerization is **phosphoglucose isomerase**, also known as **phosphoglucose isomerase** and **glucose phosphate isomerase**. In humans, the enzyme requires Mg^{2+} for activity and is highly specific for glucose-6-phosphate. The ΔG° is 1.67 kJ/mol, and the value of ΔG under cellular conditions (Table 18.1) is -2.92 kJ/mol. This small value means that the reaction operates near equilibrium in the cell and is readily reversible. Phosphoglucose isomerase proceeds through an *enediol* intermediate, as shown in Figure 18.8. Although the predominant forms of glucose-6-phosphate and fructose-6-phosphate in solution are the ring forms, the isomerase interconverts the open-chain form of G-6-P with the open-chain form of F-6-P.

18.3c Reaction 3: ATP Drives a Second Phosphorylation by Phosphofructokinase—The Second Priming Reaction

The action of phosphoglucose isomerase, moving the carbonyl group from C-1 to C-2, creates a new primary alcohol function at C-1 (see Figure 18.8). The next step in the glycolytic pathway is the phosphorylation of this group by **phosphofructokinase** (PFK). Once again, the substrate that provides the phosphoryl group is ATP. Like the

hexokinase/glucokinase reaction, the phosphorylation of fructose-6-phosphate is a priming reaction and is endergonic:

When coupled (by phosphofructokinase) with phosphoryl transfer from ATP, the overall reaction becomes exergonic:

At pH 7 and 37°C, the phosphofructokinase reaction equilibrium lies far to the right. Just as the hexokinase reaction commits the cell to taking up glucose, the phosphofructokinase reaction commits the cell to metabolizing glucose rather than converting it to another sugar or storing it. Similarly, just as the large free energy change of the hexokinase reaction makes it a likely candidate for regulation, so the phosphofructokinase reaction is an important site of regulation—indeed, the most important site in the glycolytic pathway.

Regulation of Phosphofructokinase Phosphofructokinase acts as a valve controlling the rate of glycolysis. In addition to its role as a substrate, ATP is an allosteric inhibitor of this enzyme. Thus, phosphofructokinase has two distinct binding sites for ATP; a high-affinity substrate site and a low-affinity regulatory site. In the presence of high ATP concentrations, phosphofructokinase behaves cooperatively; plots of enzyme activity versus fructose-6-phosphate are sigmoid, and the K_m for fructose-6-phosphate is increased (Figure 18.9). Thus, when ATP levels are sufficiently high in the cytosol, glycolysis is turned off. Under most cellular conditions, however, the ATP concentration does not vary over a large range. The ATP concentration in muscle during vigorous exercise, for example, is only about 10% lower than that during the resting state. The rate of glycolysis, however, varies much more. A large range of glycolytic rates cannot be directly accounted for by only a 10% change in ATP levels.

AMP reverses the inhibition due to ATP, and AMP levels in cells can rise dramatically when ATP levels decrease, due to the action of the enzyme *adenylate kinase*, which catalyzes the reaction

with the equilibrium constant:

$$K_{\text{eq}} = \frac{[\text{ATP}][\text{AMP}]}{[\text{ADP}]^2} = 0.44 \quad (18.7)$$

Adenylate kinase rapidly interconverts ADP, ATP, and AMP to maintain this equilibrium. ADP levels in cells are typically 10% of ATP levels, and AMP levels are often less than 1% of the ATP concentration. Due to the nature of the adenylate kinase equilibrium, a small decrease in ATP concentration due to ATP consumption results in a much larger relative increase in the AMP levels because of adenylate kinase activity.

Clearly, the activity of phosphofructokinase depends on both ATP and AMP levels and is a function of the cellular energy status. Phosphofructokinase activity is increased when the energy status falls and is decreased when the energy status is high. The rate of glycolytic activity thus decreases when ATP is plentiful and increases when more ATP is needed.

Glycolysis and the citric acid cycle (to be discussed in Chapter 19) are coupled via phosphofructokinase, because *citrate*, an intermediate in the citric acid cycle, is an allosteric inhibitor of phosphofructokinase. When the citric acid cycle reaches saturation, glycolysis (which feeds the citric acid cycle under aerobic conditions) slows down. The citric acid cycle directs electrons into the electron-transport chain (for the purpose of ATP synthesis

Phosphofructokinase with ADP (orange) and fructose-6-phosphate (red) (PDB id = 4PFK).

Figure 18.9 At high [ATP], phosphofructokinase (PFK) behaves cooperatively and the plot of enzyme activity versus [fructose-6-phosphate] is sigmoid. High [ATP] thus inhibits PFK, decreasing the enzyme's affinity for fructose-6-phosphate.

Figure 18.10 Fructose-2,6-bisphosphate activates phosphofructokinase, increasing the affinity of the enzyme for fructose-6-phosphate and restoring the hyperbolic dependence of enzyme activity on substrate concentration.

Figure 18.11 Fructose-2,6-bisphosphate decreases the inhibition of phosphofructokinase due to ATP.

in oxidative phosphorylation) and also provides precursor molecules for biosynthetic pathways. Inhibition of glycolysis by citrate ensures that glucose will not be committed to these activities if the citric acid cycle is already saturated.

Phosphofructokinase is also regulated by β -D-fructose-2,6-bisphosphate, a potent allosteric activator that increases the affinity of phosphofructokinase for the substrate fructose-6-phosphate (Figure 18.10). Stimulation of phosphofructokinase is also achieved by decreasing the inhibitory effects of ATP (Figure 18.11). Fructose-2,6-bisphosphate increases the net flow of glucose through glycolysis by stimulating phosphofructokinase and by inhibiting fructose-1,6-bisphosphatase, the enzyme that catalyzes this reaction in the opposite direction.

18.3d Reaction 4: Cleavage by Fructose Bisphosphate Aldolase Creates Two 3-Carbon Intermediates

Fructose bisphosphate aldolase is a glycolytic enzyme that cleaves fructose-1,6-bisphosphate between the C-3 and C-4 carbons to yield two triose phosphates. The products are dihydroxyacetone phosphate (DHAP) and glyceraldehyde-3-phosphate. The reaction has an equilibrium constant of approximately 10^{-4} M, and a corresponding $\Delta G^{\circ'}$ of +23.9 kJ/mol. These values might imply that the reaction does not proceed effectively from left to right as written. However, the reaction makes two molecules (glyceraldehyde-3-P and dihydroxyacetone-P) from one molecule (fructose-1,6-bisphosphate), and the equilibrium is thus greatly influenced by concentration. The value of ΔG in erythrocytes is actually -0.23 kJ/mol (see Table 18.1). At physiological concentrations, the reaction is essentially at equilibrium.

Two classes of aldolase enzymes are found in nature. Animal tissues produce a Class I aldolase, characterized by the formation of a covalent Schiff base intermediate between an active-site lysine and the carbonyl group of the substrate. Class I aldolases do not require a divalent metal ion. Class II aldolases are produced mainly in bacteria and fungi and do not form a covalent E-S intermediate, but they contain an active-site metal (normally zinc, Zn^{2+}). Cyanobacteria and some other simple organisms possess both classes of aldolase.

The aldolase reaction is merely the reverse of the *aldol condensation* well known to organic chemists. The latter reaction involves an attack by a nucleophilic enolate anion of an aldehyde or ketone on the carbonyl carbon of an aldehyde. The opposite reaction, aldol cleavage, begins with removal of a proton from the β -hydroxyl group, which is

Figure 18.12 A mechanism for the fructose-1,6-bisphosphate aldolase reaction. **(a)** The Schiff base formed between the substrate carbonyl and an active-site lysine acts as an electron sink, increasing the acidity of the β -hydroxyl group and facilitating cleavage as shown. The catalytic residues in the rabbit muscle enzyme are Lys²²⁹ and Asp³³. **(b)** In Class II aldolases, an active-site Zn^{2+} stabilizes the enolate intermediate, leading to polarization of the substrate carbonyl group.

followed by the elimination of the enolate anion. A mechanism for the aldol cleavage reaction of fructose-1,6-bisphosphate in the Class I-type aldolases is shown in Figure 18.12a. In Class II aldolases, an active-site metal such as Zn^{2+} behaves as an electrophile, polarizing the carbonyl group of the substrate and stabilizing the enolate intermediate (Figure 18.12b).

18.3e Reaction 5: Triose Phosphate Isomerase Completes the First Phase of Glycolysis

Of the two products of the aldolase reaction, only glyceraldehyde-3-phosphate goes directly into the second phase of glycolysis. The other triose phosphate, dihydroxyacetone phosphate, must be converted to glyceraldehyde-3-phosphate by the enzyme **triose phosphate isomerase**. This reaction thus permits both products of the aldolase reaction to continue in the glycolytic pathway and in essence makes the C-1, C-2, and C-3 carbons of the starting glucose molecule equivalent to the C-6, C-5, and C-4 carbons, respectively. The reaction mechanism involves an enediol intermediate that can donate either of its hydroxyl protons to a basic residue on the enzyme and thereby become either dihydroxyacetone phosphate or glyceraldehyde-3-phosphate (Figure 18.13). Triose phosphate isomerase is one of the enzymes that have evolved to a state of catalytic perfection, with a turnover number near the diffusion limit (see Table 13.5).

Triose phosphate isomerase with substrate analog 2-phosphoglycerate (cyan; PDB id = 1YPI).

Figure 18.13 A reaction mechanism for triose phosphate isomerase. In the enzyme from yeast, the catalytic residue is Glu¹⁶⁵.

The triose phosphate isomerase reaction completes the first phase of glycolysis, each glucose that passes through being converted to two molecules of glyceraldehyde-3-phosphate. Although the last two steps of the pathway are energetically unfavorable, the overall five-step reaction sequence has a net $\Delta G^{\circ'}$ of $+2.2 \text{ kJ/mol}$ ($K_{\text{eq}} \approx 0.43$). It is the free energy of hydrolysis from the two priming molecules of ATP that brings the overall equilibrium constant close to 1 under standard-state conditions. The net ΔG under cellular conditions is quite negative (-53.4 kJ/mol in erythrocytes).

Human Biochemistry

Methylglyoxal and Advanced Glycation End-Products—The Dark Side of Glycolysis

Sugars can react nonenzymatically and covalently with many proteins to form *advanced glycation end-products (AGEs)*, altering the functions of the proteins. AGEs are associated with multiple pathologies, including diabetes, aging, and neurodegenerative diseases. Recent studies have shown that the dicarbonyl compound *methylglyoxal* is an even greater contributor to AGE formation than sugars themselves. Methylglyoxal covalently modifies cysteine, arginine, and lysine residues at multiple sites on many cellular proteins.

Methylglyoxal is produced from dihydroxyacetone phosphate (DHAP) in glycolysis by both enzymatic and nonenzymatic routes and accounts for as much as 0.4% of the total glycolytic flux. Intracellular concentrations of methylglyoxal are kept in the low-micromolar range via the *glyoxalase cycle* (figure), which is composed of two enzymes, glyoxalase 1 (GLO1) and glyoxalase 2 (GLO2). GLO1 couples methylglyoxal with the ubiquitous antioxidant peptide glutathione to form lactoylglutathione. Hydrolysis of this intermediate by GLO2 yields D-lactate, which is excreted from the body. Methylglyoxal is elevated in diabetes, cancer, cardiovascular disease, aging, and renal failure. Future insights into the particular sites of modification on specific proteins will be central to understanding the involvement of methylglyoxal and AGEs in diabetes and other diseases.

Methylglyoxal is produced from DHAP and covalently modifies Cys, Arg, and Lys residues at multiple sites on many proteins.

18.4 What Are the Chemical Principles and Features of the Second Phase of Glycolysis?

The second half of the glycolytic pathway involves the reactions that convert the metabolic energy in the glucose molecule into ATP. Altogether, four new ATP molecules are produced. If two are considered to offset the two ATPs consumed in phase 1, a net yield of two ATPs per glucose is realized. Phase 2 starts with the oxidation of glyceraldehyde-3-phosphate, a reaction with a large enough energy kick to produce the high-energy phosphate, 1,3-bisphosphoglycerate (see Figure 18.1, Step 6). Phosphoryl transfer from 1,3-BPG to ADP to make ATP is highly favorable. The product, 3-phosphoglycerate, is converted via several steps to phosphoenolpyruvate (PEP), another high-energy phosphate. PEP readily transfers its phosphoryl group to ADP in the pyruvate kinase reaction to make another ATP.

18.4a Reaction 6: Glyceraldehyde-3-Phosphate Dehydrogenase Creates a High-Energy Intermediate

In the first glycolytic reaction to involve oxidation–reduction, glyceraldehyde-3-phosphate is oxidized to 1,3-bisphosphoglycerate by **glyceraldehyde-3-phosphate dehydrogenase**. Although the oxidation of an aldehyde to a carboxylic acid is a highly exergonic reaction, the overall reaction involves both formation of a carboxylic–phosphoric anhydride and the reduction of NAD^+ to NADH and is therefore slightly endergonic at standard state, with a $\Delta G^{\circ'}$ of +6.30 kJ/mol. The free energy that might otherwise be released as heat in this reaction is directed into the formation of a high-energy phosphate compound, 1,3-bisphosphoglycerate, and the reduction of NAD^+ . The reaction mechanism involves nucleophilic attack by a cysteine —SH group on the carbonyl carbon of glyceraldehyde-3-phosphate to form a hemithioacetal (Figure 18.14). The hemithioacetal intermediate decomposes by hydride (H^-) transfer to NAD^+ to form a high-energy thioester. Nucleophilic attack by phosphate displaces the product, 1,3-bisphosphoglycerate, from the enzyme. The enzyme can be inactivated by reaction with iodoacetate, which reacts with and blocks the essential cysteine sulfhydryl.

The glyceraldehyde-3-phosphate dehydrogenase reaction is the site of action of *arsenate* (AsO_4^{3-}), a toxic anion analogous to phosphate. Arsenate is an effective substrate in this reaction, forming *1-arseno-3-phosphoglycerate*, but acyl arsenates are quite unstable and are rapidly hydrolyzed. 1-Arseno-3-phosphoglycerate breaks down to yield *3-phosphoglycerate*, the product of the seventh reaction of glycolysis. The result is that glycolysis continues in the presence of arsenate, but the molecule of ATP formed in reaction 7 (phosphoglycerate kinase) is not made because this step has been bypassed. The lability of 1-arseno-3-phosphoglycerate effectively uncouples the oxidation and phosphorylation events, which are normally tightly coupled in the glyceraldehyde-3-phosphate dehydrogenase reaction.

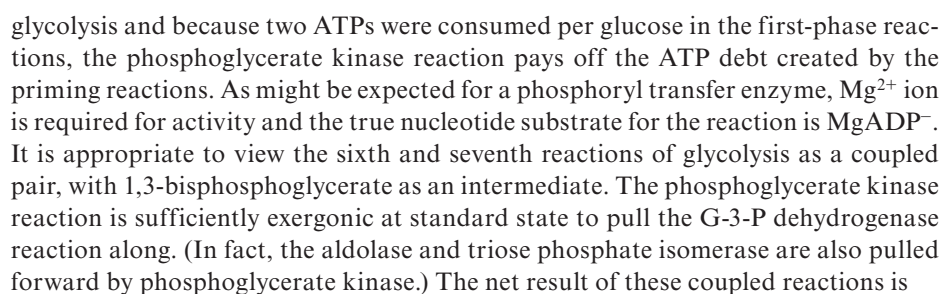

1-Arseno-3-phosphoglycerate

18.4b Reaction 7: Phosphoglycerate Kinase Is the Break-Even Reaction

The glycolytic pathway breaks even in terms of ATPs consumed and produced with reaction 7. The enzyme **phosphoglycerate kinase** transfers a phosphoryl group from 1,3-bisphosphoglycerate to ADP to form an ATP. Because each glucose molecule sends two molecules of glyceraldehyde-3-phosphate into the second phase of

Figure 18.14 A mechanism for the glyceraldehyde-3-phosphate dehydrogenase reaction. Reaction of an enzyme sulfhydryl with the carbonyl carbon of glyceraldehyde-3-P forms a thiohemiacetal, which loses a hydride to NAD^+ to become a thioester. Phosphorolysis of this thioester releases 1,3-bisphosphoglycerate. In the enzyme from rabbit muscle, the catalytic residue is Cys¹⁴⁹.

Another consequence of the coupling between these reactions is revealed in their values of ΔG under cellular conditions (Table 18.1). Despite its strongly negative ΔG° , the phosphoglycerate kinase reaction operates at equilibrium in the erythrocyte ($\Delta G = 0.1$ kJ/mol). In essence, the free energy available in the phosphoglycerate kinase reaction is used to bring the three previous reactions closer to equilibrium. Viewed in this context, it

The **(a)** open and **(b)** closed forms of phosphoglycerate kinase. ATP (*cyan*), 3-phosphoglycerate (*purple*), and Mg^{2+} (*gold*) (a: PDB id = 3PGK; b: PDB id = 1VPE).

is clear that ADP has been phosphorylated to form ATP at the expense of a substrate, namely, glyceraldehyde-3-phosphate. This is an example of **substrate-level phosphorylation**, a concept that will be encountered again. (The other kind of phosphorylation, *oxidative phosphorylation*, is driven energetically by the transport of electrons from appropriate coenzymes and substrates to oxygen.) Even though the coupled reactions exhibit a very favorable ΔG° , there are conditions (for example, high ATP and 3-phosphoglycerate levels) under which the phosphoglycerate kinase reaction can be reversed so that 3-phosphoglycerate is phosphorylated from ATP.

An important regulatory molecule, 2,3-bisphosphoglycerate, is synthesized and metabolized by a pair of reactions that make a detour around the phosphoglycerate kinase reaction. 2,3-BPG, which stabilizes the deoxy form of hemoglobin and is primarily responsible for the cooperative nature of oxygen binding by hemoglobin (see Section 15.6), is formed from 1,3-bisphosphoglycerate by **bisphosphoglycerate mutase** (Figure 18.15). Interestingly, 3-phosphoglycerate is required for this reaction, which involves phosphoryl transfer from the C-1 position of 1,3-bisphosphoglycerate to the C-2 position of 3-phosphoglycerate (Figure 18.16). Hydrolysis of 2,3-BPG is carried out by *2,3-bisphosphoglycerate phosphatase*. Although other cells contain only a trace of 2,3-BPG, erythrocytes typically contain 4 to 5 mM 2,3-BPG.

18.4c Reaction 8: Phosphoglycerate Mutase Catalyzes a Phosphoryl Transfer

The remaining steps in the glycolytic pathway prepare for synthesis of the second ATP equivalent. This begins with the **phosphoglycerate mutase** reaction, in which the phosphoryl group of 3-phosphoglycerate is moved from C-3 to C-2. (The term *mutase* is applied to enzymes that catalyze migration of a functional group within a substrate molecule.) The free energy change for this reaction is very small under cellular conditions ($\Delta G = 0.83$ kJ/mol in erythrocytes). Phosphoglycerate mutase enzymes isolated from different sources exhibit different reaction mechanisms. As shown in Figure 18.17, the enzymes isolated from yeast and from rabbit muscle form *phosphoenzyme* intermediates, use *2,3-bisphosphoglycerate* as a cofactor, and undergo *intermolecular* phosphoryl group transfers (in which the phosphate of the product 2-phosphoglycerate is not that from the 3-phosphoglycerate substrate). The prevalent form of phosphoglycerate mutase is a *phosphoenzyme*, with a phosphoryl group covalently bound to a histidine residue at the active site. This phosphoryl group is transferred to the C-2 position of the substrate to form a transient, enzyme-bound 2,3-bisphosphoglycerate, which then decomposes by a second phosphoryl transfer from the C-3 position of the intermediate to the histidine residue on the enzyme. About once in every 100 enzyme turnovers, the intermediate, 2,3-bisphosphoglycerate, dissociates from the active site,

Phosphoglycerate mutase

Figure 18.15 Formation and decomposition of 2,3-bisphosphoglycerate.

Figure 18.16 The mutase that forms 2,3-BPG from 1,3-BPG requires 3-phosphoglycerate. The reaction is an intermolecular phosphoryl transfer from C-1 of 1,3-BPG to C-2 of 3-PG.

Figure 18.17 A mechanism for the phosphoglycerate mutase reaction in rabbit muscle and in yeast. Zelda Rose of the Institute for Cancer Research in Philadelphia showed that the enzyme requires a small amount of 2,3-BPG to phosphorylate the histidine residue before the mechanism can proceed. Prior to her work, the role of the phosphohistidine in this mechanism was not understood.

leaving an inactive, unphosphorylated enzyme. The unphosphorylated enzyme can be reactivated by binding 2,3-BPG. For this reason, maximal activity of phosphoglycerate mutase requires the presence of small amounts of 2,3-BPG.

18.4d Reaction 9: Dehydration by Enolase Creates PEP

Recall that prior to synthesizing ATP in the phosphoglycerate kinase reaction, it was necessary to first make a substrate having a high-energy phosphate. Reaction 9 of glycolysis, the **enolase** reaction, similarly makes a high-energy phosphate in preparation for ATP synthesis. Enolase catalyzes the formation of *phosphoenolpyruvate* from 2-phosphoglycerate. The reaction involves the removal of a water molecule to form the enol structure of PEP. The $\Delta G^{\circ'}$ for this reaction is relatively small at 1.8 kJ/mol ($K_{eq} = 0.5$); and, under cellular conditions, ΔG is very close to zero. How can the

enolase reaction transform a substrate with a relatively low free energy of hydrolysis into a product (PEP) with a very high free energy of hydrolysis? This is possible because 2-phosphoglycerate and PEP contain about the same amount of *potential* metabolic energy, with respect to decomposition to P_i, CO₂, and H₂O. What the enolase reaction does is rearrange the substrate into a form from which more of this potential energy can be released upon hydrolysis. The enzyme is strongly inhibited by fluoride ions in the presence of phosphate. Thomas Nowak has shown that fluoride, phosphate, and a divalent cation form a transition-state-like complex in the enzyme active site, with fluoride apparently mimicking the hydroxide ion nucleophile in the enolase reaction.

Yeast enolase is a dimer of identical subunits and X-ray crystal structures of enzymes like this typically show identical active site structures for both subunits. However, if yeast enolase is crystallized in the presence of a mixture of the substrate (2-phosphoglycerate) and the product (phosphoenolpyruvate), the crystallized dimer is asymmetric! One subunit active site contains 2-phosphoglycerate, and the other contains PEP (Figure 18.18), thus providing a before-and-after picture of this glycolytic enzyme.

18.4e Reaction 10: Pyruvate Kinase Yields More ATP

The second ATP-synthesizing reaction of glycolysis is catalyzed by **pyruvate kinase**, which brings the pathway at last to its pyruvate branch point. Pyruvate kinase mediates the transfer of a phosphoryl group from phosphoenolpyruvate to ADP to make

Figure 18.18 The yeast enolase dimer is asymmetric. The active site of one subunit **(a)** contains 2-phosphoglycerate, the enolase substrate. Also shown are a Mg^{2+} ion (blue), a Li^{+} ion (purple), and His^{159} , which participates in catalysis. The other subunit **(b)** binds phosphoenolpyruvate, the product of the enolase reaction. An active-site water molecule (yellow), Mg^{2+} (blue), and His^{159} are also shown (PDB id = 2ONE).

ATP and pyruvate. The reaction requires Mg^{2+} ion and is stimulated by K^{+} and certain other monovalent cations.

The corresponding K_{eq} at 25°C is 3.63×10^5 , and it is clear that the pyruvate kinase reaction equilibrium lies very far to the right. Concentration effects reduce the magnitude of the free energy change somewhat in the cellular environment, but the ΔG in erythrocytes is still quite favorable at -23.0 kJ/mol . The high free energy change for the conversion of PEP to pyruvate is due largely to the highly favorable and spontaneous conversion of the enol tautomer of pyruvate to the more stable keto form (Figure 18.19) following the phosphoryl group transfer step.

The structure of the pyruvate kinase tetramer is sensitive to bound ligands. The inactive *E. coli* enzyme in the absence of ligands (*left*, PDB id = 1E0U). The active form of the yeast dimer, with fructose-1,6-bisphosphate (an allosteric regulator, blue), substrate analog (red), and K^{+} (gold) (PDB id = 1A3W).

Figure 18.19 The conversion of phosphoenolpyruvate (PEP) to pyruvate may be viewed as involving two steps: phosphoryl transfer followed by an enol–keto tautomerization. The tautomerization is spontaneous ($\Delta G^\circ \approx -35$ – 40 kJ/mol) and accounts for much of the free energy change for PEP hydrolysis.

The large negative ΔG of this reaction makes pyruvate kinase a suitable target site for regulation of glycolysis. For each glucose molecule in the glycolysis pathway, two ATPs are made at the pyruvate kinase stage (because two triose molecules were produced per glucose in the aldolase reaction). Because the pathway broke even in terms of ATP at the phosphoglycerate kinase reaction (two ATPs consumed and two ATPs produced), the two ATPs produced by pyruvate kinase represent the payoff of glycolysis—a net yield of two ATP molecules.

Pyruvate kinase possesses allosteric sites for numerous effectors. It is activated by AMP and fructose-1,6-bisphosphate and inhibited by ATP, acetyl-CoA, and alanine. (Note that alanine is the α -amino acid counterpart of the α -keto acid, pyruvate.) Furthermore, liver pyruvate kinase is regulated by covalent modification. Hormones such as *glucagon* activate cAMP-dependent protein kinase, which transfers a phosphoryl group from ATP to the enzyme. The phosphorylated form of pyruvate kinase is more strongly inhibited by ATP and alanine and has a higher K_m for PEP, so in the presence of physiological levels of PEP, the enzyme is inactive. Then PEP is used as a substrate for glucose synthesis in the *gluconeogenesis* pathway, instead of going on through glycolysis and the citric acid cycle (or fermentation routes). A suggested active-site geometry and mechanism for pyruvate kinase, based on NMR and EPR studies by

Human Biochemistry

Pyruvate Kinase M2 Moonlights as a Protein Kinase in Cancer

The mammalian pyruvate kinase gene family is represented by two genes that encode four isoforms—L, R, M1, and M2. L and R predominate in liver and red blood cells, respectively. M1 is found mainly in brain and skeletal muscle, but M2 is the dominant form in proliferating cells. New tissues always express M2 first and switch to other forms during tissue differentiation. However, numerous studies have shown that a shift back to M2 expression occurs during tumor formation.

PK M2 normally exists as a tetramer that exhibits high pyruvate kinase activity. However, Zhi-Ren Liu and colleagues have shown that PK M2 can dissociate to form dimers that localize to the cell nucleus. PK M2 dimers have low PK activity, but they can act as protein kinases, using PEP as the phosphorylation substrate. This novel PK M2 protein kinase activity is essential to cellular proliferation—at least a hundred proteins can be phosphorylated by this PEP-dependent protein kinase.

More recently, Young-Sam Lee and colleagues have added a surprising twist to this story. The protein kinase activity of PK M2 is stimulated by N-succinyl-5-aminoimidazole-4-carboxamide-1-ribose-5'-phosphate (SAICAR), an intermediate from the purine biosynthetic pathway. PK M2, which acts to direct glucose to the pentose phosphate pathway for ribose-5-phosphate synthesis (see Critical Developments in Biochemistry—The Warburg Effect and Cancer), also acts through its protein kinase function to activate the expression of the genes for

purine biosynthesis when nucleotides for DNA and RNA synthesis are needed—a hallmark of proliferating tissues such as tumors.

N-succinyl-5-aminoimidazole-4-carboxamide ribonucleotide (SAICAR)

Figure 18.20 A mechanism for the pyruvate kinase reaction, based on NMR and EPR studies by Albert Mildvan and colleagues. Phosphoryl transfer from phosphoenolpyruvate (PEP) to ADP occurs in four steps: (1) A water on the Mg^{2+} ion coordinated to ADP is replaced by the phosphoryl group of PEP, (2) Mg^{2+} dissociates from the α -P of ADP, (3) the phosphoryl group is transferred, and (4) the enolate of pyruvate is protonated. (Adapted from Mildvan, A., 1979. The role of metals in enzyme-catalyzed substitutions at each of the phosphorus atoms of ATP. *Advances in Enzymology* 49:103–126.)

Albert Mildvan and colleagues, is presented in Figure 18.20. The carbonyl oxygen of pyruvate and the γ -phosphorus of ATP lie within 0.3 nm of each other at the active site, consistent with direct transfer of the phosphoryl group without formation of a phosphoenzyme intermediate.

18.5 What Are the Metabolic Fates of NADH and Pyruvate Produced in Glycolysis?

In addition to ATP, the products of glycolysis are NADH and pyruvate. Their processing depends upon other cellular pathways. NADH must be recycled to NAD^+ , lest NAD^+ become limiting in glycolysis. NADH can be recycled by both aerobic and anaerobic paths, either of which results in further metabolism of pyruvate. What a given cell does with the pyruvate produced in glycolysis depends in part on the availability of oxygen. Under aerobic conditions, pyruvate can be sent into the citric acid cycle (also known as the TCA cycle). There, it is oxidized to CO_2 with the production of additional NADH (and FADH_2). Under aerobic conditions, the NADH produced in glycolysis and the citric acid cycle is reoxidized to NAD^+ in the mitochondrial electron-transport chain.

18.5a Anaerobic Metabolism of Pyruvate Leads to Lactate or Ethanol

Under anaerobic conditions, the pyruvate produced in glycolysis is reduced to ethanol in yeast, or reduced to lactate in microorganisms and animals. These processes are examples of **fermentation**—the production of ATP energy by reaction pathways in which organic molecules function as donors and acceptors of electrons. In either case, the reduction of pyruvate provides a means of reoxidizing the NADH produced in the glyceraldehyde-3-phosphate dehydrogenase reaction of glycolysis (Figure 18.21). In yeast, alcoholic fermentation is a two-step process. Pyruvate is decarboxylated to acetaldehyde by **pyruvate decarboxylase** in an essentially irreversible reaction. Thiamine pyrophosphate is a required cofactor for this enzyme. The second step, the reduction of acetaldehyde to ethanol by NADH, is catalyzed by **alcohol dehydrogenase** (Figure 18.21a). At pH 7, the reaction equilibrium strongly favors ethanol. The end products of alcoholic fermentation are thus ethanol and carbon dioxide. Alcoholic fermentations are the basis for the brewing of beers and the fermentation of grape sugar in wine making. Lactate produced by anaerobic microorganisms during lactic acid fermentation is responsible for the taste of sour milk and for the characteristic taste and fragrance of sauerkraut, which in reality is fermented cabbage.

Woodford Reserve Distillery, Versailles, KY. **(b)** In oxygen-depleted muscle, for example, during strenuous exercise (photo), NAD^+ is regenerated in the lactate dehydrogenase reaction. Hibernating fresh-water turtles, trapped beneath ice and lying in mud, become anoxic, and convert glucose reserves mainly to lactate. Their shells release minerals to buffer the lactate throughout hibernation (photo).

18.5b Lactate Accumulates Under Anaerobic Conditions in Animal Tissues

In animal tissues experiencing anaerobic conditions, pyruvate is reduced to lactate. Pyruvate reduction occurs in tissues that normally experience minimal access to blood flow (for example, the cornea of the eye) and also in rapidly contracting skeletal muscle. When skeletal muscles are exercised strenuously, the available tissue oxygen is consumed and the pyruvate generated by glycolysis can no longer be oxidized in the TCA cycle. Instead, excess pyruvate is reduced to lactate by **lactate dehydrogenase**

Critical Developments in Biochemistry

The Warburg Effect and Cancer

Otto Warburg observed in 1924 that rapidly proliferating cancer cells metabolize glucose in a manner distinct from that of quiescent (non-dividing) tissues. Warburg found that cancer cells tend to convert glucose into lactate, even in the presence of oxygen sufficient to support mitochondrial oxidative phosphorylation. (Because this occurs even in an abundance of oxygen, it is referred to as aerobic glycolysis.) This is at first surprising, because conversion of glucose to lactate produces only 2 molecules of ATP per molecule of glucose, whereas complete metabolism of glucose in oxidative phosphorylation produces more than 30 molecules of ATP. Why do proliferating cells switch to an apparently less efficient metabolism?

Lewis Cantley and co-workers have suggested that proliferating cells need more than just ATP—they must synthesize large amounts of nucleotides, amino acids, and lipids. For these purposes, cells require carbon for biomass and NADPH (reducing equivalents for anabolic metabolism). These needs cannot be met merely by converting glucose to CO_2 and ATP via oxidative phosphorylation. Some glucose must be diverted to macromolecular precursors such as glycolytic intermediates for nonessential amino acids, ribose for nucleotides, and acetate units for fatty acids. C-13 NMR measurements have shown in fact that glioblastoma (a type of cancer) cells convert as much as 90% of acquired glucose and 60% of acquired glutamine into lactate or alanine, producing large amounts of NADPH. The lactate and alanine produced in this way can be recycled by nearby specialized nonproliferating cells, and also by the liver.

Numerous signaling proteins and pathways regulate the glycolytic pathway. Phosphoinositide 3-kinase (PI3K) activates glucose transporter expression, enhancing glucose capture by hexokinase. PI3K also stimulates PFK. In contrast to quiescent cells, proliferating cells selectively express the M2 (embryonic) isoform of pyruvate kinase (PK M2), which is regulated by tyrosine-phosphorylated proteins. The activity of PK M2 is reduced by binding phosphotyrosine-containing

Otto Warburg received the Nobel Prize in Physiology or Medicine in 1931 with the citation “for his discovery of the nature and mode of action of the respiratory enzyme.” Warburg’s “respiratory enzyme” is cytochrome oxidase, the last enzyme in the electron transport pathway. Warburg, who studied under the great Emil Fischer, mentored three future recipients of the Nobel Prize, including Hans Krebs, discoverer of the tricarboxylic acid cycle.

Some of the regulatory processes that determine the metabolic fate of glucose.

proteins, allowing PK M2 to act as a gatekeeper to control the flow of carbon into biosynthetic pathways versus catabolism for ATP production. p53, the protein encoded by a prominent tumor suppressor gene, is implicated in the regulation of cellular responses to stress. The p53 gene is also mutated in most cancer cells. TIGAR, a p53-activated protein, is a fructose biphosphatase. TIGAR inhibits PFK by lowering fructose-2,6-bisphosphate levels, thereby redirecting glucose to the pentose phosphate pathway. The pentose phosphate pathway produces NADPH and a variety of sugars essential to anabolic pathways. p53 has additional effects on glycolysis and related pathways. For example, p53 inhibits the expression of glucose transporter proteins (which bring glucose into the cell) and also regulates expression of hexokinase and phosphoglycerate mutase. These effects of p53 occur in the nucleus, but cytosolic p53 directly inhibits glucose-6-P dehydrogenase (which inhibits the shunting of glucose-6-P into the pentose phosphate pathway, forestalling NADPH production for fatty acid synthesis and ribose-5-P formation for nucleotide and nucleic acid biosynthesis).

The emerging evidence highlights the role of glycolysis as a dynamically regulated system that is programmed to meet the specific needs of quiescent differentiated tissues or fit the requirements of rapidly proliferating cells.

(a) ΔG at standard state (ΔG°)(b) ΔG in erythrocytes (ΔG)

Figure 18.22 A comparison of free energy changes for the reactions of glycolysis (step 1 = hexokinase) under (a) standard-state conditions and (b) actual intracellular conditions in erythrocytes. The values of ΔG° provide little insight into the actual free energy changes that occur in glycolysis. On the other hand, under intracellular conditions, seven of the glycolytic reactions operate near equilibrium (with ΔG near zero). The driving force for glycolysis lies in the hexokinase (1), phosphofructokinase (3), and pyruvate kinase (10) reactions. The lactate dehydrogenase (step 11) reaction also exhibits a large negative ΔG under cellular conditions.

(Figure 18.21b). The rate of anaerobic glycolysis in skeletal muscle can increase up to 2000-fold almost instantaneously, for example, to support the intense demands of a sprinting animal. Large amounts of ATP are generated rapidly, at the expense of lactate accumulation. In anaerobic muscle tissue, lactate represents the end of glycolysis. Most of this lactate must be carried out of the muscle by the blood and transported to the liver, where it can be resynthesized into glucose in gluconeogenesis. Moreover, because glycolysis generates only a fraction of the total energy available from the breakdown of glucose (the rest is generated by the TCA cycle and oxidative phosphorylation), the onset of anaerobic conditions in skeletal muscle also means a reduction in the energy available from the breakdown of glucose.

Freshwater turtles (Figure 18.21b) use a remarkable adaptation of their form to survive the harsh conditions of winter, under frozen lakes for months, without breathing. Turtles in such conditions become anoxic (subsisting without oxygen). Their heart beats only once every ten minutes, and brain activity is reduced to almost nothing. They metabolize only a limited store of glycogen, rather than fat (which requires oxygen to be metabolized). The glycogen is converted to glucose, and then to lactate via glycolysis. The turtle's shell releases mineral reserves to buffer the otherwise fatal buildup of lactate in the turtle's blood, and the shell also traps some of the lactate, keeping it out of the bloodstream. Without the biochemical adaptations provided by its shell, the turtle could not survive the winter.

18.6 | How Do Cells Regulate Glycolysis?

The elegance of nature's design for the glycolytic pathway may be appreciated through an examination of Figure 18.22. The standard-state free energy changes for the 10 reactions of glycolysis and the lactate dehydrogenase reaction (Figure 18.22a) are variously positive and negative and, taken together, offer little insight into the coupling that occurs in the cellular milieu. On the other hand, the values of ΔG under cellular conditions (Figure 18.22b) fall into two distinct classes. For reactions 2 and 4 through 9, ΔG is very close to zero, meaning these reactions operate essentially at equilibrium. Small changes in the concentrations of reactants and products could push any of these reactions either forward or backward. By contrast, the hexokinase, phosphofructokinase, and pyruvate kinase reactions all exhibit large negative ΔG values under cellular conditions. These reactions are thus the sites of glycolytic regulation. When these three enzymes are active, glycolysis proceeds and glucose is readily metabolized to pyruvate or lactate. Inhibition of the three key enzymes by allosteric effectors brings glycolysis to a halt. In **gluconeogenesis**—the biosynthesis of glucose—different enzymes are used to carry out reactions 1, 3, and 10 in reverse, effecting the net synthesis of glucose. The maintenance of reactions 2 and 4 through 9 at or near equilibrium permits these reactions (and their respective enzymes!) to operate effectively in *either* the forward or reverse direction.

18.7 | Are Substrates Other Than Glucose Used in Glycolysis?

The glycolytic pathway described in this chapter begins with the breakdown of glucose, but other sugars, both simple and complex, can enter the cycle if they can be converted by appropriate enzymes to one of the intermediates of glycolysis. Figure 18.23 shows the routes by which several simple metabolites can enter the glycolytic pathway.

18.7a Fructose Catabolism in Liver Is Unregulated—and Potentially Harmful

Dietary fructose is degraded almost exclusively in the liver in an unregulated process that circumvents the PFK reaction. In the liver, fructose is phosphorylated at C-1 by the enzyme **fructokinase**:

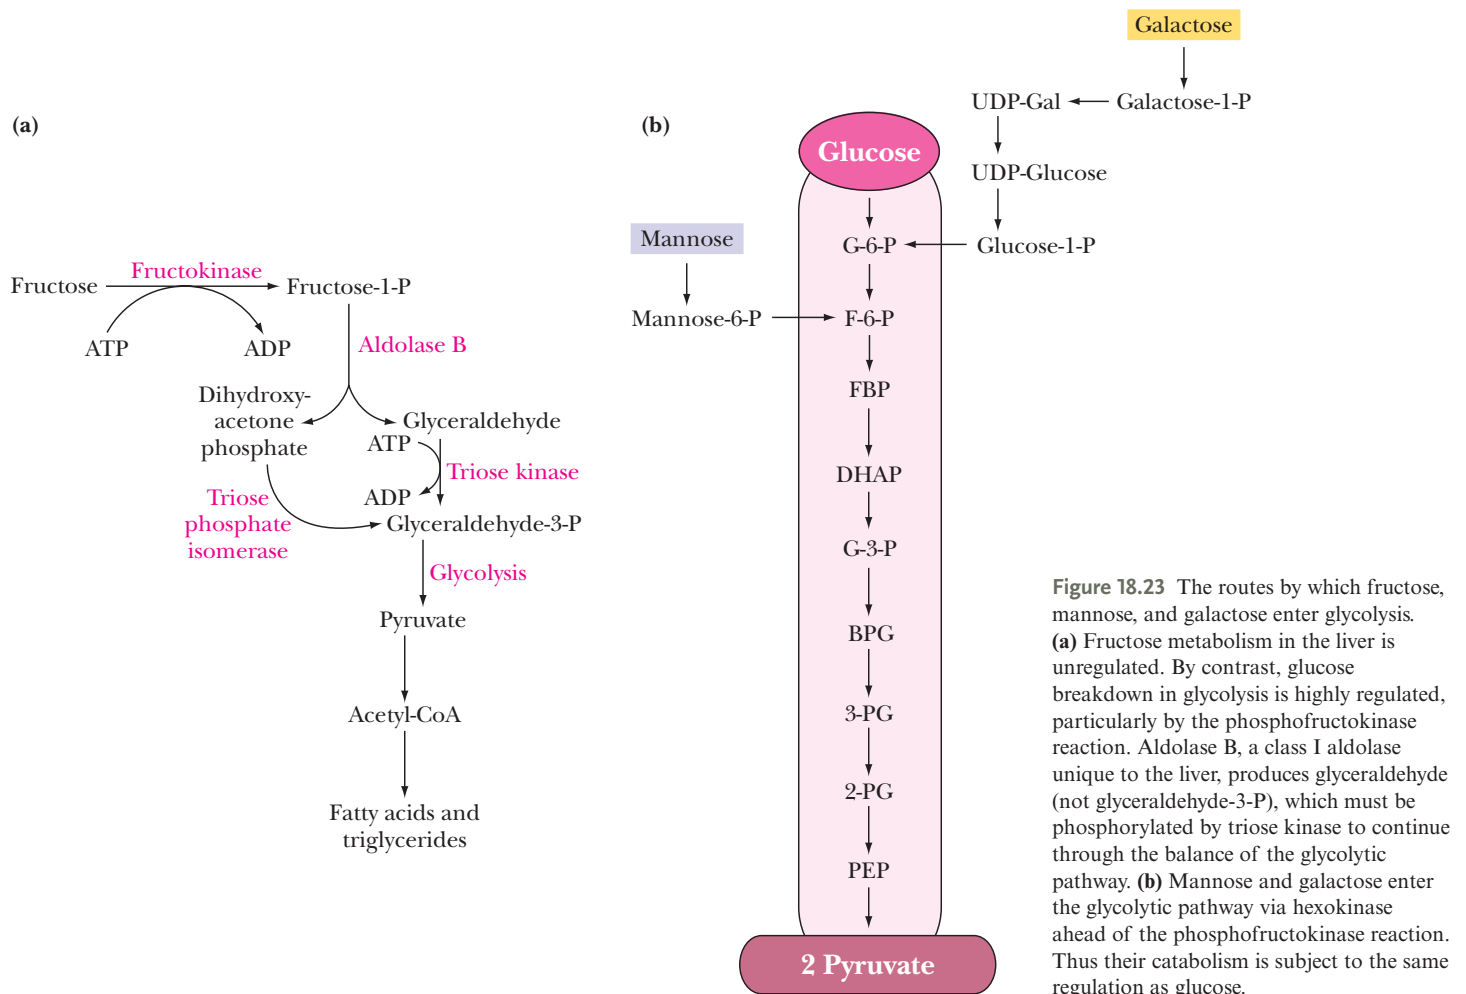

Figure 18.23 The routes by which fructose, mannose, and galactose enter glycolysis. **(a)** Fructose metabolism in the liver is unregulated. By contrast, glucose breakdown in glycolysis is highly regulated, particularly by the phosphofructokinase reaction. Aldolase B, a class I aldolase unique to the liver, produces glyceraldehyde (not glyceraldehyde-3-P), which must be phosphorylated by triose kinase to continue through the balance of the glycolytic pathway. **(b)** Mannose and galactose enter the glycolytic pathway via hexokinase ahead of the phosphofructokinase reaction. Thus their catabolism is subject to the same regulation as glucose.

Subsequent action by **fructose-1-phosphate aldolase** cleaves fructose-1-P to produce dihydroxyacetone phosphate and D-glyceraldehyde:

Dihydroxyacetone phosphate is of course an intermediate in glycolysis. D-Glyceraldehyde can be phosphorylated by **triose kinase** in the presence of ATP to form D-glyceraldehyde-3-phosphate, another glycolytic intermediate.

Most of the dihydroxyacetone phosphate and glyceraldehyde-3-P produced from fructose is converted directly to pyruvate and acetyl-CoA, and then to fatty acids and triglycerides in an unregulated process that can result in accumulation of fat in the liver (Figure 18.23a). Thus, diets high in fructose can lead to fatty liver disease and eventually cirrhosis. Liver fats can also be released into the circulation, with resulting accumulation by fat cells in other tissues. American dietary consumption of fructose has increased from 15 g/day in 1900 to approximately 90 g/day in modern times, a consequence of the prevalence of sucrose and high fructose corn syrup in beverages and processed foods. Diets high in fructose promote insulin resistance, metabolic syndrome, and obesity.

The small amounts of dietary fructose that reach the kidneys and muscle can be phosphorylated by hexokinase, which, as pointed out previously, can utilize several different hexose substrates. The free energy of hydrolysis of ATP drives the reaction forward:

Fructose-6-phosphate generated in this way enters the glycolytic pathway directly in step 3, the second priming reaction.

18.7b Mannose Enters Glycolysis in Two Steps

Another simple sugar that enters glycolysis at the same point as fructose is **mannose**, which occurs in many glycoproteins, glycolipids, and polysaccharides (see Section 7.5). Mannose is also phosphorylated from ATP by hexokinase, and the mannose-6-phosphate thus produced is converted to fructose-6-phosphate by **phosphomannoisomerase**.

18.7c Galactose Enters Glycolysis via the Leloir Pathway

A somewhat more complicated route into glycolysis is followed by **galactose**, another simple hexose sugar. The process, called the **Leloir pathway** after Luis Leloir, its discoverer, begins with phosphorylation from ATP at the C-1 position by **galactokinase**:

Human Biochemistry

Tumor Diagnosis Using Positron Emission Tomography (PET)

More than 90 years ago, Otto Warburg at the Kaiser Wilhelm Institute of Biology in Germany demonstrated that most animal and human tumors displayed a very high rate of glycolysis compared to that of normal tissue (see also the Critical Developments in Biochemistry box in Section 18.6). This observation from long ago is the basis of a modern diagnostic method for tumor detection called **positron emission tomography**, or **PET**. PET uses molecular

probes that contain a neutron-deficient, radioactive element such as carbon-11 or fluorine-18. An example is 2- ^{18}F fluoro-2-deoxyglucose (FDG), a molecular mimic of glucose. The ^{18}F nucleus is unstable and spontaneously decays by emission of a positron (an antimatter* particle) from a proton, thus converting a proton to a neutron and transforming the ^{18}F to ^{18}O . The emitted positron typically travels a short distance (less than a millimeter) and collides with an electron, annihilating both particles and creating a pair of high-energy photons—gamma rays. Detection of the gamma rays with special cameras can be used to construct three-dimensional models of the location of the radiolabeled molecular probe in the tissue of interest.

FDG is taken up by human cells and converted by hexokinase to 2- ^{18}F fluoro-2-deoxy-glucose-6-phosphate in the first step of glycolysis. Cells of a human brain, for example, accumulate FDG in direct proportion to the amount of glycolysis occurring in those cells. Tumors can be identified in PET scans as sites of unusually high FDG accumulation.

(a)

(b)

Positrons emitted by ^{18}F are annihilated by collision with electrons in tissue.

(c) PET image of human brain following administration of ^{18}F FDG. Red area indicates a large malignant tumor.

*The existence of antimatter in the form of positrons was first postulated by Robert Oppenheimer, the father of the atomic bomb.

Galactose-1-phosphate is then converted into *UDP-galactose* (a sugar nucleotide) by **galactose-1-phosphate uridylyltransferase** (Figure 18.24), with concurrent production of glucose-1-phosphate and consumption of a molecule of UDP-glucose. The uridylyltransferase reaction (Figure 18.25) proceeds via a ping-pong mechanism (see Section 13.5) with a covalent enzyme-UMP intermediate. The glucose-1-phosphate produced by the transferase reaction is a substrate for the **phosphoglucomutase** reaction (Figure 18.24), which produces glucose-6-phosphate, a glycolytic substrate. The other transferase product, UDP-galactose, is converted to UDP-glucose by **UDP-glucose-4-epimerase**. The combined action of the uridylyltransferase and epimerase thus produces glucose-1-P from galactose-1-P, with regeneration of UDP-glucose.

A rare hereditary condition known as **galactosemia** involves defects in galactose-1-P uridylyltransferase that render the enzyme inactive. Toxic levels of galactose accumulate in afflicted individuals, causing cataracts and permanent neurological disorders. These problems can be prevented by removing galactose and lactose from the diet. In adults, the toxicity of galactose appears to be less severe, due in part to the metabolism of

Figure 18.24 Galactose metabolism via the Leloir pathway.

Figure 18.25 The galactose-1-phosphate uridylyltransferase reaction involves a ping-pong kinetic mechanism.

Figure 18.26 The UDP-glucose pyrophosphorylase reaction utilizes galactose-1-P as a substrate, as well as glucose-1-P.

galactose-1-P by **UDP-glucose pyrophosphorylase**, which apparently can accept galactose-1-P in place of glucose-1-P (Figure 18.26). The levels of this enzyme may increase in galactosemic individuals to accommodate the metabolism of galactose.

18.7d Glycerol Can Also Enter Glycolysis

Glycerol is the last important simple substance whose ability to enter the glycolytic pathway must be considered. This metabolite, which is produced in substantial amounts by the decomposition of triacylglycerols, can be converted to glycerol-3-phosphate by the action of **glycerol kinase** and then oxidized to dihydroxyacetone phosphate by the action of **glycerol phosphate dehydrogenase**, with NAD^+ as the required coenzyme. The dihydroxyacetone phosphate thereby produced enters the glycolytic pathway as a substrate for triose phosphate isomerase.

18.8 | How Do Cells Respond to Hypoxic Stress?

Glycolysis is an **anaerobic** pathway—it does not require oxygen. On the other hand, operation of the TCA cycle depends on oxygen, so it is **aerobic**. When oxygen is abundant, cells prefer aerobic metabolism, which yields more energy per glucose consumed. However, as Louis Pasteur first showed, when oxygen is limited, cells adapt to make the most of glycolysis, the less energetic, anaerobic alternative. In mammalian tissues, **hypoxia** (oxygen limitation) can cause changes in gene expression

Human Biochemistry

Lactose and Lactose Intolerance: From Mother’s Milk to Yogurt

Lactose is an interesting sugar in many ways. In placental mammals, it is synthesized only in the mammary gland, and then only during late pregnancy and lactation. The synthesis is carried out by **lactose synthase**, a dimeric complex of two proteins: galactosyl transferase and α -lactalbumin. Galactosyl transferase is present in all human cells, and it is normally involved in incorporation of galactose into glycoproteins. In late pregnancy, the pituitary gland in the brain releases a protein hormone, prolactin, which triggers production of α -lactalbumin by certain cells in the breast. α -Lactalbumin, a 123-residue protein, associates with galactosyl transferase to form lactose synthase, which catalyzes the reaction:

Lactose breakdown by lactase in the small intestine provides newborn mammals with essential galactose for many purposes, including the synthesis of gangliosides in the developing brain. Lactase is a **β -galactosidase** that cleaves lactose to yield galactose

and glucose—in fact, the only human enzyme that can cleave a β -glycosidic linkage:

Lactase is an inducible enzyme in mammals, and it appears in the fetus during the late stages of gestation. Lactase activity peaks shortly after birth, but by the age of 3 to 5 years, it declines to a low level in nearly all children. Low levels of lactase make many adults lactose intolerant. Lactose intolerance occurs commonly in most parts of the world (with the notable exception of some parts of Africa and northern Europe; see table). The symptoms of lactose intolerance, including diarrhea and general discomfort, can be relieved by eliminating milk from the diet. Alternatively, products containing β -galactosidase are available commercially.

Certain bacteria, including several species of *Lactobacillus*, thrive on the lactose in milk and carry out lactic acid fermentation, converting lactose to lactate via glycolysis. This is the basis of production of yogurt, which is now popular in the Western world but of Turkish origin. Other cultures also produce yogurtlike foods. Nomadic Tatars in Siberia and Mongolia used camel milk to make *koumiss*, which was used for medicinal purposes. In the Caucasus, *kefir* is made much like yogurt, except that the starter culture contains (in addition to *Lactobacillus*) *Streptococcus lactis* and yeast, which convert some of the glucose to ethanol and CO₂, producing an effervescent and slightly intoxicating brew.

Breakdown of lactose to galactose and glucose by lactase.

that result in increased angiogenesis (the growth of new blood vessels), increased synthesis of red blood cells, and increased levels of some glycolytic enzymes (and thus a higher rate of glycolysis).

What is the molecular basis for the increased expression of glycolytic enzymes? One of the triggers for this expression is a DNA-binding protein called **hypoxia inducible factor (HIF)**. HIF is induced by inflammatory and oxidative stresses, and is also induced in tumors. HIF is a heterodimer of a constitutive, stable nuclear β subunit (HIF-1 β) and an inducible, unstable α -subunit. Both subunits are basic helix-loop-helix transcription factors that bind to hypoxia-inducible genes, and both subunits exist as a series of isoforms (for example, HIF-1 α , HIF-2 α , and HIF-3 α). HIF- α

Figure 18.27 FIH (green) bound to HIF.

subunit regulation is a multistep process that includes gene splicing, phosphorylation, acetylation, and hydroxylation. HIF-1 α is the best-studied HIF- α isoform. Under normal oxygen levels, the α -subunits are continually synthesized but quickly degraded. When oxygen is plentiful, HIF-1 α is hydroxylated by oxygen-dependent **prolyl hydroxylases (PHDs)** at Pro⁴⁰² and Pro⁵⁶⁴. These hydroxylations ensure its binding to ubiquitin E3 ligase, which leads to rapid proteolysis by the 26S proteasome (see Chapter 31). HIF-1 α binding to the ligase is also promoted by acetylation of Lys⁵³² by the ARD1 acetyltransferase. In addition, the presence of oxygen induces the hydroxylation of HIF-1 α Asn⁸⁰³ by the **hydroxylase factor-inhibiting HIF (FIH-1)**. Figure 18.27 shows the structure of FIH bound to a fragment of HIF-1 α .

Because PHDs and FIH-1 both are oxygen-dependent, lowering oxygen concentration means that HIF-1 α avoids degradation and is available to promote gene transcription (Figure 18.28). Phosphorylation of HIF-1 α by a protein kinase promotes binding of HIF-1 α to HIF-1 β , which enhances transcription. HIF-1 α -HIF-1 β dimers bind to **hypoxia responsive elements (HREs)**, activating transcription of HRE-regulated genes, including hexokinase and lactate dehydrogenase, and the genes for glucose and lactate transporters (Figure 18.28). Pasteur observed more than 100 years ago that fermentation amounted to “life without air.” The Pasteur effect depends on HIF-mediated activation of the genes encoding glycolytic enzymes in the absence of oxygen. The linking of glycolytic activity to oxygen level is the result of an exquisite dance of oxygen-sensitive enzymes with proteins, which undergo covalent modifications that control protein–protein and protein–DNA interactions, a dance that Pasteur could hardly have anticipated.

Figure 18.28 The HIF transcription factor is composed of two subunits: a ubiquitous HIF-1 β subunit and a hypoxia-responsive HIF-1 α subunit. In response to hypoxia, inactivation of the PHDs allows HIF-1 α stabilization, dimerization with HIF-1 β , binding of the dimer to the hypoxia responsive element (HRE) of HIF target genes, and activation of the transcription of these genes. VHL is the von Hippel Lindau subunit of the ubiquitin E3 ligase that targets proteins for proteasome degradation.

Foundational Biochemistry Things You Should Know after Reading Chapter 18.

- Glycolysis is an anaerobic pathway of 10 reactions that converts glucose to pyruvate.
- Glucose processed through glycolysis is normally the sole source of metabolic energy for brain, kidney medulla, and rapidly contracting skeletal muscles.
- Four of the reactions of glycolysis involve coupling to ATP.
- In the first phase of glycolysis, glucose is phosphorylated at C-1 and C-6 and the six-carbon skeleton is cleaved to yield two, three-carbon molecules of glyceraldehyde-3-phosphate.
- Hexokinase and phosphofructokinase are priming reactions that consume ATP to make more later in the pathway.
- Hexokinase is not the most important site of regulation in glycolysis because its product, glucose-6-phosphate, is a metabolic branch point.
- The phosphoglucisomerase reaction plays two roles in glycolysis: it converts C-1 to a primary hydroxyl, which is easier to phosphorylate in the next reaction, and it activates C-3, facilitating C-C bond cleavage in the fourth reaction of glycolysis.
- The mechanisms of phosphoglucisomerase and triose phosphate isomerase both involve similar enediol intermediates.
- Phosphofructokinase is the committed step in glycolysis; it is allosterically activated by fructose-2,6-bisphosphate and AMP and inhibited by ATP and citrate.
- Fructose bisphosphate aldolase cleaves fructose-1,6-bisphosphate to yield two triose phosphates, dihydroxyacetone phosphate and glyceraldehyde-3-phosphate.
- Glyceraldehyde-3-phosphate dehydrogenase converts glyceraldehyde-3-phosphate into a high-energy intermediate, 1,3-bisphosphoglycerate.
- Phosphoglycerate kinase, the break-even reaction of glycolysis, is the first ATP-producing reaction of glycolysis, termed a substrate-level phosphorylation.
- Pyruvate kinase catalyzes the transfer of a phosphoryl group from PEP to ADP, producing ATP and pyruvate.
- Pyruvate kinase is allosterically activated by fructose-1,6-bisphosphate and inhibited by ATP and acetyl-CoA.
- Under anaerobic conditions, pyruvate produced in glycolysis is converted either to lactate (in animals) or ethanol (in yeast). These conversions are examples of fermentation—the production of ATP energy by pathways in which organic molecules function as donors and acceptors of electrons.
- Under aerobic conditions, pyruvate is directed into the TCA cycle, where it is oxidized to CO₂ with production of NADH and FADH₂.
- Under cellular conditions, the hexokinase, phosphofructokinase, and pyruvate kinase reactions operate with large, negative ΔG and represent the sites of regulation of glycolysis. All the other reactions of glycolysis operate with ΔG near zero under cellular conditions.
- Fructose can be a substrate for glycolysis, but it is subject to unregulated catabolism in the liver and may be harmful.
- Galactose enters glycolysis via the Leloir pathway involving the inter-conversion of sugar nucleotides.
- In mammalian tissues, hypoxia leads to increased synthesis of glycolytic enzymes, triggered by hypoxia inducible factor (HIF).

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. Characterizing Glycolysis

- List the reactions of glycolysis that
- are energy consuming (under standard-state conditions).
 - are energy yielding (under standard-state conditions).
 - consume ATP.
 - yield ATP.
 - are strongly influenced by changes in concentration of substrate and product because of their molecularity.
 - are at or near equilibrium in the erythrocyte (see Table 18.2).

2. Radiotracer Labeling of Pyruvate from Glucose

Determine the anticipated location in pyruvate of labeled carbons if glucose molecules labeled (in separate experiments) with ¹⁴C at each position of the carbon skeleton proceed through the glycolytic pathway.

3. Effects of Changing Metabolite Concentrations on Glycolysis

In an erythrocyte undergoing glycolysis, what would be the effect of a sudden increase in the concentration of:

- ATP
- AMP
- fructose-1,6-bisphosphate
- fructose-2,6-bisphosphate
- citrate
- glucose-6-phosphate

4. Structures in the Glycolysis Pathway

Consider the structures shown and organize them in order as they appear in the glycolysis pathway.

Structure A

Structure B

Structure C

Structure D

Structure E

5. **Understanding NADH Cycling in Glycolysis** Discuss the cycling of NADH and NAD⁺ in glycolysis and the related fermentation reactions.
6. **Enzymes in the Glycolysis Pathway** Consider the enzymes listed and organize them in the order that they appear in the glycolysis pathway:
- phosphoglycerate kinase
 - enolase
 - pyruvate kinase
 - phosphoglycerate mutase
 - triose phosphate isomerase
7. **Understanding the Reaction Mechanisms of Glycolysis** For each of the following reactions, name the enzyme that carries out this reaction in glycolysis, and write a suitable mechanism for the reaction.

8. **The Reactions and Mechanisms of the Leloir Pathway** Write the reactions that permit galactose to be utilized in glycolysis. Write a suitable mechanism for one of these reactions.
9. **The Effect of Iodoacetic Acid on the Glyceraldehyde-3-P Dehydrogenase Reaction** (Integrates with Chapters 4 and 14.) How might iodoacetic acid affect the glyceraldehyde-3-phosphate dehydrogenase reaction in glycolysis? Justify your answer.
10. **Radiotracer Studies with ³²P in Glycolysis** If ³²P-labeled inorganic phosphate were introduced to erythrocytes undergoing glycolysis, would you expect to detect ³²P in glycolytic intermediates? If so, describe the relevant reactions and the ³²P incorporation you would observe.
11. **Oxidation in the Glycolysis Pathway** Although an oxidation of a carbon atom occurs in the glycolysis pathway, there is no oxygen involved. In which step does the oxidation occur and what is the oxidizing agent?
12. **Comparing Glycolysis Entry Points for Sucrose** Sucrose can enter glycolysis by either of two routes:
- Sucrose phosphorylase:**
 Sucrose + P_i ⇌ fructose + glucose-1-phosphate
- Invertase:**
 Sucrose + H₂O ⇌ fructose + glucose
- Would either of these reactions offer an advantage over the other in the preparation of hexose for entry into glycolysis?
13. **Assessing the Role of Mg²⁺ in Glycolysis** What would be the consequences of a Mg²⁺ ion deficiency for the reactions of glycolysis?
14. **D-glucose, D-fructose, and D-mannose** (Integrates with Chapter 7) Consider the Fischer projections of D-glucose, D-mannose, D-galactose and D-fructose shown in Figures 7.2 and 7.3. Apply enediol isomerism (see Figure 18.19) to show the relationship between D-glucose, D-mannose, and D-fructose. Discuss how the application of enediol

isomerism to D-galactose leads to an isomer different from D-fructose, D-glucose, or D-mannose.

15. **Energetics of the Triose Phosphate Isomerase Reaction** (Integrates with Chapter 3.) Triose phosphate isomerase catalyzes the conversion of dihydroxyacetone-P to glyceraldehyde-3-P. The standard free energy change, ΔG[°], for this reaction is +7.6 kJ/mol. However, the observed free energy change (ΔG) for this reaction in erythrocytes is +2.4 kJ/mol.
- Calculate the ratio of [dihydroxyacetone-P]/[glyceraldehyde-3-P] in erythrocytes from ΔG.
 - If [dihydroxyacetone-P] = 0.2 mM, what is [glyceraldehyde-3-P]?
16. **Energetics of the Enolase Reaction** (Integrates with Chapter 3.) Enolase catalyzes the conversion of 2-phosphoglycerate to phosphoenolpyruvate + H₂O. The standard free energy change, ΔG[°], for this reaction is +1.8 kJ/mol. If the concentration of 2-phosphoglycerate is 0.045 mM and the concentration of phosphoenolpyruvate is 0.034 mM, what is ΔG, the free energy change for the enolase reaction, under these conditions?
17. **Energetics of PEP Hydrolysis** (Integrates with Chapter 3.) The standard free energy change (ΔG[°]) for hydrolysis of phosphoenolpyruvate (PEP) is −62.2 kJ/mol. The standard free energy change (ΔG[°]) for ATP hydrolysis is −30.5 kJ/mol.
- What is the standard free energy change for the pyruvate kinase reaction:
 ADP + phosphoenolpyruvate → ATP + pyruvate
 - What is the equilibrium constant for this reaction?
 - Assuming the intracellular concentrations of [ATP] and [ADP] remain fixed at 8 mM and 1 mM, respectively, what will be the ratio of [pyruvate]/[phosphoenolpyruvate] when the pyruvate kinase reaction reaches equilibrium?
18. **Energetics of Fructose-1,6-bisP Hydrolysis** (Integrates with Chapter 3.) The standard free energy change (ΔG[°]) for hydrolysis of fructose-1,6-bisphosphate (FBP) to fructose-6-phosphate (F-6-P) and P_i is −16.7 kJ/mol:
- $$\text{FBP} + \text{H}_2\text{O} \longrightarrow \text{fructose-6-P} + \text{P}_i$$
- The standard free energy change (ΔG[°]) for ATP hydrolysis is −30.5 kJ/mol:
- $$\text{ATP} + \text{H}_2\text{O} \longrightarrow \text{ADP} + \text{P}_i$$
- What is the standard free energy change for the phosphofructokinase reaction:
 ATP + fructose-6-P → ADP + FBP
 - What is the equilibrium constant for this reaction?
 - Assuming the intracellular concentrations of [ATP] and [ADP] are maintained constant at 4 mM and 1.6 mM, respectively, in a rat liver cell, what will be the ratio of [FBP]/[fructose-6-P] when the phosphofructokinase reaction reaches equilibrium?
19. **Energetics of 1,3-Bisphosphoglycerate Hydrolysis** (Integrates with Chapter 3.) The standard free energy change (ΔG[°]) for hydrolysis of 1,3-bisphosphoglycerate (1,3-BPG) to 3-phosphoglycerate (3-PG) and P_i is −49.6 kJ/mol:
- $$1,3\text{-BPG} + \text{H}_2\text{O} \longrightarrow 3\text{-PG} + \text{P}_i$$
- The standard free energy change (ΔG[°]) for ATP hydrolysis is −30.5 kJ/mol:
- $$\text{ATP} + \text{H}_2\text{O} \longrightarrow \text{ADP} + \text{P}_i$$
- What is the standard free energy change for the phosphoglycerate kinase reaction:
 ADP + 1,3-BPG → ATP + 3-PG
 - What is the equilibrium constant for this reaction?

- c. If the steady-state concentrations of [1,3-BPG] and [3-PG] in an erythrocyte are $1\ \mu\text{M}$ and $120\ \mu\text{M}$, respectively, what will be the ratio of [ATP]/[ADP], assuming the phosphoglycerate kinase reaction is at equilibrium?
- 20. Energetics of the Hexokinase Reaction** The standard-state free energy change, ΔG° , for the hexokinase reaction is $-16.7\ \text{kJ/mol}$. Use the values in Table 18.2 to calculate the value of ΔG for this reaction in the erythrocyte at 37°C .
- 21. Analyzing the Concentration Dependence of the Adenylate Kinase Reaction** Taking into consideration the equilibrium constant for the adenylate kinase reaction (Equation 18.7), calculate the change in concentration in AMP that would occur if 8% of the ATP in an erythrocyte (red blood cell) were suddenly hydrolyzed to ADP. In addition to the concentration values in Table 18.2, it may be useful to assume that the initial concentration of AMP in erythrocytes is $5\ \mu\text{M}$.
- 22. Distinguishing the Mechanisms of Class I and Class II Aldolases** Fructose biphosphate aldolase in animal muscle is a class I aldolase, which forms a Schiff base intermediate between substrate (for example, fructose-1,6-bisphosphate or dihydroxyacetone phosphate) and a lysine at the active site (see Figure 18.12). The chemical evidence for this intermediate comes from studies with aldolase and the reducing agent sodium borohydride, NaBH_4 . Incubation of the enzyme with dihydroxyacetone phosphate and NaBH_4 inactivates the enzyme. Interestingly, no inactivation is observed if NaBH_4 is added to the enzyme in the absence of substrate. Write a mechanism that explains these observations and provides evidence for the formation of a Schiff base intermediate in the aldolase reaction.
- 23. Understanding the Ping-Pong Mechanism of Gal-1-P Uridyltransferase** As noted in Figure 18.25, the galactose-1-phosphate uridylyltransferase reaction proceeds via a ping-pong mechanism. Consult Section 13.5c, to refresh your knowledge of ping-pong mechanisms, and draw a diagram to show how a ping-pong mechanism would proceed for the uridylyltransferase.
- 24. Understanding the Mechanism of Hemolytic Anemia** Genetic defects in glycolytic enzymes can have serious consequences for humans. For example, defects in the gene for pyruvate kinase can result in a condition known as hemolytic anemia. Consult a reference to learn about hemolytic anemia, and discuss why such genetic defects lead to this condition.
- 25. The Consumer Can Be Fooled, but Not the Consumer's Biochemistry** A fat-free food item contains the following nutritional facts:
- Total fat: = 0 g (0%); Cholesterol = 0 mg (0%); Sodium = 80 mg (3%); Total carbohydrate = 40 g (30%), which includes 28 g added sugars; Protein = 3 g. The first item on the list of ingredients is high fructose corn syrup. Explain why technically the food item is fat free, but not to our biochemistry.
- 26.** Regarding phosphofructokinase, which of the following statements is true:
- Low [ATP] stimulates the enzyme, but fructose-2,6-bisphosphate inhibits.
 - High [ATP] stimulates the enzyme, but fructose-2,6-bisphosphate inhibits.
 - High [ATP] stimulates the enzyme, and fructose-2,6-bisphosphate activates.
 - The enzyme is more active at low [ATP] than at high, and fructose-2,6-bisphosphate activates the enzyme.
 - [ATP] and fructose-2,6-bisphosphate both inhibit the enzyme.
- 27.** Based on your reading of this chapter, what would you expect to be the most immediate effect on glycolysis if the steady-state concentration of glucose-6-P were $8.3\ \text{mM}$ instead of $0.083\ \text{mM}$?

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

- 28.** Examine the PSafe model for alcohol dehydrogenase and describe the structure and function of the catalytic zinc center.
- 29.** Based on your knowledge of the structure of NAD^+ and an assumption that coenzyme dissociation is the rate limiting step of the alcohol dehydrogenase mechanism, hypothesize why a N249W mutation at the coenzyme binding site would increase the rate of catalysis.
- 30.** Using the PSafe model for phosphofructokinase (*Trypanosoma*), describe the difference between the APO1, APO2, and holoenzyme conformations.

Think-Pair-Share Question

^{14}C -labeled D-glucose was used to study the alcoholic fermentation in *Saccharomyces cerevisiae*. Depending on the carbon that was labeled, either $^{14}\text{CH}_3\text{-CH}_2\text{OH}$, $\text{CH}_3\text{-}^{14}\text{CH}_2\text{OH}$, or $^{14}\text{CO}_2$ were formed. Which carbon(s) in D-glucose were labeled to obtain these products? (Use the numbering system of the carbons as discussed in Chapter 7.) Would similar results be obtained if D-fructose or D-mannose were used as starting molecules?

The Tricarboxylic Acid Cycle

19

*Thus times do shift, each thing his turn does hold;
New things succeed, as former things grow old.*

Robert Herrick
Hesperides (1648), “Ceremonies for Christmas Eve”

Richard Cummins/Corbis

◀ A time-lapse photograph of a Ferris wheel at night. Aerobic cells use a metabolic wheel—the tricarboxylic acid cycle—to generate energy by acetyl-CoA oxidation.

Essential Question

The glycolytic pathway converts glucose to pyruvate and produces two molecules of ATP per glucose—only a small fraction of the potential energy available from glucose. Under anaerobic conditions, pyruvate is reduced to lactate in animals and ethanol in yeast, and much of the potential energy of the glucose molecule remains untapped. In the presence of oxygen, however, a much more interesting and thermodynamically complete story unfolds. **How is pyruvate oxidized to CO₂ under aerobic conditions, and what is the chemical logic that dictates how this process occurs?**

Under aerobic conditions, pyruvate from glycolysis is converted to acetyl-coenzyme A (acetyl-CoA) and oxidized to CO₂ in the **tricarboxylic acid (TCA) cycle** (also called the **citric acid cycle**). The electrons liberated by this oxidative process are passed via NADH and FADH₂ through an elaborate, membrane-associated **electron-transport pathway** to O₂, the final electron acceptor. Electron transfer is coupled to creation of a proton gradient across the membrane. Such a gradient represents an energized state, and the energy stored in this gradient is used to drive the synthesis of many equivalents of ATP.

ATP synthesis as a consequence of electron transport is termed **oxidative phosphorylation**; the complete process is diagrammed in Figure 19.1. Aerobic pathways permit the production of 30 to 38 molecules of ATP per glucose oxidized. Although two molecules of ATP come from glycolysis and two more directly out of the TCA cycle, most of the ATP arises from oxidative phosphorylation. Specifically, reducing equivalents released in the oxidative reactions of glycolysis, pyruvate decarboxylation, and the TCA cycle are captured in the form of NADH and enzyme-bound FADH₂, and these reduced coenzymes fuel the electron-transport pathway and oxidative phosphorylation.

Complete oxidation of glucose to CO₂ involves the removal of 24 electrons—that is, it is a 24-electron oxidation. In glycolysis, four electrons are removed as NADH, and four more electrons exit as two more NADH in the decarboxylation of two molecules

Key Questions

- 19.1 What Is the Chemical Logic of the TCA Cycle?
- 19.2 How Is Pyruvate Oxidatively Decarboxylated to Acetyl-CoA?

Figure 19.1 The pathways of catabolic metabolism, from glucose to ATP. (a) Pyruvate produced in glycolysis is oxidized in (b) the citric acid cycle. (c) Electrons liberated in this oxidation flow through the electron-transport chain and drive the synthesis of ATP in oxidative phosphorylation. In eukaryotic cells, this overall process occurs in mitochondria.

of pyruvate to two acetyl-CoA (Figure 19.1). For each acetyl-CoA oxidized in the TCA cycle, eight more electrons are removed (as three NADH and one FADH₂):

In the electron-transport pathway, these eight electrons combine with oxygen to form water:

So, the net reaction for the TCA cycle and electron-transport pathway is

As German biochemist Hans Krebs showed in the 1930s, the eight-electron oxidation of acetate by the TCA cycle is accomplished with the help of oxaloacetate. (In his honor, the TCA cycle is often referred to as the **Krebs cycle**.) Beginning with acetate, a series of five reactions produces two molecules of CO₂, with four electrons extracted in the form of NADH and four electrons passed to oxaloacetate to produce a molecule of succinate. The pathway becomes a cycle with three additional reactions that accomplish the four-electron oxidation of succinate back to oxaloacetate; *first, oxidation of a single bond to a double bond, then addition of the elements of water across the double bond, and finally oxidation of the resulting alcohol to a carbonyl*. This special trio of reactions is used repeatedly in metabolism: in fatty acid oxidation, in reverse in fatty acid synthesis, and also in amino acid synthesis and breakdown.

19.1 | What Is the Chemical Logic of the TCA Cycle?

The entry of new carbon units into the cycle is through acetyl-CoA. This entry metabolite can be formed either from pyruvate (from glycolysis) or from oxidation of fatty acids. Transfer of the two-carbon acetyl group from acetyl-CoA to the four-carbon

oxaloacetate to yield six-carbon citrate is catalyzed by citrate synthase. A dehydration–rehydration rearrangement of citrate yields isocitrate. Two successive decarboxylations produce α -ketoglutarate and then succinyl-CoA, a CoA conjugate of a four-carbon unit. Several steps later, oxaloacetate is regenerated and can combine with another two-carbon unit of acetyl-CoA. Thus, carbon enters the cycle as acetyl-CoA and exits as CO_2 . In the process, metabolic energy is captured in the form of ATP, NADH, and enzyme-bound FADH_2 (symbolized as $[\text{FADH}_2]$).

The TCA cycle provides a chemically feasible way of cleaving a two-carbon compound. The cycle shown in Figure 19.2 at first appears to be a complicated way to oxidize acetate units to CO_2 , but there is a chemical basis for the apparent complexity. Oxidation of an acetyl group to a pair of CO_2 molecules requires C—C cleavage:

In many instances, C—C cleavage reactions in biological systems occur between carbon atoms α and β to a carbonyl group:

A good example of such a cleavage is the fructose biphosphate aldolase reaction (see Figure 18.12).

Another common type of C—C cleavage is α -cleavage of an α -hydroxyketone:

This type of cleavage occurs in the transketolase reaction in the pentose phosphate pathway.

Neither of these cleavage strategies is suitable for acetate. It has no β -carbon, and the second method would require hydroxylation—not a favorable reaction for acetate. Instead, living things have evolved the clever chemistry of condensing acetate with oxaloacetate and then carrying out a β -cleavage. The TCA cycle combines this β -cleavage reaction with oxidation to form CO_2 , regenerate oxaloacetate, and capture the liberated metabolic energy in NADH and ATP.

Careers in Chemistry

Rochelle Diamond

Rochelle Diamond earned her degree in Biochemistry and Molecular Biology from the University of California, Santa Barbara. Her 40-year research career has included appointments at the University of Southern California School of Medicine, the City of Hope Research Institute, and UCLA. She was a member of the City of Hope/Genentech research team that cloned the human gene for insulin in 1978. Diamond is presently Manager of the Flow Cytometry/Cell Sorting Facility at the California Institute of Technology, where she specializes in cell separation and analysis

employing many techniques besides cytometry such as magnetic bead separation, centrifugation, antibody panning, lectin binding, and sieve filtration.

She founded Out to Innovate, a career summit presented by the National Organization of Gay and Lesbian Scientists and Technical Professionals) and was also a founding member of the Southern California Flow Cytometry Association. For her efforts, Diamond has received numerous awards, including the Walt Westman Service Award. She is a Fellow at the American Association for Advancement of Science.

Figure 19.2 The TCA cycle.

19.2 | How Is Pyruvate Oxidatively Decarboxylated to Acetyl-CoA?

Pyruvate produced by glycolysis is a significant source of acetyl-CoA for the TCA cycle. Because, in eukaryotic cells, glycolysis occurs in the cytoplasm, whereas the TCA cycle reactions and all subsequent steps of aerobic metabolism take place in the mitochondria, pyruvate must first enter the mitochondria to enter the TCA cycle. The oxidative decarboxylation of pyruvate to acetyl-CoA

is the connecting link between glycolysis and the TCA cycle. The reaction is catalyzed by pyruvate dehydrogenase, a multienzyme complex.

The **pyruvate dehydrogenase complex (PDC)** is formed from multiple copies of three enzymes: *pyruvate dehydrogenase* (E1), *dihydrolipoamide acetyltransferase* (E2), and *dihydrolipoamide dehydrogenase* (E3). All are involved in the conversion of pyruvate to acetyl-CoA. In addition, eukaryotic PDC contains a unique subunit, termed E3BP, that has no known enzymatic function. The active sites of all three enzymes are not far removed from one another, and the product of the first enzyme is passed directly to the second enzyme, and so on, without diffusion of substrates and products through the solution. Eukaryotic PDC, one of the largest-known multienzyme complexes (with a diameter of approximately 500 Å), is a 9.5 MDa assembly.

The central core of PDC consists of E2 subunits (and E3BP in eukaryotes), forming either a 24-meric octahedron (in gram-negative bacteria) or a 60-meric pentagonal dodecahedron (in the mitochondria of eukaryotes and gram-positive bacteria). In mitochondria, six E3BP dimers and 48 E2 subunits comprise the core structure, and binding of E3 is mediated by these substituted E3BPs. Thirty E1 $\alpha_2\beta_2$ heterotetramers and 12 E3 homodimers are bound to the E2/E3BP core. Eukaryotic E2 subunits consist of an inner catalytic (IC) domain and an outer globular domain, itself composed of two lipoic-acid binding domains (L1 and L2) and a small E1-binding domain, connected by Ala- and Pro-rich hinge regions 20 to 30 residues in length (Figure 19.3a). Human E3BP is composed of three linker-connected domains in a configuration similar to that of human E2, and its IC domain has 50% sequence identity with E2. The flexible linker segments in E2 and E3BP impart the flexibility that allows the lipoic acid groups to visit all three active sites during catalysis. Two regulatory enzymes, a pyruvate dehydrogenase kinase (PDK, a homodimer), and a pyruvate dehydrogenase phosphatase (PDP, a heterodimer) are bound to L1, L2, and/or L3.

The pyruvate dehydrogenase reaction (Figure 19.4) is a tour de force of mechanistic chemistry, involving a total of three enzymes and five different coenzymes. The first step of this reaction, the decarboxylation of pyruvate and transfer of the acetyl group to lipoic acid, depends on accumulation of negative charge on the transferred two-carbon fragment, as facilitated by the quaternary nitrogen on the thiazolium group of thiamine pyrophosphate (TPP). As shown in Figure 19.5, this cationic imine nitrogen plays two distinct roles in TPP-catalyzed reactions:

1. It provides electrostatic stabilization of the thiazole carbanion formed upon removal of the C-2 proton. (The sp^2 hybridization and the availability of vacant d orbitals on the adjacent sulfur probably also facilitate proton removal at C-2.)
2. TPP attack on pyruvate leads to decarboxylation. The TPP cationic imine nitrogen can act as an effective electron sink to stabilize the negative charge that must develop on the carbon that has been attacked. This stabilization takes place by resonance interaction through the double bond to the nitrogen atom.

This resonance-stabilized intermediate can be protonated to give **hydroxyethyl-TPP**. The reaction of hydroxyethyl-TPP with the oxidized form of lipoic acid yields the

Figure 19.4 The reaction mechanism of the pyruvate dehydrogenase complex. In step 1, decarboxylation of pyruvate occurs with formation of hydroxyethyl-TPP. Transfer of the two-carbon unit to lipoic acid in step 2 is followed by formation of acetyl-CoA in step 3. Lipoic acid is reoxidized in step 4 of the reaction.

Figure 19.5 The mechanistic details of the first three steps of the pyruvate dehydrogenase complex reaction.

energy-rich acetyl-thiol ester of reduced lipoic acid through oxidation of the hydroxyl-carbon of the two-carbon substrate unit. Nucleophilic attack by CoA on the carbonyl carbon (a characteristic feature of CoA chemistry) results in transfer of the acetyl group from lipoic acid to CoA. The subsequent oxidation of lipoic acid is catalyzed by the FAD-dependent dihydrolipoyl dehydrogenase, and NAD^+ is reduced.

A Deeper Look

The Coenzymes of the Pyruvate Dehydrogenase Complex

Coenzymes are small molecules that bring unique chemistry to enzyme reactions. Five coenzymes are used in the pyruvate dehydrogenase reaction.

Thiamine Pyrophosphate

TPP assists in the decarboxylation of α -keto acids (here) and in the formation and cleavage of α -hydroxy ketones (as in the transketolase reaction).

The Nicotinamide Coenzymes

NAD^+/NADH and $\text{NADP}^+/\text{NADPH}$ carry out hydride (H^-) transfer reactions. All reactions involving these coenzymes are two-electron transfers.

(Continued)

The Flavin Coenzymes—FAD/FADH₂

Coenzyme A

The two main functions of CoA are:

1. Activation of acyl groups for transfer by nucleophilic attack
2. Activation of the α -hydrogen of the acyl group for abstraction as a proton

The reactive sulfhydryl group on CoA mediates both of these functions. The sulfhydryl group forms **thioester** linkages with acyl groups. The two main functions of CoA are illustrated in the citrate synthase reaction (see Figure 19.6).

**Lipoic Acid**

Lipoic acid functions to couple acyl-group transfer and electron transfer during oxidation and decarboxylation of α -keto acids. It is

found in pyruvate dehydrogenase and α -ketoglutarate dehydrogenase. Lipoic acid is covalently bound to relevant enzymes through amide bond formation with the ϵ -NH₂ group of a lysine side chain.

19.3 How Are Two CO₂ Molecules Produced from Acetyl-CoA?

The TCA cycle involves entry and capture of an acetyl group, followed by a series of reactions that accomplish an eight-electron oxidation and, ultimately, departure of two CO₂ molecules.

19.3a The Citrate Synthase Reaction Initiates the TCA Cycle

The first reaction within the TCA cycle, the one by which carbon atoms are introduced, is the **citrate synthase reaction** (Figure 19.6). Here acetyl-CoA reacts with

Figure 19.6 Citrate is formed in the citrate synthase reaction from oxaloacetate and acetyl-CoA. The mechanism involves nucleophilic attack by the carbanion of acetyl-CoA on the carbonyl carbon of oxaloacetate, followed by thioester hydrolysis. The pro-S and pro-R groups around the central pro-chiral carbon are indicated.

Table 19.1 The Enzymes and Reactions of the TCA Cycle

Reaction	Enzyme	ΔG° (kJ/mol)	ΔG (kJ/mol)
1. Acetyl-CoA + oxaloacetate + H ₂ O $\rightleftharpoons$ CoASH + citrate	Citrate synthase	−31.4	−53.9
2. Citrate $\rightleftharpoons$ isocitrate	Aconitase	+6.7	+0.8
3. Isocitrate + NAD ⁺ $\rightleftharpoons$ α -ketoglutarate + NADH + CO ₂	Isocitrate dehydrogenase	−8.4	−17.5
4. α -Ketoglutarate + CoASH + NAD ⁺ $\rightleftharpoons$ succinyl-CoA + NADH + CO ₂	α -Ketoglutarate dehydrogenase complex	−30	−43.9
5. Succinyl-CoA + GDP + P _i $\rightleftharpoons$ succinate + GTP + CoASH	Succinyl-CoA synthetase	−3.3	≈0
6. Succinate + [FAD] $\rightleftharpoons$ fumarate + [FADH ₂]	Succinate dehydrogenase	+0.4	≈0
7. Fumarate + H ₂ O $\rightleftharpoons$ L-malate	Fumarase	−3.8	≈0
8. L-Malate + NAD ⁺ $\rightleftharpoons$ oxaloacetate + NADH + H ⁺	Malate dehydrogenase	+29.7	≈0

oxaloacetate in a **Perkin condensation** (a carbon–carbon condensation between a ketone or aldehyde and an ester). The acyl group is activated in two ways in an acyl-CoA molecule: The carbonyl carbon is activated for attack by nucleophiles, and the C $_{\alpha}$ carbon is more acidic and can be deprotonated to form a carbanion. The citrate synthase reaction depends upon the latter mode of activation. As shown in Figure 19.6, a general base on the enzyme accepts a proton from the methyl group of acetyl-CoA, producing a stabilized α -carbanion of acetyl-CoA. This strong nucleophile attacks the α -carbonyl of oxaloacetate, yielding citryl-CoA. This part of the reaction has an equilibrium constant near 1, but the overall reaction is driven to completion by the subsequent hydrolysis of the high-energy thioester to citrate and free CoA. The overall ΔG° is −31.4 kJ/mol, and under standard conditions the reaction is essentially irreversible. Although the mitochondrial concentration of oxaloacetate is very low (much less than 1 μ M—see example in Section 19.4), the strong, negative ΔG° drives the reaction forward.

Citrate Synthase Is a Dimer Citrate synthase in mammals is a dimer of 49 kDa subunits (Table 19.1). On each subunit, oxaloacetate and acetyl-CoA bind to the active site, which lies in a cleft between two domains and is surrounded mainly by α -helical segments (Figure 19.7). Binding of oxaloacetate induces a conformational change that facilitates the binding of acetyl-CoA and closes the active site so that the reactive carbanion of acetyl-CoA is protected from protonation by water.

NADH Is an Allosteric Inhibitor of Citrate Synthase Citrate synthase is the first step in the TCA cycle and as stated the reaction has a large negative ΔG° . As might be expected, it is a highly regulated enzyme. NADH, a product of the TCA cycle, is an allosteric inhibitor of citrate synthase, as is succinyl-CoA, the product of the fifth step in the cycle (and an acetyl-CoA analog).

19.3b Citrate Is Isomerized by Aconitase to Form Isocitrate

In its role as an intermediate in this pathway, citrate itself poses a problem: It is a poor candidate for further oxidation because it contains a tertiary alcohol, which could be oxidized only by breaking a carbon–carbon bond. A simple solution to this problem is to isomerize the tertiary alcohol to a secondary alcohol, which the cycle proceeds to do in the next step.

Citrate is isomerized to isocitrate by **aconitase** in a two-step process involving aconitate as an intermediate (Figure 19.8). In this reaction, the elements of water are first abstracted from citrate to yield aconitate, which is then rehydrated with H— and HO— adding back in opposite positions to produce isocitrate. The net effect is the conversion of a tertiary alcohol (citrate) to a secondary alcohol (isocitrate). Oxidation of the secondary alcohol of isocitrate involves breakage of a C—H bond, a simpler matter than the C—C cleavage required for the direct oxidation of citrate.

Figure 19.7 Citrate synthase. In the monomer shown here, citrate is blue, and CoA is red. (Top: PDB id = 1CTS; bottom: PDB id = 2CTS.)

Figure 19.8 The aconitase reaction and the structure of the active site of aconitase from pig. **(a)** The aconitase reaction converts citrate to *cis*-aconitate and then to isocitrate. Aconitase is stereospecific and removes the pro-*R* hydrogen from the pro-*R* arm of citrate. **(b)** The active site of aconitase. The iron–sulfur cluster (pink) is coordinated by cysteines (orange) and isocitrate (purple) (PDB id = 1B0J).

Inspection of the citrate structure shows a total of four chemically equivalent hydrogens, but only one of these—the pro-*R* H atom of the pro-*R* arm of citrate—is abstracted by aconitase, which is quite stereospecific. Formation of the double bond of aconitate following proton abstraction requires departure of hydroxide ion from the C-3 position. Hydroxide is a relatively poor leaving group, and its departure is facilitated in the aconitase reaction by coordination with an iron atom in an iron–sulfur cluster.

Aconitase Utilizes an Iron–Sulfur Cluster Aconitase contains an **iron–sulfur cluster** consisting of three iron atoms and four sulfur atoms in a near-cubic arrangement (Figure 19.9). Cysteine residues from the enzyme coordinate the three iron atoms. In the inactive state of the enzyme, one corner of the cube is vacant. Binding of iron (as Fe^{2+}) to this position activates aconitase. The iron atom in this position can coordinate the C-3 carboxyl and hydroxyl groups of citrate. This iron atom thus acts as a Lewis acid, accepting an unshared pair of electrons from the hydroxyl, making it a better leaving group. The equilibrium for the aconitase reaction favors citrate, and an equilibrium mixture typically contains about 90% citrate, 4% *cis*-aconitate, and 6% isocitrate. The ΔG° is +6.7 kJ/mol.

Fluoroacetate Blocks the TCA Cycle Fluoroacetate (which occurs naturally in plants in Australia, Brazil, and Africa) is an extremely poisonous agent that blocks the TCA cycle in vivo, although it has no apparent effect on any of the isolated enzymes. Its LD_{50} , the lethal dose for 50% of animals consuming it, is 0.2 mg per kilogram of body

Figure 19.9 The iron–sulfur cluster of aconitase. Binding of Fe^{2+} to the vacant position of the cluster activates aconitase. The added iron atom coordinates the C-3 carboxyl and hydroxyl groups of citrate and acts as a Lewis acid, accepting an electron pair from the hydroxyl group and making it a better leaving group.

weight; it has been used as a rodent poison. The action of fluoroacetate has been traced to aconitase. Fluoroacetate is converted in two steps *in vivo* to fluorocitrate as shown, and aconitase is inhibited by fluorocitrate.

Fluoroacetate readily crosses both the cellular and the mitochondrial membranes, and in mitochondria it is converted to fluoroacetyl-CoA by acetyl-CoA synthetase. Fluoroacetyl-CoA is a substrate for citrate synthase, which condenses it with oxaloacetate to form fluorocitrate. Fluoroacetate may thus be viewed as a **Trojan horse inhibitor**. Analogous to the giant Trojan horse of legend—which the soldiers of Troy took into their city, not knowing that Greek soldiers were hidden inside it and waiting to attack—fluoroacetate enters the TCA cycle innocently enough, in the citrate synthase reaction. Citrate synthase converts fluoroacetate to fluorocitrate, which inhibits aconitase, thus blocking the TCA cycle.

19.3c Isocitrate Dehydrogenase Catalyzes the First Oxidative Decarboxylation in the Cycle

In the next step of the TCA cycle, isocitrate is oxidatively decarboxylated to yield α -ketoglutarate, with concomitant reduction of NAD⁺ to NADH in the isocitrate dehydrogenase reaction (Figure 19.10). The reaction has a net $\Delta G^{\circ'}$ of -8.4 kJ/mol, and it is sufficiently exergonic to pull the aconitase reaction forward. This two-step reaction involves (1) oxidation of the C-2 alcohol of isocitrate to form oxalosuccinate,

Figure 19.10 The isocitrate dehydrogenase reaction. (a) The mechanism of the reaction. (b) The active site of isocitrate dehydrogenase. Isocitrate is blue, NADP⁺ (as an NAD⁺ analog) is gold, with Ca²⁺ in red (PDB id = 1AI2).

followed by (2) a β -decarboxylation reaction that expels the central carboxyl group as CO_2 , leaving the product α -ketoglutarate. Oxalosuccinate, the β -keto acid produced by the initial dehydrogenation reaction, is unstable and thus is readily decarboxylated.

Isocitrate Dehydrogenase Links the TCA Cycle and Electron Transport Isocitrate dehydrogenase provides the first connection between the TCA cycle and the electron-transport pathway and oxidative phosphorylation, via its production of NADH. As a connecting point between two metabolic pathways, isocitrate dehydrogenase is a regulated reaction. NADH and ATP are allosteric inhibitors, whereas ADP acts as an allosteric activator, lowering the K_m for isocitrate by a factor of 10. The enzyme is virtually inactive in the absence of ADP. Also, the product, α -ketoglutarate, is a crucial α -keto acid for aminotransferase reactions (see Section 13.5c), connecting the TCA cycle (that is, carbon metabolism) with nitrogen metabolism.

19.3d α -Ketoglutarate Dehydrogenase Catalyzes the Second Oxidative Decarboxylation of the TCA Cycle

A second oxidative decarboxylation occurs in the α -ketoglutarate dehydrogenase reaction.

Like the pyruvate dehydrogenase complex, α -ketoglutarate dehydrogenase is a multi-enzyme complex—consisting of α -ketoglutarate dehydrogenase, dihydrolipoyl transsuccinylase, and dihydrolipoyl dehydrogenase—that employs five different coenzymes (Table 19.2). The dihydrolipoyl dehydrogenase in this reaction is identical to that in the pyruvate dehydrogenase reaction. The mechanism is analogous to that of pyruvate dehydrogenase. As with the pyruvate dehydrogenase reaction, this reaction produces NADH and a thioester product—in this case, succinyl-CoA. Succinyl-CoA and NADH products are energy-rich species that are important sources of metabolic energy in subsequent cellular processes.

19.4 How Is Oxaloacetate Regenerated to Complete the TCA Cycle?

The completion of the TCA cycle involves one reaction that generates a nucleoside triphosphate, followed by three reactions that convert a carbon in a C—C single bond to a carbonyl. These latter three reactions turn out to be nature's preferred

Table 19.2 Composition of the α -Ketoglutarate Dehydrogenase Complex from *Escherichia coli*

Enzyme	Coenzyme	Enzyme M _r	Number of Subunits	Subunit M _r	Number of Subunits per Complex
α-Ketoglutarate dehydrogenase	Thiamine pyrophosphate	192,000	2	96,000	24
Dihydrolipoyl transsuccinylase	Lipoic acid, CoASH	1,700,000	24	70,000	24
Dihydrolipoyl dehydrogenase	FAD, NAD ⁺	112,000	2	56,000	12

method for accomplishing this conversion, and the same chemistry is used in multiple pathways—fatty acid oxidation, fatty acid synthesis, amino acid breakdown, and amino acid synthesis, to name just a few.

19.4a Succinyl-CoA Synthetase Catalyzes Substrate-Level Phosphorylation

The NADH produced in the foregoing steps can be routed through the electron-transport pathway to make high-energy phosphates via oxidative phosphorylation. However, succinyl-CoA is itself a high-energy intermediate and is utilized in the next step of the TCA cycle to drive the phosphorylation of GDP to GTP (in mammals) or ADP to ATP (in plants and bacteria).

The reaction is catalyzed by **succinyl-CoA synthetase**, sometimes called **succinate thio-kinase**. The free energies of hydrolysis of succinyl-CoA and GTP or ATP are similar, and the net reaction has a $\Delta G^{\circ'}$ of -3.3 kJ/mol. Succinyl-CoA synthetase provides another example of a **substrate-level phosphorylation** (see Section 18.4b), in which a substrate (rather than an electron-transport chain or proton gradient) provides the energy for phosphorylation. It is the only such reaction in the TCA cycle. The GTP produced by mammals in this reaction can exchange its terminal phosphoryl group with ADP via the **nucleoside diphosphate kinase reaction**:

The Mechanism of Succinyl-CoA Synthetase Involves a Phosphohistidine The mechanism of succinyl-CoA synthetase is postulated to involve displacement of CoA by phosphate, forming succinyl phosphate at the active site, followed by transfer of the phosphoryl group to an active-site histidine (making a phosphohistidine intermediate) and release of succinate. The phosphoryl moiety is then transferred to GDP to form GTP (Figure 19.11). This sequence of steps preserves the energy of the thioester bond of succinyl-CoA in a series of high-energy intermediates that lead to a molecule of ATP:

The First Five Steps of the TCA Cycle Produce NADH, CO₂, GTP (ATP), and Succinate This is a good point to pause in our trip through the TCA cycle and see what has happened. A two-carbon acetyl group has been introduced as acetyl-CoA and linked to oxaloacetate, and two CO₂ molecules have been liberated. The cycle has produced two molecules of NADH and one of GTP or ATP and has left a molecule of succinate.

The TCA cycle can now be completed by converting succinate to oxaloacetate. This latter process represents a net oxidation. The TCA cycle breaks it down into (consecutively) an oxidation step, a hydration reaction, and a second oxidation step. The oxidation steps are accompanied by the reduction of an [FAD] and an NAD^+ . The reduced coenzymes, $[\text{FADH}_2]$ and NADH , subsequently provide reducing power in the electron-transport chain. Virtually the same chemical strategy is used in β -oxidation of fatty acids.

Condensation A reaction between two or more molecules that results in formation of a larger molecule, with elimination of some simpler molecule, such as water (as in dehydration synthesis).

Synthase An enzyme-catalyzed condensation reaction that does not require a nucleoside triphosphate as an energy source.

Synthetase An enzyme-catalyzed condensation reaction that requires a nucleoside triphosphate (often ATP) as an energy source.

Figure 19.11 The mechanism of the succinyl-CoA synthetase reaction.

Figure 19.12 The covalent bond between FAD and succinate dehydrogenase involves the C-8a methylene group of FAD and the N-3 of a histidine residue on the enzyme.

19.4b Succinate Dehydrogenase Is FAD-Dependent

The oxidation of succinate to fumarate is carried out by **succinate dehydrogenase**, a membrane-bound enzyme that is actually part of the electron-transport chain.

Succinate dehydrogenase is also known as the succinate–coenzyme Q reductase of the electron-transport chain. In contrast with all of the other enzymes of the TCA cycle, which are soluble proteins found in the mitochondrial matrix, succinate dehydrogenase is an integral membrane protein tightly associated with the inner mitochondrial membrane. Succinate oxidation involves removal of H atoms across a C—C bond, rather than a C—O or C—N bond, and produces the *trans*-unsaturated fumarate. This reaction (the oxidation of an alkane to an alkene) is not sufficiently exergonic to reduce NAD^+ , but it does yield enough energy to reduce [FAD]. (By contrast, oxidations of alcohols to ketones or aldehydes are more energetically favorable and provide sufficient energy to reduce NAD^+ .)

Succinate dehydrogenase is a dimeric protein, with subunits of molecular masses 70 and 27 kDa. FAD is covalently bound to the larger subunit; the bond involves a methylene group of C-8a of FAD and N-3 of a histidine on the protein (Figure 19.12). Succinate dehydrogenase also contains three different iron–sulfur clusters: a 4Fe-4S cluster, a 3Fe-4S cluster, and a 2Fe-2S cluster, shown below.

Viewed from either end of the succinate molecule, the reaction involves dehydrogenation α,β to a carbonyl (actually, a carboxyl) group. The dehydrogenation is stereospecific, with the pro-*S* hydrogen removed from one carbon atom and the pro-*R* hydrogen removed from the other. The electrons captured by [FAD] in this reaction are passed directly into the iron–sulfur clusters of the enzyme and on to coenzyme Q (UQ). The covalently bound FAD is first reduced to [FADH₂] and then reoxidized to form [FAD] and the reduced form of coenzyme Q, UQH₂. Electrons captured by UQH₂ then flow through the rest of the electron-transport chain.

Note that flavin coenzymes can carry out either one-electron or two-electron transfers. The succinate dehydrogenase reaction represents a net two-electron reduction of FAD.

19.4c Fumarase Catalyzes the *Trans*-Hydration of Fumarate to Form L-Malate

Fumarate is hydrated in a stereospecific reaction by fumarase to give L-malate.

The reaction involves *trans*-addition of the elements of water across the double bond. Recall that aconitase carries out a similar reaction and that *trans*-addition of —H and —OH occurs across the double bond of *cis*-aconitate. Although the exact mechanism is uncertain, it may involve protonation of the double bond to form an

(a) Carbonium ion mechanism

(b) Carbanion mechanism

Figure 19.13 Two possible mechanisms for the fumarase reaction. (a) Carbonium ion mechanism. (b) Carbanion mechanism.

intermediate carbonium ion (Figure 19.13a) or possibly attack by water or OH[−] anion to produce a carbanion, followed by protonation (Figure 19.13b).

19.4d Malate Dehydrogenase Completes the Cycle by Oxidizing Malate to Oxaloacetate

In the last step of the TCA cycle, L-malate is oxidized to oxaloacetate by malate dehydrogenase. This reaction is very endergonic, with a $\Delta G^{\circ'}$ of +30 kJ/mol.

Consequently, the concentration of oxaloacetate in the mitochondrial matrix is usually quite low. The reaction, however, is pulled forward by the favorable citrate synthase reaction. Oxidation of malate is coupled to reduction of yet another molecule of NAD⁺, the third one of the cycle. Counting the [FAD] reduced by succinate dehydrogenase, this makes the fourth coenzyme reduced through oxidation of a single acetate unit.

Malate dehydrogenase is structurally and functionally similar to other dehydrogenases, notably lactate dehydrogenase (Figure 19.14). Both consist of alternating β -sheet and α -helical segments. Binding of NAD⁺ causes a conformational change in the 20-residue segment that connects the D and E strands of the β -sheet. The change is triggered by an interaction between the adenosine phosphate moiety of NAD⁺ and an arginine residue in this loop region. Such a conformational change is consistent with an ordered single-displacement mechanism for NAD⁺-dependent dehydrogenases (see Section 13.5b).

19.5 What Are the Energetic Consequences of the TCA Cycle?

The net reaction accomplished by the TCA cycle, as follows, shows two molecules of CO₂, one ATP, and four reduced coenzymes produced per acetate group oxidized. The cycle is exergonic, with a net $\Delta G^{\circ'}$ for one pass around the cycle of approximately −40 kJ/mol. Table 19.1 compares the $\Delta G^{\circ'}$ values for the individual reactions with the overall $\Delta G^{\circ'}$ for the net reaction.

Figure 19.14 The active site of malate dehydrogenase. Malate is yellow; NAD⁺ is pink (PDB id = 1EMD).

Glucose metabolized via glycolysis produces two molecules of pyruvate and thus two molecules of acetyl-CoA, which can enter the TCA cycle. Combining glycolysis and the TCA cycle gives the net reaction:

The stoichiometries of glycolysis and the TCA cycle can be summarized as:

Glycolysis:

Net: 2 ATP + 2 NADH + 2 H⁺ from 4 H and the cleavage of 1 C—C bond.

TCA Cycle (including pyruvate dehydrogenase):

Net: 2 ATP and 8 NADH + 8 H⁺ + 2 FADH₂ from 20 H and the cleavage of 4 C—C bonds.

All six carbons of glucose are liberated as CO₂, and a total of four molecules of ATP are formed thus far in substrate-level phosphorylations. The 12 reduced coenzymes produced up to this point can eventually produce as many as 34 molecules of ATP in the electron-transport and oxidative phosphorylation pathways. A stoichiometric relationship for these subsequent processes would be

Thus, a total of three ATP per NADH and two ATP per FADH₂ may be produced through the processes of electron transport and oxidative phosphorylation.

19.5a The Carbon Atoms of Acetyl-CoA Have Different Fates in the TCA Cycle

It is instructive to consider how the carbon atoms of a given acetate group are routed through several turns of the TCA cycle. As shown in Figure 19.15, neither of the two carbon atoms of a labeled acetate unit is lost as CO₂ in the first turn of the cycle. The CO₂ released in any turn of the cycle derives from the carboxyl groups of the oxaloacetate acceptor (produced in the previous turn), not from incoming acetyl-CoA. On the other hand, succinate labeled on one end from the original labeled acetate forms two different labeled oxaloacetates. The carbonyl carbon of acetyl-CoA is evenly distributed between the two carboxyl carbons of oxaloacetate, and the labeled methyl carbon of incoming acetyl-CoA ends up evenly distributed between the methylene and carbonyl carbons of oxaloacetate.

When these labeled oxaloacetates enter a second turn of the cycle, both of the carboxyl carbons are lost as CO₂, but the methylene and carbonyl carbons survive through the second turn. Thus, the methyl carbon of a labeled acetyl-CoA survives two full turns of the cycle. In the third turn of the cycle, one-half of the carbon from the original methyl group of acetyl-CoA has become one of the carboxyl carbons of oxaloacetate and is thus lost as CO₂. In the fourth turn of the cycle, further scrambling results in loss of half of the remaining labeled carbon (one-fourth of the original methyl carbon label of acetyl-CoA), and so on.

It can be seen that the carbonyl and methyl carbons of labeled acetyl-CoA have very different fates in the TCA cycle. The carbonyl carbon survives the first turn intact but is completely lost in the second turn. The methyl carbon survives two full turns, then undergoes a 50% loss through each succeeding turn of the cycle.

It is worth noting that the carbon-carbon bond cleaved in the TCA pathway entered as an acetate unit in the previous turn of the cycle. Thus, the oxidative decarboxylations that cleave this bond are just a cleverly disguised acetate C—C cleavage and oxidation.

(a) Fate of the carboxyl carbon of acetate unit

(b) Fate of methyl carbon of acetate unit

Figure 19.15 The fate of the carbon atoms of acetate in successive TCA cycles. Assume at the start, labeled acetate is added to cells containing unlabeled metabolites. The pink arrows lead from one turn of the TCA cycle to a subsequent one. **(a)** The carbonyl carbon of acetyl-CoA is fully retained through one turn of the cycle but is lost completely in a second turn of the cycle. **(b)** The methyl carbon of a labeled acetyl-CoA survives two full turns of the cycle but becomes equally distributed among the four carbons of oxaloacetate by the end of the second turn. In each subsequent turn of the cycle, one-half of this carbon (the original labeled methyl group) is lost.

A Deeper Look

Steric Preferences in NAD⁺-Dependent Dehydrogenases

The enzymes that require nicotinamide coenzymes are stereospecific and transfer hydride to either the pro-*R* or the pro-*S* positions selectively.

What accounts for this stereospecificity? It arises from the fact that the enzymes (and especially the active sites of enzymes) are inherently asymmetric structures. The nicotinamide coenzyme (and the substrate) fit the active site in only one way. Malate dehydrogenase, the citric acid cycle enzyme, transfers hydride to the H_R position of NADH, but glyceraldehyde-3-P dehydrogenase in the glycolytic pathway transfers hydride to the H_S position, as shown in the accompanying figure. Dehydrogenases are stereospecific with respect to the substrates as well. Note that alcohol dehydrogenase removes hydrogen from the pro-*R* position of ethanol and transfers it to the pro-*R* position of NADH.

Stereochemistry of dehydrogenase reactions: (a) the malate dehydrogenase reaction; (b) the glyceraldehyde-3-phosphate dehydrogenase reaction; (c) the alcohol dehydrogenase reaction.

19.6 Can the TCA Cycle Provide Intermediates for Biosynthesis?

Until now we have viewed the TCA cycle as a catabolic process because it oxidizes acetate units to CO₂ and converts the liberated energy to ATP and reduced coenzymes. The TCA cycle is, after all, the end point for breakdown of food materials, at least in terms of carbon turnover. However, as shown in Figure 19.16, four-, five-, and six-carbon species produced in the TCA cycle also fuel a variety of **biosynthetic processes**. α-Ketoglutarate, succinyl-CoA, fumarate, and oxaloacetate are all precursors of important cellular species. (To participate in eukaryotic biosynthetic processes, however, they must first be transported out of the mitochondria.) A transamination reaction converts α-ketoglutarate directly to glutamate, which can then serve as a versatile precursor for proline, arginine, and glutamine. Succinyl-CoA provides most of the carbon atoms of the porphyrins. Oxaloacetate can be transaminated to

Figure 19.16 The TCA cycle provides intermediates for numerous biosynthetic processes in the cell. Amino acids are highlighted in orange.

produce aspartate. Aspartic acid itself is a precursor of the pyrimidine nucleotides and, in addition, is a key precursor for the synthesis of asparagine, methionine, lysine, threonine, and isoleucine. Oxaloacetate can also be decarboxylated to yield PEP, which is a key element of several pathways, namely (1) synthesis (in plants and microorganisms) of the aromatic amino acids phenylalanine, tyrosine, and tryptophan;

Human Biochemistry

Leber's Hereditary Optic Neuropathy Arises from Mitochondrial DNA Mutations

Diseases arising from defects in mitochondrial enzymes are quite rare, because major defects in the TCA cycle (and the respiratory chain) are incompatible with life and affected embryos rarely survive to birth. Even so, about 150 different hereditary mitochondrial diseases have been reported. Although mitochondria carry their own DNA, many of the reported diseases map to the nuclear genome, because most of the mitochondrial proteins are imported from the cytosol.

An interesting disease linked to mitochondrial DNA mutations is Leber's hereditary optic neuropathy (LHON), in which the genetic defects are located primarily in the mitochondrial DNA coding for the subunits of NADH-CoQ reductase, also known as Complex I of the electron-transport chain. Leber's disease is the most common form of blindness in otherwise healthy young men and occurs less often in women.

(2) formation of 3-phosphoglycerate and conversion to the amino acids serine, glycine, and cysteine; and (3) gluconeogenesis, the pathway that synthesizes new glucose and many other carbohydrates.

Finally, citrate can be exported from the mitochondria then broken down by **ATP-citrate lyase** to yield oxaloacetate and acetyl-CoA, a precursor of fatty acids. Oxaloacetate produced in this reaction is rapidly reduced to malate, which can then be processed in either of two ways: It may be transported into mitochondria, where it is reoxidized to oxaloacetate, or it may be oxidatively decarboxylated to pyruvate by **malic enzyme**, with subsequent mitochondrial uptake of pyruvate. This cycle permits citrate to provide acetyl-CoA for biosynthetic processes, with return of the malate and pyruvate by-products to the mitochondria.

19.7 | What Are the Anaplerotic, or Filling Up, Reactions?

In a sort of reciprocal arrangement, the cell also feeds many intermediates back into the TCA cycle from other reactions. Because such reactions replenish the TCA cycle intermediates, Hans Kornberg proposed that they be called **anaplerotic reactions** (literally, the filling-up reactions). For example, **PEP carboxylase** and **pyruvate carboxylase** synthesize oxaloacetate from pyruvate (Figure 19.17).

Pyruvate carboxylase is the most important of the anaplerotic enzymes. It exists in the mitochondria of animal cells but not in plants, and it provides a direct link between glycolysis and the TCA cycle. Pyruvate carboxylase is tetrameric and contains covalently bound biotin and an Mg^{2+} site on each subunit. Pyruvate carboxylase has an absolute allosteric requirement for acetyl-CoA. Thus, when acetyl-CoA levels exceed the oxaloacetate supply, allosteric activation of pyruvate carboxylase by acetyl-CoA raises oxaloacetate levels, so the excess acetyl-CoA can enter the TCA cycle.

PEP carboxylase occurs in yeast, bacteria, and higher plants, but not in animals. The enzyme is specifically inhibited by aspartate, which is produced by transamination of oxaloacetate. Thus, organisms using this enzyme control aspartate production by regulation of PEP carboxylase. Malic enzyme is found in the cytosol or mitochondria of many animal and plant cells and is an NADPH-dependent enzyme.

Figure 19.17 Pyruvate carboxylase, phosphoenolpyruvate (PEP) carboxylase, and malic enzyme catalyze anaplerotic reactions, replenishing TCA cycle intermediates.

Anaplerosis Plays a Critical Role in Insulin Secretion

The β -cells of the islets of Langerhans in the pancreas release insulin in response to an increase of blood glucose. A rise in blood glucose induces an increase in β -cell glucose metabolism, leading to insulin release. But what cellular processes mediate this response? For many years, it was widely accepted that ATP (produced from the processes of glycolysis, the TCA cycle, electron transport, and oxidative phosphorylation) activated K^+ channels in the plasma membrane, triggering insulin release. However, recent research has shown that anaplerotic enzymes feed alternative pathways that produce cytosolic signal molecules that also support insulin secretion.

Pancreatic β -cells maintain high levels of the anaplerotic enzyme pyruvate carboxylase. In these cells, only about half the pyruvate from glycolysis enters the TCA cycle via pyruvate dehydrogenase, leading to oxidative processes that generate ATP. The rest of the pyruvate is converted by pyruvate carboxylase to oxaloacetate, much of which is converted to malate and exported to the cytosol, as part of a **pyruvate/malate cycle** (see figure). NADPH and other metabolites generated from this cycle act as intracellular messengers that appear to be as significant as ATP in provoking insulin secretion.

In support of this new model for insulin secretion, Jamie Joseph and his colleagues have shown that β -cells that lack hypoxia-

inducible factor-1 beta (HIF-1 β) display reduced anaplerotic activity, reduced activities of pyruvate carboxylase and cytosolic malic enzyme, and reduced insulin secretion.

Anaplerosis also appears to play a role in peripheral tissues. In insulin-resistant individuals, exercise increases anaplerotic activity, increases fatty acid oxidation, and restores insulin sensitivity.

The pyruvate/malate cycle in pancreatic β -cells. Oxaloacetate produced by high levels of pyruvate carboxylase is converted to malate, then exported to the cytosol. Cytosolic malic enzyme (MEc) converts malate to pyruvate, which is returned to the mitochondrial matrix. NADPH and other cytosolic signals produced by this and related cycles provoke insulin secretion.

It is worth noting that the reaction catalyzed by **PEP carboxykinase** could also function as an anaplerotic reaction, were it not for the particular properties of the enzyme.

CO_2 binds weakly to PEP carboxykinase, whereas oxaloacetate binds very tightly ($K_D = 2 \times 10^{-6} \text{ M}$), and, as a result, the enzyme favors formation of PEP from oxaloacetate.

The catabolism of amino acids provides pyruvate, acetyl-CoA, oxaloacetate, fumarate, α -ketoglutarate, and succinate, all of which may be oxidized by the TCA cycle. In this way, proteins as nutrients are excellent sources of energy.

Fool's Gold and the Reductive Citric Acid Cycle—The First Metabolic Pathway?

How did life arise on the planet Earth? It was once supposed that a reducing atmosphere, together with random synthesis of organic compounds, gave rise to a prebiotic soup in which the first living things appeared. However, certain key compounds, such as arginine, lysine, and histidine; the straight-chain fatty acids; porphyrins; and essential coenzymes, have not been convincingly synthesized under simulated prebiotic conditions. This and other problems have led researchers to consider other models for the evolution of life.

One of these alternative models, postulated by Günter Wächtershäuser, involves an archaic version of the TCA cycle running in the reverse (reductive) direction. Reversal of the TCA cycle results in assimilation of CO_2 and fixation of carbon as shown. For each turn of the reversed cycle, two carbons are fixed in the formation of isocitrate and two more are fixed in the reductive transformation of acetyl-CoA to oxaloacetate. Thus, for every succinate that enters the reversed cycle, two succinates are returned, making the cycle highly autocatalytic. Because TCA cycle intermediates are involved in many biosynthetic pathways (see Section 19.6), a reversed TCA cycle would be a bountiful and broad source of metabolic substrates.

A reversed, reductive TCA cycle would require energy input to drive it. What might have been the thermodynamic driving force for such a cycle? Wächtershäuser hypothesizes that the anaerobic reaction of FeS and H_2S to form insoluble FeS_2 (pyrite, also known as fool's gold) in the prebiotic milieu could have been the driving reaction:

This reaction is highly exergonic, with a standard-state free energy change (ΔG°) of -38 kJ/mol . Under the conditions that might have existed in a prebiotic world, this reaction would have been sufficiently exergonic to drive the reductive steps of a reversed TCA cycle.

Wächtershäuser has also suggested that early metabolic processes first occurred on the surface of pyrite and other related mineral materials. The iron–sulfur chemistry that prevailed on these mineral surfaces may have influenced the evolution of the iron–sulfur proteins that control and catalyze many reactions in modern pathways (including the succinate dehydrogenase and aconitase reactions of the TCA cycle). This reductive citric acid cycle has been shown to occur in certain extant archaea and bacteria, where it serves all their carbon needs.

▲ A reductive, reversed TCA cycle.

19.8 | How Is the TCA Cycle Regulated?

Situated as it is between glycolysis and the electron-transport chain, the TCA cycle must be carefully controlled. If the cycle were permitted to run unchecked, large amounts of metabolic energy could be wasted in overproduction of reduced coenzymes and ATP; conversely, if it ran too slowly, ATP would not be produced rapidly enough to satisfy the needs of the cell. Also, as just seen, the TCA cycle is an important source of precursors for biosynthetic processes and must be able to provide them as needed.

What are the sites of regulation in the TCA cycle? Based on our experience with glycolysis (see Figure 18.22), we might anticipate that some of the reactions of the TCA cycle would operate near equilibrium under cellular conditions (with $\Delta G \approx 0$), whereas others—the sites of regulation—would be characterized by large negative ΔG values. Estimates for the values of ΔG in mitochondria, based on mitochondrial concentrations of metabolites, are summarized in Table 19.1. Three enzyme reactions of the cycle—citrate synthase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase—operate with large negative ΔG values under mitochondrial conditions and are thus the primary sites of regulation in the cycle.

The regulatory actions that control the TCA cycle are shown in Figure 19.18. As one might expect, the principal regulatory signals are the concentrations of acetyl-CoA, ATP, NAD^+ , and NADH, with additional effects provided by several other metabolites. The main sites of regulation are pyruvate dehydrogenase, citrate synthase, isocitrate

Figure 19.18 Regulation of the TCA cycle. Green plus symbols represent activation; red circles with slashes indicate inhibition.

dehydrogenase, and α -ketoglutarate dehydrogenase. All of these enzymes are inhibited by NADH, so when the cell has produced all the NADH that can conveniently be turned into ATP, the cycle shuts down. For similar reasons, ATP is an inhibitor of pyruvate dehydrogenase and isocitrate dehydrogenase. The TCA cycle is turned on, however, when either the ADP/ATP or NAD^+ /NADH ratio is high, an indication that the cell has run low on ATP or NADH. Regulation of the TCA cycle by NADH, NAD^+ , ATP, and ADP thus reflects the energy status of the cell. On the other hand, succinyl-CoA is an intracycle regulator, inhibiting citrate synthase and α -ketoglutarate dehydrogenase. Acetyl-CoA acts as a signal to the TCA cycle that glycolysis or fatty acid breakdown is producing two-carbon units. Acetyl-CoA activates pyruvate carboxylase, the anaplerotic reaction that provides oxaloacetate, the acceptor for increased flux of acetyl-CoA into the TCA cycle.

19.8a Pyruvate Dehydrogenase Is Regulated by Phosphorylation/Dephosphorylation

Most organisms can synthesize sugars such as glucose from pyruvate. However, animals cannot synthesize glucose from acetyl-CoA. For this reason, the pyruvate dehydrogenase complex, which converts pyruvate to acetyl-CoA, plays a pivotal role

Figure 19.19 Regulation of the pyruvate dehydrogenase reaction.

in metabolism. Conversion to acetyl-CoA commits nutrient carbon atoms either to oxidation in the TCA cycle or to fatty acid synthesis. Because this choice is so crucial to the organism, pyruvate dehydrogenase is a carefully regulated enzyme. It is subject to product inhibition and is further regulated by nucleotides. Finally, activity of pyruvate dehydrogenase is regulated by phosphorylation and dephosphorylation of the enzyme complex itself.

High levels of either product, acetyl-CoA or NADH, allosterically inhibit the pyruvate dehydrogenase complex. Acetyl-CoA specifically blocks dihydrolipoyl trans-acetylase, and NADH acts on dihydrolipoyl dehydrogenase. The mammalian pyruvate dehydrogenase is also regulated by covalent modifications. As shown in Figure 19.19, a Mg²⁺-dependent **pyruvate dehydrogenase kinase** is associated with the enzyme in mammals. This kinase is allosterically activated by NADH and acetyl-CoA, and when levels of these metabolites rise in the mitochondrion, they stimulate phosphorylation of three residues (Ser²⁰³, Ser²⁶⁴, and Ser²⁷¹) on the pyruvate dehydrogenase α -subunit, blocking the first step of the pyruvate dehydrogenase reaction, the decarboxylation of pyruvate. Inhibition of the dehydrogenase in this manner eventually lowers the levels of NADH and acetyl-CoA in the matrix of the mitochondrion. Reactivation of the enzyme is carried out by **pyruvate dehydrogenase phosphatase**, a Ca²⁺-activated enzyme that binds to the dehydrogenase complex and hydrolyzes the phosphoserine moieties on the dehydrogenase subunit. At low ratios of NADH to NAD⁺ and low acetyl-CoA levels, the phosphatase maintains the dehydrogenase in an activated state, but a high level of acetyl-CoA or NADH once again activates the kinase and leads to the inhibition of the dehydrogenase. Insulin and Ca²⁺ ions activate dephosphorylation, and pyruvate inhibits the phosphorylation reaction.

Pyruvate dehydrogenase is also sensitive to the energy status of the cell. AMP activates pyruvate dehydrogenase, whereas GTP inhibits it. High levels of AMP are a sign that the cell may be energy-poor. Activation of pyruvate dehydrogenase under such conditions commits pyruvate to energy production.

19.8b Isocitrate Dehydrogenase Is Strongly Regulated

The mechanism of regulation of isocitrate dehydrogenase (Figure 19.18) is in some respects the reverse of pyruvate dehydrogenase. The mammalian isocitrate dehydrogenase is subject only to allosteric activation by ADP and NAD⁺ and to inhibition by ATP and NADH. Thus, high NAD⁺/NADH and ADP/ATP ratios stimulate isocitrate dehydrogenase and TCA cycle activity.

It may seem surprising that isocitrate dehydrogenase is strongly regulated, because it is not an apparent branch point within the TCA cycle. However, the citrate/isocitrate ratio controls the rate of production of cytosolic acetyl-CoA, because acetyl-CoA in the cytosol is derived from citrate exported from the mitochondrion. (Breakdown of cytosolic citrate produces oxaloacetate and acetyl-CoA, which can be used in a variety of biosynthetic processes.) Thus, isocitrate dehydrogenase activity in the mitochondrion favors catabolic TCA cycle activity over anabolic utilization of acetyl-CoA in the cytosol.

19.8c Regulation of TCA Cycle Enzymes by Acetylation

Lysine acetylation is a dynamic, reversible, and regulatory post-translational modification that enables cells to sense energy status and respond to environmental changes and stresses (Chapter 15). All of the TCA cycle enzymes are acetylated in organisms from bacteria to plants to mammals, and acetylation inhibits TCA enzyme activity in the cases that have been studied, particularly isocitrate dehydrogenase, succinate dehydrogenase, and malate dehydrogenase (see Figure 15.11). SIRT3 is a mitochondrial NAD⁺-dependent deacetylase of the sirtuin family (Chapter 15) that can deacetylate and activate all these TCA enzymes (Figure 19.20). SIRT3 expression is a function of exercise status in humans. Adults who exercise vigorously for an hour six days a week express SIRT3 at levels nearly three times those of sedentary adults. Elevated levels of SIRT3 presumably activate TCA cycle enzymes, and studies have shown that increased levels of SIRT3 are correlated with extended lifespans in humans.

Figure 19.20 Structure of human SIRT3 with a bound peptide substrate analog (shown in ball-and-stick). The small domain of SIRT3 is at the top; the large domain is at the bottom (PDB id = 3GLT).

Human Biochemistry

TCA Metabolites Play Roles in Many Pathways via Post-Translational Modifications

Post-translational modifications (PTMs) of enzymes and other proteins play important roles in most if not all biological pathways. Several TCA metabolites in particular modify and regulate the activities of metabolic enzymes. For example, Matthias Mann and colleagues have shown that acetyl-CoA is the substrate for acetylation of 3600 lysine residues on 1750 proteins in human cell lines (see figure a)—lysine acetylation was first observed with histone proteins in the cell nucleus; thus lysine acetylation enzymes are referred to as **histone acetyltransferases** or **HATs**. Nearly every enzyme in glycolysis, the TCA cycle, gluconeogenesis, and glycogen metabolism, fatty acid oxidation, and the urea cycle is acetylated in this way.

Some post-translational modifications that involve TCA metabolites as substrates. (a) Acetylation of lysine by acetyl-CoA. (b) Succinylation of lysine by succinyl-CoA. (c) Succination of cysteine by fumarate.

Similarly, succinyl-CoA is the substrate for succinylation of lysine residues on many proteins (figure b). For example, David Lombard and Yingming Zhao have identified 2565 lysine succinylation sites on 779 proteins in mammalian cells. This reaction is reversible, with the desuccinylation reaction catalyzed by a **sirtuin** referred to as **SIRT5**.

Interestingly, fumarate can also serve as a PTM substrate in a reaction with Cys residues on proteins that is irreversible and is termed **succination** because the final product is a covalently bound succinate group (figure c). This is an example of a **Michael addition**.

How could these modifications affect protein or enzyme function? Steric factors and alteration of surface charge may well play a role. Acetylation neutralizes the positive charge of the involved lysine residue, whereas succinylation changes a lysine ϵ -amino positive charge to a negative charge on the associated carboxyl group. On the other hand, succination changes the cysteine-SH group into a pair of adjacent negatively charged carboxyl groups.

All these PTMs with TCA metabolites are involved with multiple alterations of major cellular functions. Increases in cellular fumarate concentration are observed in diabetes and certain cancers. Obese mice (an animal model of type 2 diabetes), with high serum glucose levels, exhibit elevated levels of fumarate and greatly increased succination of proteins in several types of fat cells (adipocytes). In diabetic rats, glyceraldehyde-3-phosphate dehydrogenase (in glycolysis) is succinated and irreversibly inhibited in muscle tissue. Similarly, kidney tumors are characterized by mutations in fumarate that lead to elevated mitochondrial fumarate concentrations and massive increases in succination of cellular proteins, decreased activity of aconitase in the TCA cycle, and metabolic reprogramming that contributes to cancer cell proliferation.

19.8d Two Covalent Modifications Regulate *E. coli* Isocitrate Dehydrogenase

Interestingly, the *E. coli* isocitrate dehydrogenase is regulated by two different covalent modifications. Serine residues on each subunit of the dimeric enzyme are phosphorylated by the protein kinase activity of **AceK**, a bifunctional kinase/phosphatase, causing inhibition of the isocitrate dehydrogenase activity. Activity is restored by the action of the phosphatase activity of AceK. When TCA cycle and glycolytic intermediates—such as isocitrate, 3-phosphoglycerate, pyruvate, PEP,

and oxaloacetate—are high, the kinase is inhibited, the phosphatase is activated, and the TCA cycle operates normally. When levels of these intermediates fall, the kinase is activated, isocitrate dehydrogenase is inhibited, and isocitrate is diverted to the glyoxylate pathway, as explained in the next section. Interestingly, the kinase and phosphatase activities of AceK depend on acetylation of AceK by lysine acetyltransferases and removal of these acetyl groups by deacetylases. Acetylated AceK displays a reduced ability to inactivate isocitrate dehydrogenase (by phosphorylation) but at the same time an increased ability to activate isocitrate dehydrogenase (via dephosphorylation by the phosphatase).

19.8e TCA Metabolites Can Act as Cellular Signals

In addition to their role in catabolic metabolism, some TCA cycle metabolites also participate in cell signaling. Succinate accumulates in macrophages (white blood cells that engulf and digest dead cells and cellular debris) during inflammation, acting as a signal to activate pro-inflammatory gene expression. Succinate also increases in tissues during ischemia (inadequate blood supply to an organ or part of the body). In its signaling role, succinate is exported from mitochondria to the cytosol, inhibiting prolyl hydroxylases and activating HIF-1 α , thus enhancing expression of pro-inflammatory genes (Section 18.8). It also can be exported from cells where it binds to SUCNR1, a G-protein-coupled receptor, either on adjacent cells or on the cells from which it was released, provoking pro-inflammatory responses.

By contrast, itaconate, derived from *cis*-aconitate in the aconitate decarboxylase reaction, acts as an anti-inflammatory signal, counteracting the pro-inflammatory pathways activated by succinate. Itaconate acts by inhibiting succinate dehydrogenase and also can be exported from cells, where it alkylates cysteine residues on the protein KEAP1, enhancing the expression of antioxidant and anti-inflammatory genes. Itaconate also inhibits the induction of interferons, immune system proteins that stimulate or inhibit several hundred genes involved in antiviral defense mechanisms, inflammation, adaptive immunity, angiogenesis, and other processes.

19.8f The TCA Cycle Operates as a Metabolon

The enzymes of the TCA cycle associate as a metabolon (Section 17.2). Selfassembly of the TCA enzymes into a supercomplex allows the channeling of substrate from one enzyme to another, enabling a much higher metabolic flux than would be the case for separate enzymes distributed throughout the mitochondrial matrix. Cross-linking experiments *in vivo* and mass spectrometry studies confirm that the seven TCA enzymes in the matrix form a complex that associates with SDH of the inner mitochondrial membrane, and this entire eight-enzyme complex apparently functions as one unit (Figure 19.21). Fei Wu and Shelley Minter have shown that computer simulations and analysis of surface electrostatic potential in models are consistent with a continuous positively charged surface across the assembled supercomplex, which could facilitate transport of the negatively charged TCA substrates from one active site to the next.

19.9 Can Any Organisms Use Acetate as Their Sole Carbon Source?

Plants (particularly seedlings, which cannot yet accomplish efficient photosynthesis) as well as some bacteria and algae can use acetate as the only source of carbon for all the carbon compounds they produce. Although we saw that the TCA cycle can supply

intermediates for some biosynthetic processes, the cycle gives off two CO_2 for every two-carbon acetate group that enters and cannot effect the net synthesis of TCA cycle intermediates. Thus, it would not be possible for the cycle to produce the massive amounts of biosynthetic intermediates needed for acetate-based growth unless alternative reactions were available. In essence, the TCA cycle is geared primarily to energy production, and it wastes carbon units by giving off CO_2 . Modification of the cycle to support acetate-based growth would require eliminating the CO_2 -producing reactions and enhancing the net production of four-carbon units (that is, oxaloacetate). Plants and bacteria employ a modification of the TCA cycle called the **glyoxylate cycle** to produce four-carbon dicarboxylic acids (and eventually even sugars) from two-carbon acetate units. The glyoxylate cycle bypasses the two oxidative decarboxylations of the TCA cycle and instead routes isocitrate through the **isocitrate lyase** and **malate synthase** reactions (Figure 19.22). Glyoxylate produced by isocitrate lyase reacts with a second molecule of acetyl-CoA to form L-malate. The net effect is to conserve carbon units, using two acetyl-CoA molecules per cycle to generate oxaloacetate. Some of this is converted to PEP and then to glucose by pathways of carbohydrate metabolism.

19.9a The Glyoxylate Cycle Operates in Specialized Organelles

The enzymes of the glyoxylate cycle in plants are contained in **glyoxysomes**, organelles devoted to this cycle. Yeast and algae carry out the glyoxylate cycle in the cytoplasm. The enzymes common to both the TCA and glyoxylate pathways exist as isozymes, with spatially and functionally distinct enzymes operating independently in the two cycles.

Figure 19.22 The glyoxylate cycle. The first two steps are identical to TCA cycle reactions. The third step bypasses the CO_2 -evolving steps of the TCA cycle to produce succinate and glyoxylate. The malate synthase reaction forms malate from glyoxylate and another acetyl-CoA. The result is that one turn of the cycle consumes one oxaloacetate and two acetyl-CoA molecules but produces two molecules of oxaloacetate. (Succinate produced in the isocitrate lyase reaction is converted to oxaloacetate by TCA cycle reactions.) The net for this cycle is one oxaloacetate from two acetyl-CoA molecules.

19.9b Isocitrate Lyase Short-Circuits the TCA Cycle by Producing Glyoxylate and Succinate

The **isocitrate lyase** reaction (Figure 19.23) produces succinate, a four-carbon product of the cycle, as well as glyoxylate, which can then combine with a second molecule of acetyl-CoA. Isocitrate lyase catalyzes an aldol cleavage and is similar to the reaction mediated by aldolase in glycolysis. The malate synthase reaction (see Figure 19.22), a Claisen condensation of acetyl-CoA with the aldehyde of glyoxylate to yield malate, is quite similar to the citrate synthase reaction. Compared with the TCA cycle, the glyoxylate cycle (1) contains only five steps (as opposed to eight), (2) lacks the CO_2 -liberating reactions, (3) consumes two molecules of acetyl-CoA per cycle, and (4) produces four-carbon units (oxaloacetate) as opposed to one-carbon units.

Figure 19.23 The isocitrate lyase reaction.

19.9c The Glyoxylate Cycle Helps Plants Grow in the Dark

The existence of the glyoxylate cycle explains how certain seeds grow underground (or in the dark), where photosynthesis is impossible. Many seeds (peanuts, soybeans, and castor beans, for example) are rich in lipids, and most organisms degrade the fatty acids of lipids to acetyl-CoA. Glyoxysomes form in seeds as germination begins, and the glyoxylate cycle uses the acetyl-CoA produced in fatty acid oxidation to provide large amounts of oxaloacetate and other intermediates for carbohydrate synthesis. Once the growing plant begins photosynthesis and can fix CO₂ to produce carbohydrates, the glyoxysomes disappear.

19.9d Glyoxysomes Must Borrow Three Reactions from Mitochondria

Glyoxysomes do not contain all the enzymes needed to run the glyoxylate cycle: Succinate dehydrogenase, fumarase, and malate dehydrogenase are absent. Consequently, glyoxysomes must cooperate with mitochondria to run their cycle (Figure 19.24). Succinate travels from the glyoxysomes to the mitochondria, where it is converted to oxaloacetate. Transamination to aspartate follows because oxaloacetate cannot be transported out of the mitochondria. Aspartate formed in this way then moves from the mitochondria back to the glyoxysomes, where a reverse transamination with α -ketoglutarate forms oxaloacetate, completing the shuttle. Finally, to balance the transaminations, glutamate shuttles from glyoxysomes to mitochondria.

Figure 19.24 Glyoxysomes lack three of the enzymes needed to run the glyoxylate cycle. Succinate dehydrogenase, fumarase, and malate dehydrogenase are all borrowed from the mitochondria in a shuttle in which succinate and glutamate are passed to the mitochondria and α -ketoglutarate and aspartate are passed to the glyoxysome.

Foundational Biochemistry Things You Should Know after Reading Chapter 19.

- Pyruvate is converted to acetyl-CoA and oxidized to CO_2 in the tricarboxylic acid cycle (also known as the citric acid cycle or Krebs cycle).
- Reducing equivalents released in the oxidative reactions of glycolysis, pyruvate decarboxylation, and the TCA cycle are captured in the form of NADH and enzyme-bound FADH_2 .
- Glycolysis in one equation:
 $\text{C}_6\text{H}_{12}\text{O}_6 \longrightarrow 2 \text{CH}_3\text{COCOO}^- + 2\text{H}^+ + 4 \text{H} = 2 \text{C}_3\text{H}_4\text{O}_3 + 4 \text{H}$
 Net: 2 ATP + 2 NADH + 2 H^+ from 4 H and the cleavage of 1 C—C bond
- TCA Cycle (including pyruvate dehydrogenase) in one equation:
 $2 \text{C}_3\text{H}_4\text{O}_3 + 6 \text{H}_2\text{O} \longrightarrow 6 \text{CO}_2 + 20 \text{H}$
 Net: 2 ATP and 8 NADH + 8 H^+ + 2 FADH_2 from 20 H and the cleavage of 4 C—C bonds
- Carbon enters the TCA cycle as acetyl-CoA and exits as CO_2 .
- Pyruvate is oxidatively decarboxylated to acetyl-CoA by the pyruvate dehydrogenase complex.
- Acetyl-CoA reacts with oxaloacetate in the citrate synthase reaction of the TCA cycle to produce citrate.
- Citrate is isomerized to form isocitrate by aconitase in the TCA cycle.
- Isocitrate dehydrogenase catalyzes the first oxidative decarboxylation of the TCA cycle, the conversion of isocitrate to α -ketoglutarate.
- α -Ketoglutarate is oxidatively decarboxylated to succinyl-CoA by α -ketoglutarate dehydrogenase.
- Succinyl-CoA synthetase catalyzes a substrate-level phosphorylation, the conversion of succinyl-CoA to succinate, and the attendant conversion of GDP and P_i to GTP.
- Succinate dehydrogenase oxidizes succinate to fumarate, a reaction that is part of the mitochondrial electron-transport chain.
- Fumarase catalyzes the *trans*-hydration of fumarate to form L-malate in the TCA cycle.
- Malate is oxidized to oxaloacetate by malate dehydrogenase, the final reaction of the TCA cycle.
- The ΔG° for one pass around the TCA cycle is -40 kJ/mol .
- The carbonyl carbon of acetyl-CoA is fully retained through one turn of the TCA cycle but is lost completely in a second turn of the cycle.
- The methyl carbon of acetyl-CoA survives two full turns of the TCA cycle. However, in each subsequent turn of the cycle, one-half of the remaining carbon is lost.
- The four-, five-, and six-carbon species produced in the TCA cycle fuel a variety of biosynthetic processes. α -Ketoglutarate, succinyl-CoA, fumarate, and oxaloacetate are all precursors of important cellular species.
- Several cellular reactions (termed anaplerotic reactions), including pyruvate carboxylase, PEP carboxylase, and malic enzyme, replenish TCA cycle intermediates.
- The main sites of regulation in the TCA cycle are pyruvate dehydrogenase, citrate synthase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase. All of these are inhibited by NADH. ATP is an inhibitor of pyruvate dehydrogenase and isocitrate dehydrogenase.
- Pyruvate dehydrogenase is inhibited by phosphorylation and activated by dephosphorylation.
- The activities of TCA cycle enzymes are modulated by covalent modifications including acetylation, phosphorylation, succinylation, and succination.
- The enzymes of the TCA cycle associate and operate as a metabolon.
- Plants as well as some bacteria and algae employ a modification of the TCA cycle called the glyoxylate cycle, and thus can use acetate as their sole carbon source. Humans and other animals cannot.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Radiolabeling with ^{14}C -Glutamate** Describe the labeling pattern that would result from the introduction into the TCA cycle of glutamate labeled at C_γ with ^{14}C .
- Structures in the TCA Cycle** Consider the structures shown and organize them in the order in which they appear in the TCA cycle.

- Enzymes in the TCA Cycle** Consider the enzymes listed and organize them in the order in which they appear in the TCA cycle: (a) fumarase, (b) α -ketoglutarate dehydrogenase, (c) succinate dehydrogenase, (d) aconitase, (e) malate dehydrogenase, and (f) isocitrate dehydrogenase.
- Assessing the Effects of Substrate Concentrations on the TCA Cycle** Describe the effect on the TCA cycle of (a) increasing the

concentration of NAD^+ , (b) reducing the concentration of ATP, or (c) increasing the concentration of isocitrate.

- Assessing the Effect of Active-Site Phosphorylation on Enzyme Activity** (Integrates with Chapter 15.) The serine residue of isocitrate dehydrogenase that is phosphorylated by protein kinase lies within the active site of the enzyme. This situation contrasts with most other examples of covalent modification by protein phosphorylation, where the phosphorylation occurs at a site remote from the active site. What direct effect do you think such active-site phosphorylation might have on the catalytic activity of isocitrate dehydrogenase? (See Barford, D., 1991. Molecular mechanisms for the control of enzymic activity by protein phosphorylation. *Biochimica et Biophysica Acta* **1133**:55–62.)
- Understanding the Mechanism of the α -Ketoglutarate Dehydrogenase Reaction** The first step of the α -ketoglutarate dehydrogenase reaction involves decarboxylation of the substrate and leaves a covalent TPP intermediate. Write a reasonable mechanism for this reaction.
- Understanding the Action of Fluoroacetate on the TCA Cycle** In a tissue where the TCA cycle has been inhibited by fluoroacetate, what difference in the concentration of each TCA cycle metabolite would you expect, compared with a normal, uninhibited tissue?
- Designing an Assay for Succinate Dehydrogenase** On the basis of the descriptions of the physical properties of FAD and FADH_2 , suggest a method for the measurement of the enzyme activity of succinate dehydrogenase.

9. **Understanding the Oxidative Processes in the TCA Cycle** Starting with citrate, isocitrate, α -ketoglutarate, and succinate, state which of the individual carbons of the molecule undergo oxidation in the next step of the TCA cycle. Which molecules undergo a net oxidation?
10. **The Mechanism of Citrate Synthase** Deuterated acetyl-coenzyme A ($-CD_3$ instead of $-CH_3$) was used in an experiment to study the TCA cycle. Upon analysis of the metabolites, it was found that deuterium (D) was present in a wide variety of compounds; even compounds not associated with the citric acid cycle. Explain how this could be.
11. **Designing Substrate Analog Inhibitors for the TCA Cycle** In addition to fluoroacetate, consider whether other analogs of TCA cycle metabolites or intermediates might be introduced to inhibit other, specific reactions of the cycle. Explain your reasoning.
12. **Understanding the Mechanism of the Pyruvate Dehydrogenase Reaction** Based on the action of thiamine pyrophosphate in catalysis of the pyruvate dehydrogenase reaction, suggest a suitable chemical mechanism for the pyruvate decarboxylase reaction in yeast:
- $$\text{Pyruvate} \longrightarrow \text{acetaldehyde} + \text{CO}_2$$
13. **Regulation by Ca^{2+} (Integrates with Chapter 15)** Revisit Sections 16.1 and 16.2 on the molecular mechanism of muscle contraction. In contracting muscles, Ca^{2+} is released from the sarcoplasmic reticulum. Would you predict that Ca^{2+} inhibits or activates the pyruvate dehydrogenase complex and the TCA cycle in muscle cells? Explain your answer.
14. **Understanding the Energetics of the Aconitase Reaction** (Integrates with Chapter 3.) Aconitase catalyzes the citric acid cycle reaction:
- $$\text{Citrate} \rightleftharpoons \text{isocitrate}$$
- The standard free energy change, ΔG° , for this reaction is +6.7 kJ/mol. However, the observed free energy change (ΔG) for this reaction in pig heart mitochondria is +0.8 kJ/mol. What is the ratio of [isocitrate]/[citrate] in these mitochondria? If [isocitrate] = 0.03 mM, what is [citrate]?
15. **Radiolabeling with $^{14}\text{CO}_2$ in the Pyruvate Carboxylase** Describe the labeling pattern that would result if $^{14}\text{CO}_2$ were incorporated into the TCA cycle via the pyruvate carboxylase reaction.
16. **Consequences of Radiolabeling With $^{14}\text{CO}_2$ in the Reductive TCA Cycle** Describe the labeling pattern that would result if the reductive, reversed TCA cycle (see A Deeper Look in Section 19.7) operated with $^{14}\text{CO}_2$.
17. **Consequences of Radiolabeling with $^{14}\text{CH}_3$ -Acetyl-CoA in the Glyoxylate Cycle** Describe the labeling pattern that would result in the glyoxylate cycle if a plant were fed acetyl-CoA labeled at the $-\text{CH}_3$ carbon.
18. **Understanding the Mechanism of the Malate Synthase Reaction** The malate synthase reaction, which produces malate from acetyl-CoA and glyoxylate in the glyoxylate pathway, involves chemistry similar to the citrate synthase reaction. Write a mechanism for the malate synthase reaction, and explain the role of CoA in this reaction.
19. **Understanding How Cells Provide Acetate Units for Fatty Acid Synthesis in the Cytosol** In most cells, fatty acids are synthesized from acetate units in the cytosol. However, the primary source of acetate units is the TCA cycle in mitochondria, and acetate cannot be transported directly from the mitochondria to the cytosol. Cells solve this problem by exporting citrate from the mitochondria and then converting citrate to acetate and oxaloacetate. Then, because cells cannot transport oxaloacetate into mitochondria directly, they must convert it to malate or pyruvate, both of which can be taken up by mitochondria. Draw a complete pathway for citrate export, conversion of citrate to malate and pyruvate, and import of malate and pyruvate by mitochondria.
- Which of the reactions in this cycle might require energy input?
 - What would be the most likely source of this energy?
 - Do you recognize any of the enzyme reactions in this cycle?
 - What coenzymes might be required to run this cycle?
20. **Assessing the Equilibrium Concentrations in the Malate Dehydrogenase Reaction** A typical intramitochondrial concentration of malate is 0.22 mM. If the ratio of NAD^+ to NADH in mitochondria is 20, and if the malate dehydrogenase reaction is at equilibrium, calculate the concentration of oxaloacetate in the mitochondrion at 20°C. A typical mitochondrion can be thought of as a cylinder 1 μm in diameter and 2 μm in length. Calculate the number of molecules of oxaloacetate in a mitochondrion. In analogy with pH (the negative logarithm of $[\text{H}^+]$), what is pOAA?
21. **Understanding the Oxidation of Glucose and Its Products in the TCA Cycle** Glycolysis, the pyruvate dehydrogenase reaction, and the TCA cycle result in complete oxidation of a molecule of glucose to CO_2 . Review the calculation of oxidation numbers for individual atoms in any molecule, and then calculate the oxidation numbers of the carbons of glucose, pyruvate, the acetyl carbons of acetyl-CoA, and the metabolites of the TCA cycle to convince yourself that complete oxidation of glucose involves removal of 24 electrons and that each acetyl-CoA through the TCA cycle gives up 8 electrons.
22. **A Simple Way to Understand and Remember the Reactions of the TCA Cycle** Recalling all reactions of the TCA cycle can be a challenging proposition. One way to remember these is to begin with the simplest molecule—succinate, which is a symmetric four-carbon molecule. Begin with succinate, and draw the eight reactions of the TCA cycle. Remember that succinate $\longrightarrow$ oxaloacetate is accomplished by a special trio of reactions: oxidation of a single bond to a double bond, hydration across the double bond, and oxidation of an alcohol to a ketone. From there, a molecule of acetyl-CoA is added. If you remember the special function of acetyl-CoA (see A Deeper Look, in Section 19.2), this is an easy reaction to draw. From there, you need only isomerize, carry out the two oxidative decarboxylations, and remove the CoA molecule to return to succinate.
23. **Understanding the Mechanism-Based Inactivation of Aconitase by Fluoroacetate** Aconitase is rapidly inactivated by 2R, 3R-fluorocitrate, which is produced from fluoroacetate in the citrate synthase reaction. Interestingly, inactivation by fluorocitrate is accompanied by stoichiometric release of fluoride ion (i.e., one F^- ion is lost per aconitase active site). This observation is consistent with mechanism-based inactivation of aconitase by fluorocitrate. Suggest a mechanism for this inactivation, based on formation of 4-hydroxy-*trans*-aconitate, which remains tightly bound at the active site. To assess your answer, consult this reference: Lauble, H., et al., 1996. The reaction of fluorocitrate with aconitase and the crystal structure of the enzyme-inhibitor complex. *Proceedings of the National Academy of Sciences, USA* 93:13699–13703.
24. The post-translational modification of cysteine residues on proteins by fumarate (Human Biochemistry—TCA Metabolites Play Roles in Many Pathways via Post-Translational Modifications, in Section 19.8) is termed a *succination* and proceeds via a mechanism known as *Michael addition*. Write a detailed mechanism for this Michael addition reaction.
25. **Fatty Acid Metabolism in the TCA Cycle** Complete oxidation of a 16-carbon fatty acid can yield about 114 molecules of ATP. Study Figure 19.2 and determine how many ATP molecules would be generated if a 16-carbon fatty acid were metabolized solely by the TCA cycle, in the form of 8 acetyl-CoA molecules.
26. **TCA Cycle** Study Figure 19.18 and decide which of the following statements is false.
- Pyruvate dehydrogenase is inhibited by NADH.
 - Pyruvate dehydrogenase is inhibited by ATP.
 - Citrate synthase is inhibited by NADH.
 - Succinyl-CoA activates citrate synthase.
 - Acetyl-CoA activates pyruvate carboxylase.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

27. Examine the PSAFE structure for isocitrate dehydrogenase, and identify the α -helices, 3_{10} helices, and β -sheets in this structure. Locate the enzyme residues involved in catalysis.

Think-Pair-Share Question

Consider the isotopically labeled oxaloacetate structure shown. Use it as a starting point for one round of the TCA cycle and predict

the intermediates that could contain the isotopes. Draw the labeled intermediates.

Electron Transport and Oxidative Phosphorylation

20

In all things of nature there is something of the marvelous.

Aristotle (384–322 B.C.)

Wall Piece #IV (1985), a kinetic sculpture by George Rhoads

◀ Wall Piece #IV (1985), a kinetic sculpture by George Rhoads. This complex mechanical art form can be viewed as a metaphor for the molecular apparatus underlying electron transport and ATP synthesis by oxidative phosphorylation.

Essential Question

Living cells save up metabolic energy predominantly in the form of fats and carbohydrates, and they spend this energy for biosynthesis, membrane transport, and movement. In both directions, energy is exchanged and transferred in the form of ATP. Most of the metabolic energy that is obtainable from substrates entering glycolysis and the TCA cycle is funneled via oxidation–reduction reactions into NADH and reduced flavoproteins, the latter symbolized by [FADH₂]. **How do cells oxidize NADH and [FADH₂] and convert their reducing potential into the chemical energy of ATP?**

Whereas ATP made in glycolysis and the TCA cycle is the result of substrate-level phosphorylation, NADH-dependent ATP synthesis is the result of **oxidative phosphorylation**. Electrons stored in the form of the reduced coenzymes, NADH or [FADH₂], are passed through an elaborate and highly organized chain of proteins and coenzymes, the **electron-transport chain**, finally reaching O₂ (molecular oxygen), the terminal electron acceptor. Each component of the chain can exist in (at least) two oxidation states, and each component is successively reduced and reoxidized as electrons move through the chain from NADH (or [FADH₂]) to O₂. In the course of electron transport, a proton gradient is established across the inner mitochondrial membrane. It is the energy of this proton gradient that drives ATP synthesis.

20.1 | Where in the Cell Do Electron Transport and Oxidative Phosphorylation Occur?

The processes of electron transport and oxidative phosphorylation are **membrane associated**. Prokaryotes are the simplest life form, and prokaryotic cells typically consist of a single cellular compartment surrounded by a plasma membrane and a more

Key Questions

- 20.1 Where in the Cell Do Electron Transport and Oxidative Phosphorylation Occur?
- 20.2 How Is the Electron-Transport Chain Organized?
- 20.3 What Are the Thermodynamic Implications of Chemiosmotic Coupling?
- 20.4 How Does a Proton Gradient Drive the Synthesis of ATP?
- 20.5 What Is the P/O Ratio for Mitochondrial Oxidative Phosphorylation?
- 20.6 How Are the Electrons of Cytosolic NADH Fed into Electron Transport?
- 20.7 How Do Mitochondria Mediate Apoptosis?

rigid cell wall. In such a system, the conversion of energy from NADH and [FADH₂] to the energy of ATP via electron transport and oxidative phosphorylation is carried out at (and across) the plasma membrane.

In eukaryotic cells, electron transport and oxidative phosphorylation are localized in mitochondria, which are also the sites of TCA cycle activity and fatty acid oxidation. Mammalian cells contain 800 to 2500 mitochondria; other types of cells may have as few as one or two or as many as half a million mitochondria. Human erythrocytes, whose purpose is simply to transport oxygen to tissues, contain no mitochondria at all. The typical mitochondrion is about $0.5 \pm 0.3 \mu\text{m}$ in diameter and from 0.5 to several microns long; its overall shape is sensitive to metabolic conditions in the cell, as will be described in the next section.

20.1a Mitochondrial Functions Are Localized in Specific Compartments

Mitochondria are surrounded by a simple **outer membrane** and a more complex **inner membrane** (Figure 20.1). The space between the inner and outer membranes is referred to as the **intermembrane space**. Several enzymes that utilize ATP (such as creatine kinase and adenylate kinase) are found in the intermembrane space. The smooth outer membrane is about 30% to 40% lipid and 60% to 70% protein and has a relatively high concentration of phosphatidylinositol. The outer membrane contains significant amounts of **porins**—transmembrane proteins, rich in β -sheets, that form large channels across the membrane, permitting free diffusion of molecules with molecular weights of about 10,000 or less. The outer membrane plays a prominent role in maintaining the shape of the mitochondrion. The inner membrane is richly packed with proteins, which account for nearly 80% of its weight; thus, its density is higher than that of the outer membrane. The fatty acids of inner membrane lipids are highly unsaturated. Cardiolipin and diphosphatidylglycerol (see Chapter 8) are abundant. The inner membrane lacks cholesterol and is quite impermeable to molecules and ions. Species that must cross the mitochondrial inner membrane—ions, substrates, fatty acids for oxidation, and so on—are carried by specific transport proteins in the membrane. Notably, the inner membrane is extensively folded (Figure 20.1). The folds, known as **cristae**, provide the inner membrane with a large surface area in a small volume. During periods of active respiration, the inner membrane appears to shrink significantly, leaving a comparatively large intermembrane space.

The internal structure of mitochondria. *Trends in Biochemical Sciences* 25:319–324.)

Human Biochemistry

Mitochondrial Dynamics in Human Diseases

Mitochondria are mobile and versatile organelles that exist in dynamic networks. They continuously divide by **fission** and join by the process of **fusion**. The dynamic cycle of fission and fusion modulates numerous cellular processes, including the interactions between mitochondria and the endoplasmic reticulum, biogenesis of mitochondria, the programmed death of mitochondria (termed **mitophagy**), the dynein- and kinesin-mediated transport of mitochondria along microtubule tracks in the cell, and sensing of and response to oxygen in the cell.

Both fission and fusion are driven by proteins that hydrolyze GTP (GTPases). Fission of mitochondria is mediated by **dynamitin-related protein 1 (DRP1)**, a cytosolic protein that, when activated, migrates to the outer mitochondrial membrane and multimerizes to form a ringlike structure that constricts and divides the organelle (figure a). Fusion is accomplished by two GTPases in the outer mitochondrial membrane known as **mitofusin-1** and **mitofusin-2** and by an inner

membrane protein, **OPA1** (figure b). Mitofusins initiate fusion by forming homodimeric or heterodimeric, antiparallel, coiled-coil linkages between adjacent mitochondria, thus joining the two outer membranes. On the other hand, proteolytic cleavage of OPA1 stimulates inner membrane fusion. Fusion and fission are both modulated by lipids generated by phospholipase D, particularly phosphatidic acid. The small, negatively charged head group of phosphatidic acid causes curvature of lipid bilayers and recruits adaptor proteins, promoting fusion. In contrast, hydrolysis of phosphatidic acid by **lipin-1** produces diacylglycerol, which promotes fission.

Abnormalities of mitochondrial dynamics are involved in cardiovascular disease, as well as neurodegenerative, endocrine, and neoplastic diseases, including cancer. For example, impaired fusion and enhanced fission result in fragmentation of the mitochondrial network in pulmonary arterial hypertension (bottom left).

20.1b The Mitochondrial Matrix Contains the Enzymes of the TCA Cycle

The space inside the inner mitochondrial membrane is called the **matrix**, and it contains most of the enzymes of the TCA cycle and fatty acid oxidation. (An important exception, succinate dehydrogenase of the TCA cycle, is located in the inner membrane itself.) In addition, mitochondria contain circular DNA molecules, along with ribosomes and the enzymes required to synthesize proteins coded within the mitochondrial genome. Although some of the mitochondrial proteins are made this way, most are encoded by nuclear DNA and synthesized by cytosolic ribosomes.

20.2 | How Is the Electron-Transport Chain Organized?

As we have seen, the metabolic energy from oxidation of food materials—sugars, fats, and amino acids—is funneled into formation of reduced coenzymes (NADH) and reduced flavoproteins ([FADH₂]). The electron-transport chain reoxidizes the coenzymes and channels the free energy obtained from these reactions into the creation of a proton gradient. This reoxidation process involves the removal of both protons and electrons from the coenzymes. Electrons move from NADH and [FADH₂] to molecular oxygen, O₂, which is the terminal acceptor of electrons in the chain. The reoxidation of NADH,

involves the following half-reactions:

Here, half-reaction 20.3 is the electron acceptor and half-reaction 20.2 is the electron donor. Then

$$\Delta \mathcal{E}_o' = 0.816 - (-0.32) = 1.136 \text{ V} \quad (20.4)$$

and, according to Equation 3.22c, the standard-state free energy change, ΔG° , is -219 kJ/mol . Molecules along the electron-transport chain have reduction potentials between the values for the NAD⁺/NADH couple and the oxygen/H₂O couple, so electrons move down the energy scale toward progressively more positive reduction potentials (Figure 20.2).

Although electrons move from more negative to more positive reduction potentials in the electron-transport chain, it should be emphasized that the electron carriers do not operate in a simple linear sequence. This will become evident when the individual components of the electron-transport chain are discussed in the following paragraphs.

Careers in Chemistry

Dr. Vincent Wu

Dr. Vincent Wu is a research scientist at Triplebar, a company dedicated to creating products that nourish, heal, and sustain our population and the planet. Vincent is currently engineering fungi genetically to produce bovine milk proteins, thus avoiding the carbon footprint and resource intensity of traditional dairy production.

Dr. Wu's career began with a bachelor's degree in Marine Biology and Biological Oceanography at UCLA, followed by a Ph.D. in Plant and Microbial Biology at the University of California, Berkeley. His graduate research in the laboratory

of Professor Louise Glass focused on fungal genetics and involved studies of transcriptional regulation of plant cell wall degrading enzymes in *Neurospora crassa*. Dr. Wu believes that a strong grasp of the principles of biochemistry is required to utilize the tools and methods of genetic engineering. He hopes that his work on liquid fermentation with genetically engineered fungi will optimize production of proteins from host strains and enable sustainable production of milk proteins and development of vegan and lactose-free milk alternatives.

20.2a The Electron-Transport Chain Can Be Isolated in Four Complexes

The electron-transport chain involves several different molecular species, including:

1. **Flavoproteins**, which contain tightly bound FMN or FAD as prosthetic groups and which may participate in one- or two-electron transfer events.
2. **Coenzyme Q**, also called **ubiquinone** (and abbreviated **CoQ** or **UQ**) (see Figure 20.4), which can function in either one- or two-electron transfer reactions.
3. Several **cytochromes** (proteins containing heme prosthetic groups [see Chapter 5], which function by carrying or transferring electrons), including cytochromes *b*, *c*, *c*₁, *a*, and *a*₃. Cytochromes are one-electron transfer agents in which the heme iron is converted from Fe^{2+} to Fe^{3+} and back.
4. A number of **iron–sulfur proteins**, which participate in one-electron transfers involving the Fe^{2+} and Fe^{3+} states.
5. Protein-bound **copper**, a one-electron transfer site that converts between Cu^+ and Cu^{2+} .

All these intermediates except for cytochrome *c* are membrane associated (either in the mitochondrial inner membrane of eukaryotes or in the plasma membrane of prokaryotes). Three types of proteins involved in this chain—flavoproteins, cytochromes, and iron–sulfur proteins—possess electron-transferring *prosthetic groups*.

The components of the electron-transport chain can be purified from the mitochondrial inner membrane. Solubilization of the membranes containing the electron-transport chain results in the isolation of four distinct protein complexes, and the complete chain can thus be considered to be composed of four parts: (I) **NADH–coenzyme Q reductase**, (II) **succinate–coenzyme Q reductase**, (III) **coenzyme Q–cytochrome *c* reductase**, and (IV) **cytochrome *c* oxidase** (Figure 20.3). Complex I accepts electrons from NADH, serving as a link between glycolysis, the TCA cycle, fatty acid oxidation, and the electron-transport chain. Complex II includes succinate dehydrogenase and thus forms a direct link between the TCA cycle and electron transport. Complexes I and II produce

Figure 20.3 An overview of the complexes and pathways in the mitochondrial electron-transport chain. (Adapted from Nicholls, D. G., and Ferguson, S. J., *Bioenergetics* 3, London: Academic Press, 2022.)

a common product, reduced coenzyme Q (UQH₂), which is the substrate for coenzyme Q-cytochrome *c* reductase (Complex III). As shown in Figure 20.3, there are two other ways to feed electrons to UQ: the **electron-transferring flavoprotein**, which transfers electrons from the flavoprotein-linked step of fatty acyl-CoA dehydrogenase, and ***sn*-glycerophosphate dehydrogenase**, which converts dihydroxyacetone to ***sn*-glycerol 3-phosphate**. Complex III oxidizes UQH₂ while reducing cytochrome *c*, which in turn is the substrate for Complex IV, cytochrome *c* oxidase. Complex IV is responsible for reducing molecular oxygen. Each of the complexes shown in Figure 20.3 is a large multisubunit complex embedded within the inner mitochondrial membrane.

20.2b Complex I Oxidizes NADH and Reduces Coenzyme Q

Complex I, also known as NADH dehydrogenase, transfers a pair of electrons from NADH to coenzyme Q, a small, hydrophobic, yellow compound. Another common name for this enzyme complex is *NADH dehydrogenase*. The complex from mammalian heart mitochondria (with an estimated mass of 980 kDa) involves 45 polypeptide chains, one molecule of flavin mononucleotide (FMN), and nine Fe-S clusters, together containing a total of 20 to 26 iron atoms (Table 20.1). Bacterial complex I is much simpler, with just 14 subunits and a mass of 500 kDa, but the cofactors in mitochondrial and bacterial complex I are the same. By virtue of its dependence on FMN, NADH-UQ reductase is a flavoprotein.

Although the precise mechanism of the NADH-UQ reductase is unknown, the first step involves binding of NADH to the enzyme on the matrix side of the inner mitochondrial membrane and transfer of electrons from NADH to tightly bound FMN:

The second step involves the transfer of electrons from the reduced [FMNH₂] to a series of Fe-S proteins, including both 2Fe-2S and 4Fe-4S clusters (see Figure 20.6). The versatile redox properties of the flavin group of FMN are important here. NADH is a two-electron donor, whereas the Fe-S proteins are one-electron transfer agents. The flavin of FMN has three redox states—the oxidized, semiquinone, and reduced states. It can act as either a one-electron or a two-electron transfer agent and may serve as a critical link between NADH and the Fe-S proteins.

Table 20.1 Protein Complexes of the Mitochondrial Electron-Transport Chain

Complex	Mass (kDa)	Subunits	Prosthetic Group	Binding Site for:
NADH–UQ reductase	980	45	FMN Fe-S	NADH (matrix side) UQ (lipid core)
Succinate–UQ reductase	140	4	FAD Fe-S	Succinate (matrix side) UQ (lipid core)
UQ–Cyt <i>c</i> reductase	250	9–10	Heme <i>b_L</i> Heme <i>b_H</i> Heme <i>c</i> ₁ Fe-S	Cyt <i>c</i> (intermembrane space side)
Cytochrome <i>c</i>	13	1	Heme <i>c</i>	Cyt <i>c</i> ₁ Cyt <i>a</i>
Cytochrome <i>c</i> oxidase	162	13	Heme <i>a</i> Heme <i>a</i> ₃ Cu _A Cu _B	Cyt <i>c</i> (intermembrane space side)

The final step of the reaction involves the transfer of two electrons from iron–sulfur clusters to coenzyme Q. Coenzyme Q is a **mobile electron carrier**. Its isoprenoid tail makes it highly hydrophobic, and it diffuses freely in the hydrophobic core of the inner mitochondrial membrane. As a result, it shuttles electrons from Complexes I and II to Complex III. The redox cycle of UQ is shown in Figure 20.4. The structural and functional organization of Complex I is shown in Figure 20.5.

Complex I Transports Protons from the Matrix to the Cytosol The oxidation of one NADH and the reduction of one UQ by NADH–UQ reductase results in the net transport of protons from the matrix side to the cytosolic side of the inner membrane. The cytosolic side, where H^+ accumulates, is referred to as the **P** (for positive) face; similarly, the matrix side is the **N** (for negative) face. Some of the energy liberated by the flow of electrons through this complex is used in a coupled process to drive the transport of protons across the membrane. (This is an example of active transport, a

Figure 20.4 Coenzyme Q, also known as ubiquinone, is a lipid-soluble carrier of electrons in the electron transport pathway. (a) The three oxidation states of coenzyme Q. (b) A space-filling model of coenzyme Q.

Figure 20.5 Structural organization of mammalian Complex I, based on cryo-electron microscopy, showing functional relationships within the L-shaped complex. **(a)** All redox centers of Complex I are located in the peripheral arm (PA), except ubiquinone, which is located in the hydrophobic membrane domain (MD). Electron flow from NADH to UQH₂ in the membrane pool is indicated. **(b)** Structure of the entire Complex I from mouse (*Mus musculus*) (PDB id = 6G2J). The 14 core subunits are in color and labeled accordingly, and the 31 supernumerary subunits are in white. The positions of the flavin mononucleotide (FMN) at the NADH binding site and of FeS cluster N₂, the immediate electron donor to ubiquinone, are indicated with circles. The structure of the cofactor chain, together with the modeled structure of ubiquinone-10, is also shown separately in the inset. The distance from one center to the next is about 1 nm. Leonard Sazanov has proposed a coupling mechanism for complex I in all organisms, in which protons are taken up from the matrix exclusively by subunits ND4 and ND5. Protons then move back and forth along the hydrated, hydrophilic axis (part a), involving all the protein subunits of the inner membrane (part b) in a series of electrostatically driven ‘domino effect’ events that result in release of protons to the intermembrane space only through ND5. (Part b adapted from Agip, A., Blaza, J., Bridges, H., et al., 2018. Cryo-EM structures of complex I from mouse heart mitochondria in two biochemically defined states. *Nature Struct. Mol. Biol.* **25**:548–556.)

phenomenon examined in detail in Chapter 9.) Available experimental evidence suggests a stoichiometry of four H^+ transported per two electrons passed from NADH to UQ.

Electrostatic Interactions Along a Hydrophilic Axis Drive Proton Transport The structure of Complex I is elegantly suited to its biological function. This multi-subunit complex consists of a large hydrophilic domain extending into the mitochondrial matrix (termed the peripheral arm-PA, Figure 20.5a) and a large hydrophobic domain in the inner mitochondrial membrane (the membrane domain-MD). The core of this structure is composed of 14 subunits, plus a varying number of so-called

Human Biochemistry

Solving a Medical Mystery Revolutionized Our Treatment of Parkinson's Disease

A tragedy among illegal drug users was the impetus for a revolutionary treatment of Parkinson's disease. In 1982, several mysterious cases of paralysis came to light in southern California. The victims, some of them teenagers, were frozen like living statues, unable to talk or move. The case was baffling at first, but it was soon traced to a batch of synthetic heroin that contained MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) as a contaminant. MPTP is rapidly converted in the brain to MPP^+ (1-methyl-4-phenylpyridine) by

the enzyme monoamine oxidase B. MPP^+ is a potent inhibitor of mitochondrial Complex I (NADH–UQ reductase), and it acts preferentially in the *substantia nigra*, an area of the brain that is essential to movement and also the region of the brain that deteriorates slowly in Parkinson's disease.

Parkinson's disease results from the inability of the brain to produce sufficient quantities of dopamine, a neurotransmitter. Neurologist J. William Langston, asked to consult on the treatment of some of these patients, recognized that the symptoms of this drug-induced disorder were in fact similar to those of parkinsonism. He began treatment of the patients with L-dopa, which is decarboxylated in the brain to produce dopamine. The treated patients immediately regained movement. Langston then took a bold step. He implanted fetal brain tissue into the brains of several of the affected patients, prompting substantial recovery from the Parkinson's-like symptoms. Langston's innovation sparked a revolution in the use of tissue implantation for the treatment of neurodegenerative diseases.

Other toxins may cause similar effects in neural tissue. Timothy Greenamyre at Emory University has shown that rats exposed to the pesticide rotenone (see Figure 20.26) over a period of weeks experience a gradual loss of function in dopaminergic neurons and then develop symptoms of parkinsonism, including limb tremors and rigidity. This finding supports earlier research that links long-term pesticide exposure to Parkinson's disease.

“supernumerary” subunits, for example 31 in mammals, that contribute to assembly, stability or regulation, or fulfill independent metabolic roles. These subunits are essentially identical in all species that have them (Figure 20.5b). The hydrophilic domain is essentially a superhighway for electrons, from the FMN cofactor site through a chain of seven Fe-S clusters that extends approximately 95 Å through the protein to a UQ site deep in the membrane (Figure 20.5a). Electronic structure calculations by Tomoyuki Hayashi and Alexei Stuchebrukhov have shown that electron transfer between the redox centers in Complex I occurs by quantum mechanical tunneling. (See Section 14.5 for a discussion of quantum mechanical tunneling.) The distance from one redox center to the next in Complex I is roughly 1 nm. All redox centers of the enzyme except the UQ site are located outside the membrane domain. Therefore, in contrast to other proton-pumping respiratory complexes, the redox centers of Complex I cannot participate directly in proton translocation. The highly hydrophobic ubiquinone fits into a narrow channel at the junction between the peripheral arm (PA) and the membrane domain (MD).

The membrane domain contains a novel feature, rarely found in other membrane proteins—a highly hydrated central axis containing 23 hydrophilic residues (8 Lys, 7 Glu, 2 Asp, and 6 His) (Figure 20.5a). High resolution cryo-EM studies have identified about 90 water molecules in this central axis within 6 Å of the hydrophilic residues. Leonid Sazanov and others have postulated that these waters and hydrophilic residues are involved in the pumping of protons across Complex I from the mitochondrial matrix to the intermembrane space.

A crevice in subunit ND1, termed the E-channel, connects the site of ubiquinone reduction to the first putative proton pump, consisting of subunits ND1, ND3, ND6, and ND4L. The other three likely proton channels are located in subunits ND2, ND4, and ND5. These latter three are homologous to a well-characterized class of antiporter channel proteins and are thus termed the antiporter subunits of Complex I. To drive proton pumping, the energy released during ubiquinone reduction is converted into

conformational changes in the proton channel subunits. Different conceptual schemes have been proposed, but all these models involve a wave of electrostatic interactions propagating from the ubiquinone site to the proton pumping channels. These interactions are presumed to involve reversible protonation of the hydrophilic residues and water molecules in the central axis.

20.2c Complex II Oxidizes Succinate and Reduces Coenzyme Q

Complex II is perhaps better known by its other name—succinate dehydrogenase, the only TCA cycle enzyme that is an integral membrane protein in the inner mitochondrial membrane. This complex (Figure 20.6) has a mass of 124 kDa and is

Figure 20.6 Complex II of the electron transport pathway. (a) A scheme for electron flow in Complex II. Oxidation of succinate occurs with reduction of [FAD]. Electrons are then passed to Fe-S centers and then to coenzyme Q (UQ). Proton transport does not occur in this complex. (b) The structure of Complex II from pig heart (PDB id = 1ZOY). (c) The arrangement of redox centers. Electron flow is from bottom to top.

composed of two hydrophilic subunits, (a flavoprotein (Fp, 68 kDa) and an iron–sulfur protein (Ip, 29 kDa)) and two hydrophobic, membrane-anchored subunits (15 kDa and 11 kDa), which contain one heme *b* and provide the binding site for UQ. Fp contains an FAD covalently bound to a His residue (see Figure 19.12), and Ip contains three Fe-S centers: a 4Fe-4S cluster, a 3Fe-4S cluster, and a 2Fe-2S cluster. When succinate is converted to fumarate in the TCA cycle, concomitant reduction of bound [FAD] to [FADH₂] occurs in succinate dehydrogenase. This [FADH₂] transfers its electrons immediately to Fe-S centers, which pass them on to UQ. Electron flow from succinate to UQ:

This yields a net reduction potential of 0.029 V. (Note that the first half-reaction is written in the direction of the e^- flow. As always, $\Delta \mathcal{E}_o'$ is calculated according to Equation 3.23.) The small free energy change of this reaction does not contribute to the transport of protons across the inner mitochondrial membrane.

This is a crucial point because proton transport is coupled with ATP synthesis. Oxidation of one [FADH₂] in the electron-transport chain results in synthesis of approximately two molecules of ATP, compared with the approximately three ATPs produced by the oxidation of one NADH. Other flavoproteins can also supply electrons to UQ, including mitochondrial *sn*-glycerophosphate dehydrogenase, an inner membrane-bound shuttle enzyme, and the fatty acyl-CoA dehydrogenases, three soluble matrix enzymes involved in fatty acid oxidation (Figure 20.7). The path of electrons from succinate to UQ is shown in Figure 20.6.

20.2d Complex III Mediates Electron Transport from Coenzyme Q to Cytochrome *c*

In Complex III of the electron-transport chain, reduced coenzyme Q (UQH₂) passes its electrons to cytochrome *c* via a unique redox pathway known as the **Q cycle**. Referring to the reaction it catalyzes, Complex III is called UQ–cytochrome *c* reductase (UQ–cyt *c* reductase), and it involves three different cytochromes and an Fe-S protein. In the cytochromes of these and similar complexes, the iron atom at the center of the porphyrin ring cycles between the reduced Fe²⁺ (ferrous) and oxidized Fe³⁺ (ferric) states.

Cytochromes were first named and classified on the basis of their absorption spectra (Figure 20.8), which depend upon the structure and environment of their heme groups. The ***b* cytochromes** contain *iron protoporphyrin IX* (Figure 20.9), the same heme found in hemoglobin and myoglobin. The ***c* cytochromes** contain *heme c*, derived from iron protoporphyrin IX by the covalent attachment to cysteine residues from the associated protein. (One other heme variation, heme *a*, is found in **cytochrome *a***, a component of Complex IV of the electron transport chain. Heme *a* contains a 15-carbon isoprenoid chain on a modified vinyl group and a formyl group in place of one of the

methylys [see Figure 20.9].) UQ-cyt *c* reductase (Figure 20.10) contains a *b*-type cytochrome, of 30 to 40 kDa, with two different heme sites and one *c*-type cytochrome. The two hemes on the *b* cytochrome polypeptide in UQ-cyt *c* reductase are distinguished by their reduction potentials and the wavelength ($\lambda_{\max}$) of the so-called α -band. One of these hemes, known as b_L or b_{566} , has a standard reduction potential, $\mathcal{E}_o'$, of -0.100 V and a wavelength of maximal absorbance ($\lambda_{\max}$) of 566 nm. The other, known as b_H or b_{562} , has a standard reduction potential of $+0.050$ V and a $\lambda_{\max}$ of 562 nm. (*H* and *L* here refer to high and low reduction potential.)

The structure of the UQ-cyt *c* reductase, also known as the **cytochrome *bc*₁ complex**, was determined by Johann Deisenhofer and his colleagues. (Deisenhofer was a co-recipient of the Nobel Prize in Chemistry for his work on the structure of a

photosynthetic reaction center). The complex is a dimer, with each monomer consisting of 11 protein subunits and 2165 amino acid residues (monomer mass, 248 kDa). Each monomer consists of three domains: a large domain that extends 75 Å into the mitochondrial matrix, a transmembrane domain consisting of 13 transmembrane α -helices in each monomer, and a small domain that extends 38 Å into the intermembrane space (Figure 20.10). Most of the *Rieske protein* (an Fe-S protein named for its discoverer) is mobile in the crystal (only 62 of its 196 residues are shown in the structure in Figure 20.10), and Deisenhofer has postulated that mobility of this subunit could be required for electron transfer in the function of this complex.

Complex III Drives Proton Transport As with Complex I, passage of electrons through the Q cycle of Complex III is accompanied by proton transport across the inner mitochondrial membrane. The postulated pathway for electrons in this system is shown in Figure 20.11. A large pool of UQ and UQH₂ exists in the inner mitochondrial membrane. The Q cycle is initiated when a molecule of UQH₂ from this pool diffuses to a site (called Q_p) on Complex III near the cytosolic face of the membrane.

Oxidation of this UQH₂ occurs in two steps (Figure 20.11a). First, an electron from UQH₂ is transferred to the Rieske protein and then to cytochrome *c*₁. This releases two H⁺ to the cytosol and leaves UQ • ⁻, a semiquinone anion form of UQ, at the Q_p site. The second electron is then transferred to the b_L heme, converting UQ • ⁻ to UQ. The Rieske protein and cytochrome *c*₁ are similar in structure; each has a globular domain and is anchored to the inner mitochondrial membrane by a hydrophobic segment. However, the hydrophobic segment is N-terminal in the Rieske protein and C-terminal in cytochrome *c*₁.

(a) First half of Q cycle

(b) Second half of Q cycle

Figure 20.11 The Q cycle in mitochondria. **(a)** The electron-transfer pathway following oxidation of the first UQH₂ at the Q_p site near the cytosolic face of the membrane. **(b)** The pathway following oxidation of a second UQH₂.

Figure 20.12 The structure of mitochondrial cytochrome *c*. The heme is shown at the center of the structure. It is covalently linked to the protein via two sulfur atoms. A third sulfur from a methionine residue coordinates the iron (PDB id = 2B4Z).

Figure 20.13 Bovine cytochrome *c* oxidase consists of 13 subunits. The 3 largest subunits (shown here)—I (purple), II (yellow), and III (blue)—contain the proton channels and the redox centers (PDB id = 2EIJ).

The electron on the b_L heme facing the cytosolic side of the membrane is now passed to the b_H heme on the matrix side of the membrane. This electron transfer occurs against a membrane potential of 0.15 V and is driven by the loss of redox potential as the electron moves from b_L ($\mathcal{E}_o' = -0.100$ V) to b_H ($\mathcal{E}_o' = +0.050$ V). The electron is then passed from b_H to a molecule of UQ at a second quinone-binding site, Q_n , converting this UQ to $UQ \cdot^-$. The resulting $UQ \cdot^-$ remains firmly bound to the Q_n site. This completes the first half of the Q cycle (Figure 20.11a).

The second half of the cycle (Figure 20.11b) is similar to the first half, with a second molecule of UQH_2 oxidized at the Q_p site, one electron being passed to cytochrome c_1 and the other transferred to heme b_L and then to heme b_H . In this latter half of the Q cycle, however, the b_H electron is transferred to the semiquinone anion, $UQ \cdot^-$, at the Q_n site. With the addition of two H^+ from the mitochondrial matrix, this produces a molecule of UQH_2 , which is released from the Q_n site and returns to the coenzyme Q pool, completing the Q cycle. Thus, two UQH_2 are taken from the UQ/UQH_2 pool and one is returned; the Q cycle accomplishes the net oxidation of one UQH_2 .

The Q Cycle Is an Unbalanced Proton Pump Why has nature chosen this rather convoluted path for electrons in Complex III? First of all, Complex III takes up two protons on the matrix side of the inner membrane and releases four protons on the cytoplasmic side for each pair of electrons that passes through the Q cycle. Thus, it is referred to as an unbalanced proton pump. The other significant feature of this mechanism is that it offers a convenient way for a two-electron carrier, UQH_2 , to interact with the b_L and b_H hemes, the Rieske protein Fe-S cluster, and cytochrome c_1 , all of which are one-electron carriers.

Cytochrome *c* Is a Mobile Electron Carrier Electrons traversing Complex III are passed through cytochrome c_1 to **cytochrome *c***. Cytochrome *c* is the only one of the mitochondrial cytochromes that is water soluble. Its structure (Figure 20.12) is globular; the planar heme group lies near the center of the protein, surrounded predominantly by hydrophobic amino acid residues. The iron in the porphyrin ring is coordinated both to a histidine nitrogen and to the sulfur atom of a methionine residue. Coordination with ligands in this manner on both sides of the porphyrin plane precludes the binding of oxygen and other ligands, a feature that distinguishes cytochrome *c* from hemoglobin (see Chapter 15).

Cytochrome *c*, like UQ, is a mobile electron carrier. It associates loosely with the inner mitochondrial membrane (in the intermembrane space on the cytosolic side of the inner membrane) to acquire electrons from the Fe-S–cyt c_1 aggregate of Complex III, and then it migrates along the membrane surface in the reduced state, carrying electrons to cytochrome *c* oxidase, the fourth complex of the electron-transport chain.

20.2e Complex IV Transfers Electrons from Cytochrome *c* to Reduce Oxygen on the Matrix Side

Complex IV is called cytochrome *c* oxidase because it accepts electrons from cytochrome *c* and directs them to the four-electron reduction of O_2 to form H_2O :

Thus, cytochrome *c* oxidase and O_2 are the final destination for the electrons derived from the oxidation of food materials. In concert with this process, cytochrome *c* oxidase also drives transport of protons across the inner mitochondrial membrane. The combined processes of oxygen reduction and proton transport involve a total of $8H^+$ in each catalytic cycle—four H^+ for O_2 reduction and four H^+ transported from the matrix to the intermembrane space.

The total number of subunits in cytochrome *c* oxidase varies from 2 to 4 (in bacteria) to 13 (in mammals). Three subunits (I, II, and III) are common to most organisms (Figure 20.13). This minimal complex, which contains two hemes (termed a and a_3) and three copper ions (two in the Cu_A center and one in the Cu_B site), is sufficient to carry out both oxygen reduction and proton transport.

The total mass of the protein in mammalian Complex IV is 204 kDa. All 13 subunits are shown in Figure 20.14. In mammals, subunits I through III, the largest ones, are encoded by mitochondrial DNA, synthesized in the mitochondrion, and inserted into the inner membrane from the matrix side. The 10 smaller subunits are coded by nuclear DNA, are synthesized in the cytosol, and are presumed to play regulatory roles in the complex.

In the bovine structure, subunit I is cylindrical in shape and consists of 12 transmembrane helices, without any significant extramembrane parts. Hemes a and a_3 , which lie perpendicular to the membrane plane, and Cu_B are cradled by the helices of subunit I (Figure 20.15). Subunits II and III lie on opposite sides of subunit I and do not contact each other (see Figure 20.13). Subunit II has an extramembrane domain on the outer face of the inner mitochondrial membrane. This domain consists of a 10-strand β -barrel that holds the two copper ions of the Cu_A site 7 Å from the nearest surface atom of the subunit. Subunit III consists of seven transmembrane helices with no significant extramembrane domains.

Figure 20.14 The complete structure of bovine cytochrome c oxidase. The 3 largest subunits—I (purple), II (yellow), and III (blue)—contain the proton channels and the redox centers. (PDB id = 2EIJ).

Electron Transfer in Complex IV Involves Two Hemes and Two Copper Sites Electron transfer through Complex IV begins with binding of cytochrome c to the β -barrel of subunit II. Four electrons are transferred sequentially (one each from four molecules of cytochrome c) first to the Cu_A center, next to heme a , and finally to the Cu_B /heme a_3 active site, where O_2 is reduced to H_2O (Figure 20.15):

The Cu_A site (Figure 20.16a) is the entry point for electrons from cytochrome c . It lies in a hydrophobic patch on subunit II, surrounded by a ring of negatively charged Asp and Glu residues. Electrons flow rapidly from Cu_A to heme a , which is coordinated by a pair of His residues (Figure 20.16b), and then to the Cu_B /heme a_3 complex. The Fe atom in heme a_3 is five coordinate (Figure 20.16c), with four ligands from the

Figure 20.15 The electron-transfer pathway for cytochrome oxidase. Cytochrome c binds on the cytosolic side, transferring electrons through the copper and heme centers to reduce O_2 on the matrix side of the membrane (PDB id = 2EIJ).

Figure 20.16 Structures of the redox centers of bovine cytochrome *c* oxidase. **(a)** The Cu_A site, **(b)** the heme *a* site, and **(c)** the binuclear Cu_B/heme *a*₃ site (PDB id = 2EIJ).

heme plane and one from His³⁷⁶. This leaves a sixth position free, and this is the catalytic site where O₂ binds and is reduced. Cu_B is about 5 Å from the Fe atom of heme *a*₃ and is coordinated by three histidine ligands, including His²⁴⁰, His²⁹⁰, and His²⁹¹ (Figure 20.16c). An unusual crosslink between His²⁴⁰ and Tyr²⁴⁴ lowers the p*K*_a of the Tyr hydroxyl so that it can participate in proton transport across the membrane.

20.2f Proton Transport Across Cytochrome *c* Oxidase Is Coupled to Oxygen Reduction

Proton transport in *Rhodobacter sphaeroides* cytochrome *c* oxidase takes place via two channels denoted the D- and K-pathways (Figure 20.17a). Both these channels contain water molecules, and they are lined with polar residues that can either protonate and deprotonate or form hydrogen bonds. The D-pathway is named for Asp¹³² at the channel opening, and the K-pathway is named for Lys³⁶², a critical residue located midway in the channel. These two channels converge at the binuclear Cu_B/heme *a*₃ site

Figure 20.17 The proton channels of cytochrome *c* oxidase from *R. sphaeroides*. **(a)** Functional residues in the D- and K-pathways are indicated. The shaded D- and K-pathways converge at the Cu_B/heme *a*₃ center. The proton exit channel is lined by residues 320 to 340 of subunit I (PDB id = 1M56). **(b)** Protons are presumed to hop along arrays of water molecules in the proton transport channels of cytochrome *c* oxidase. Two steps in the hopping model are shown. Such a chain of protonation and deprotonation events means that the proton eventually released from the exit channel is far removed from the proton that entered the D-pathway and initiated the cascade.

midway across the complex and the membrane. Here, Glu²⁸⁶ serves as a branch point, shuttling protons either to the catalytic site for O₂ reduction (to form H₂O) or to the exit channel (residues 320 to 340) that leads protons to the intermembrane space (Figure 20.17a). In each catalytic cycle, two H⁺ pass through the K-pathway and six H⁺ traverse the D-pathway. The K-pathway protons and two of the D-pathway protons participate in the reduction of one O₂ to two H₂O, and the remaining four D-pathway protons are passed across the membrane and released to the intermembrane space.

How are protons driven across cytochrome *c* oxidase? The mechanism involves three key features:

- The p*K*_a values of protein side chains in the proton channels are shifted (by the local environment) to make them effective proton donors or acceptors during transport. For example, the p*K*_a of Glu²⁸⁶ is unusually high at 9.4. (This is similar to the behavior of Asp⁸⁵ and Asp⁹⁶ in bacteriorhodopsin; see Figure 9.58.)
- Electron-transfer events induce conformation changes that control proton transport. For example, redox events at the Cu_B/heme *a*₃ site are sensed by Glu²⁸⁶ and an adjacent proton-gating loop (residues 169 to 175), controlling H⁺ binding and release by Glu²⁸⁶ and proton movement through the exit channel.
- Protons are transported via chains of hydrogen-bonded water molecules in the proton channels (Figure 20.17b). Sequential hopping of protons along these proton wires essentially transfers a positive charge between distant residues in the channel. (Note that the H⁺ that arrives at an accepting residue is not the same proton that left the donating residue.)

20.2g Reversal of Complex II May Short-Circuit the Electron Transfer Pathway

Oxygen produced by Complex IV is usually the terminal acceptor of electrons in the electron transport pathway. However, in certain tissues and especially when oxygen is limiting, fumarate may act as an alternate terminal electron acceptor via reversal of Complex II. Fumarate reduction to succinate by such a reversal has been observed under low-oxygen conditions in multiple tissues, but kidney, liver, and brain show constitutive production of succinate from fumarate regardless of oxygen availability. Reversal of Complex II in this way may allow tissues to cope with reductive stress—a condition in which flow of electrons through the electron transport pathway may exceed the capacity of the pathway to reduce oxygen.

20.2h The Complexes of Electron Transport May Function as Supercomplexes

For many years, the complexes of the electron-transport chain were thought to exist and function independently in the mitochondrial inner membrane because each complex could be isolated in a pure yet functional state. Growing experimental evidence, however, supports the existence of multimeric **supercomplexes** of the four electron-transport complexes. These supercomplexes, also known as **respirasomes**, may represent functional states, and association of two or more of the individual complexes may be advantageous for the organism. Supercomplexes can be identified by single particle electron microscopy, and kinetic measurements support the operation of the respiratory chain as one functional unit. Mutation studies show that Complex III is required to maintain Complex I in the mitochondria of human and mouse cells in culture, and Complex IV is necessary for proper assembly of Complex I in mouse fibroblasts.

As shown in Figure 20.18, the CI₂III₂IV₂ supercomplex (containing two units each of Complexes I, III, and IV) forms a circular structure with the dimeric CIII located in the center, where it is surrounded by two copies each of CI and CIV. Two cytochrome *c* (Cyt.*c*) molecules are positioned to accept electrons on the surface of the CIII dimer.

Substantial evidence points to a requirement for cardiolipin (see Figure 8.6) in the assembly and stability of mitochondrial supercomplexes. For example, association of Complexes III and IV requires the presence of cardiolipin. Studies by Carola

Figure 20.18 The complexes of the electron transport chain operate as supercomplexes in the inner mitochondrial membrane. **(a)** Cryo-EM images of a supercomplex formed from two units each of Complex I, Complex III, and Complex IV. The structure is shown in three differently rotated views (left, side view along the inner membrane; right, top view from the matrix side; bottom, bottom view from the intermembrane side). The transmembrane region is indicated by two dashed lines. M, matrix; IM, inner membrane; IMS, intermembrane space. The cofactors are shown in spheres. **(b)** A model for the electron-transport pathway in the mitochondrial inner membrane. UQ/UQH₂ and cytochrome *c* are mobile electron carriers and function by transferring electrons between the complexes. The proton transport driven by Complexes I, III, and IV is indicated. (Images in part a adapted from Gou, R., Zong, S., Wu, M. et al., 2017. Architecture of human mitochondrial respiratory megacomplex I₂III₂IV₂. *Cell* **170**:1247–1257. Images kindly provided by Maojun Yang.)

Hunte and colleagues show that cardiolipin stabilizes supercomplexes by neutralizing the charges of lysine residues at the binding interface between Complex III and Complex IV.

The Model of Electron Transport Is a Dynamic One The model that emerges for electron transport is shown in Figure 20.18b. Coenzyme Q collects electrons from NADH–UQ reductase and succinate–UQ reductase and delivers them (by diffusion through the membrane core) to UQ–cyt *c* reductase. Cytochrome *c* is water soluble and moves freely in the intermembrane space, carrying electrons from UQ–cyt *c* reductase to cytochrome *c* oxidase. In the process of these electron transfers, protons are driven across the inner membrane (from the matrix side to the intermembrane space). The proton gradient generated by electron transport represents an enormous source of potential energy. As seen in the next section, this potential energy is used to synthesize ATP as protons flow back into the matrix.

20.2i Electron Transfer Energy Stored in a Proton Gradient: The Mitchell Hypothesis

In 1961, Peter Mitchell, a British biochemist, proposed that the energy stored in a proton gradient across the inner mitochondrial membrane by electron transport drives the synthesis of ATP in cells. The proposal became known as **Mitchell's chemiosmotic hypothesis**. In this hypothesis, protons are driven across the membrane from the matrix to the intermembrane space and cytosol by the events of electron transport. This mechanism stores the energy of electron transport in an electrochemical potential. As protons are driven out of the matrix, the pH rises and the matrix becomes negatively charged with respect to the cytosol (Figure 20.19). Electron transport-driven proton pumping thus creates a pH gradient and an electrical gradient across the inner membrane, both of which tend to attract protons back into the matrix from the cytoplasm. Flow of protons down this electrochemical gradient, an energetically favorable process, drives the synthesis of ATP.

Figure 20.19 The proton and electrochemical gradients existing across the inner mitochondrial membrane. The electrochemical gradient is generated by the transport of protons across the membrane by Complexes I, III, and IV in the inner mitochondrial membrane.

The ratio of protons transported per pair of electrons passed through the chain—the so-called $\text{H}^+/\text{2e}^-$ ratio—has been an object of great interest for many years. Nevertheless, the ratio has remained extremely difficult to determine. The consensus estimate for the electron-transport pathway from succinate to O_2 is $6\text{H}^+/\text{2e}^-$. The ratio for Complex I by itself remains uncertain, but recent best estimates place it as high as $4\text{H}^+/\text{2e}^-$. On the basis of this value, the stoichiometry of transport for the pathway from NADH to O_2 is $10\text{H}^+/\text{2e}^-$. Although this is the value assumed in Figure 20.18, it is important to realize that this value is tentative and represents a consensus drawn from many experiments.

20.3 | What Are the Thermodynamic Implications of Chemiosmotic Coupling?

Mitchell's chemiosmotic hypothesis revolutionized our thinking about the energy coupling that drives ATP synthesis by means of an electrochemical gradient. How much energy is stored in this electrochemical gradient? For the transmembrane flow of protons across the inner membrane (from inside [matrix] to outside), we could write

The free energy difference for protons across the inner mitochondrial membrane includes a term for the concentration difference and a term for the electrical potential. This is expressed as

$$\Delta G = RT \ln \frac{[c_2]}{[c_1]} + Z\mathcal{F}\Delta\psi \quad (20.12)$$

where c_1 and c_2 are the proton concentrations on the two sides of the membrane, Z is the charge on a proton, $\mathcal{F}$ is Faraday's constant, and $\Delta\psi$ is the potential difference across the membrane. For the case at hand, this equation becomes

$$\Delta G = RT \ln \frac{[\text{H}^+]_{\text{out}}}{[\text{H}^+]_{\text{in}}} + Z\mathcal{F}\Delta\psi \quad (20.13)$$

In terms of the matrix and cytoplasm pH values, the free energy difference is

$$\Delta G = -2.303 RT(\text{pH}_{\text{out}} - \text{pH}_{\text{in}}) + \mathcal{F}\Delta\psi \quad (20.14)$$

Reported values for $\Delta\psi$ and ΔpH vary, but the membrane potential is always found to be positive outside and negative inside, and the pH is always more acidic outside and more basic inside. Taking typical values of $\Delta\psi = 0.18 \text{ V}$ and $\Delta\text{pH} = 1$ unit, the free energy change associated with the movement of one mole of protons from inside to outside is

$$\Delta G = 2.3 RT + \mathcal{F}(0.18 \text{ V}) \quad (20.15)$$

With $\mathcal{F} = 96.485 \text{ kJ/V} \cdot \text{mol}$, the value of ΔG at 37°C is

$$\Delta G = 5.9 \text{ kJ} + 17.4 \text{ kJ} = 23.3 \text{ kJ} \quad (20.16)$$

which is the free energy change for movement of a mole of protons across an inner membrane. Note that the free energy terms for both the pH difference and the potential difference are unfavorable for the outward transport of protons, with the latter term making the greater contribution. On the other hand, the ΔG for inward flow of protons is -23.3 kJ/mol . It is this energy that drives the synthesis of ATP, in accord with Mitchell's model. Peter Mitchell was awarded the Nobel Prize in Chemistry in 1978.

20.4 | How Does a Proton Gradient Drive the Synthesis of ATP?

The great French chemist Antoine Lavoisier showed in 1777 that foods undergo combustion in the body. Since then, chemists and biochemists have wondered how energy from food oxidation is captured by living things. Mitchell paved the way by

suggesting that a proton gradient across the inner mitochondrial membrane could drive the synthesis of ATP. But how could the proton gradient be coupled to ATP production? The answer lies in a mitochondrial complex called F_1F_0 -ATP synthase, or sometimes F_1F_0 -ATPase (for the reverse reaction it catalyzes). The F_1 portion of the ATP synthase was first identified in early electron micrographs of mitochondrial preparations as spherical, 8.5 nm projections or particles on the inner membrane. The purified particles catalyze ATP hydrolysis, the reverse reaction of the ATP synthase. Stripped of these particles, the membranes can still carry out electron transfer but cannot synthesize ATP. In one of the first reconstitution experiments with membrane proteins, Efraim Racker showed that adding the particles back to stripped membranes restored electron transfer-dependent ATP synthesis.

20.4a ATP Synthase Is Composed of F_1 and F_0 Complexes

ATP synthase is a remarkable molecular machine. It is an enzyme, a proton pump, and a rotating molecular motor. Nearly all the ATP that fuels our cellular processes is made by this multifaceted molecular superstar. The spheres observed in electron micrographs make up the **F_1 unit**, which catalyzes ATP synthesis (Figure 20.20a, b). These F_1 spheres are attached to an integral membrane protein aggregate called the **F_0 unit**. F_1 consists of five polypeptide chains named α , β , γ , δ , and ϵ , with a subunit

*The number of *c*-subunits varies among organisms: bovine mitochondria, 8; yeast mitochondria and *E. coli*, 10; *llyobacter tartaricus*, 11; spinach chloroplasts, 14; *Spirulina platensis*, 15.
†The subunit nomenclature can be confusing. *E. coli* ATP synthase lacks a δ-subunit in its rotor; its δ-subunit is analogous structurally and functionally to the mitochondrial OSCP. Similarly, subunit F6 in the bovine ATP synthase is weakly homologous to subunit h in yeast.

Figure 20.21 Two views of the F₁ unit of the F₁F₀-ATP synthase. **(a)** An axial view of the F₁ unit of the F₁F₀-ATP synthase, showing alternating α- and β-subunits in a hexameric array, with the γ-subunit (purple) visible in the center of the structure. **(b)** A side view of the F₁ unit, with one α-subunit and one β-subunit removed to show how the γ-subunit (red) extends through the center of the α₃β₃ hexamer. Also shown are the δ-subunit (aqua) and the ε-subunit (pink), which link the γ-subunit to the F₀ unit (PDB id = 1E79).

stoichiometry α₃β₃γδϵ (Table 20.2 and Figure 20.21). F₀ includes 12 different subunits denoted as *a*, *b*, *c*, *d*, *e*, *f*, *g*, F₆, 6.8pl, OSCP, DAPIT, and ATP8. F₀ forms the trans-membrane pore or channel through which protons move to drive ATP synthesis. The F₀ structures in prokaryotic organisms and plants have 10 to 15 *c*-subunits, whereas *c*-rings of only 8 subunits are found in the F₀ structures of vertebrates and all or most invertebrates (Table 20.2).

All of the subunits of F₀ except *c* form part of the **stator**—a stationary component anchored in the membrane—and a ring of 8 to 15 *c*-subunits (see Table 20.3) constitutes a major component of the **rotor** of the motor. Protons flowing through the *a*–*c* complex cause the *c*-ring to rotate in the membrane. Each *c*-subunit is a folded pair of α-helices joined by a short loop, whereas the *a*-subunit is composed of a cluster of α-helices. The *b*-subunit, together with the *d*- and F₆-subunits and the oligomycin sensitivity-conferring protein (OSCP), form a long, slender **peripheral stalk (PS)** that connects F₀ in the membrane with F₁, which extends out into the matrix. The *b*-, *d*-, and F₆-subunits form long α-helical segments that comprise the stalk, and OSCP adds a helical bundle cap that sits at the top of an α-subunit of F₁ (Figure 20.20). The stalk is a stable link between F₀ and F₁, essentially joining the two, both structurally and functionally.

Structural accommodations in the mitochondrial membrane suit different numbers of subunits in the circular ring of *c*-subunits. Nobelist John Walker and colleagues have shown that Lys⁴³ of the *c*-subunits in bovine mitochondria are completely trimethylated, forming a bulky quaternary amino group on each subunit, adjacent to the phospholipid headgroups of the inner membrane. This bulky group would clash with phospholipid headgroups, but Walker has postulated that cardiolipin, which is essential to ATP synthase activity and which contains two phosphatidylglycerol groups but no headgroup, can accommodate the trimethylamino groups and link adjacent *c*-subunits in the relatively small 8-subunit *c*-ring. No organism with *c*-rings of more than 8 subunits are trimethylated at Lys⁴³.

The ATP synthase assembles into V-shaped dimers in the mitochondrial inner membrane (Figure 20.20c). Long ribbons of these dimers bend the mitochondrial inner membrane and form folds or cristae, the highly folded membrane structures that maximize the surface area available for respiration and ATP formation.

20.4b The Catalytic Sites of ATP Synthase Adopt Three Different Conformations

The α - and β -subunits of the F_1 structure are similar, each consisting of an N-terminal domain with six β -strands, a central nucleotide-binding domain made of both α -helices and β -strands, and an α -helical C-terminal domain containing six α -helices in the β -subunits and seven in the α -subunits. The F_1 structure appears at first to be a symmetric hexamer of α - and β -subunits. However, it is asymmetric in several ways. The α - and β -subunits, arranged in an alternating pattern in the hexamer, are similar but not identical. The hexamer contains six ATP-binding sites, each of them arranged at the interface of adjacent subunits. Three of these, each located mostly on a β -subunit but with some residues contributed by an α -subunit, are catalytic sites for ATP synthesis. The other three, each located mostly on an α -subunit but with residues contributed by a β -subunit, are noncatalytic and inactive. The noncatalytic α -sites have similar structures. Significantly, the single γ -subunit of F_1 introduces asymmetry to the $\alpha_3\beta_3$ hexamer that forces *the three catalytic β -sites to have three quite different conformations*. In the crystal structure first characterized by John Walker, one of the β -subunit ATP sites contains AMP-PNP (a nonhydrolyzable analog of ATP), another contains ADP, and the third site is empty.

β , γ -Imidoadenosine 5'-triphosphate (AMP-PNP)

Walker's work provided structural verification for a novel hypothesis first advanced by Paul Boyer, the **binding change mechanism** for ATP synthesis. Walker and Boyer, whose efforts provided complementary insights into the workings of this molecular motor, shared in the Nobel Prize for Chemistry in 1997.

20.4c Boyer's ^{18}O Exchange Experiment Identified the Energy-Requiring Step

The elegant studies by Boyer of ^{18}O exchange in ATP synthase provided important insights into the mechanism of the enzyme. Boyer and his colleagues studied the ability of the synthase to incorporate labeled oxygen from H_2^{18}O into P_i . This reaction (Figure 20.22) occurs via synthesis of ATP from ADP and P_i , followed by hydrolysis of ATP with incorporation of oxygen atoms from the solvent. Although net production of ATP requires coupling with a proton gradient, Boyer observed that this exchange reaction occurs readily, even in the absence of a proton gradient. The exchange reaction was so efficient that, eventually, all four oxygens of phosphate were labeled with ^{18}O . This important

In the absence of a proton gradient:

Figure 20.22 ATP–ADP exchange in the absence of a proton gradient. Exchange leads to incorporation of ^{18}O in phosphate as shown. Boyer's experiments showed that ^{18}O could be incorporated into all four positions of phosphate, demonstrating that the free energy change for ATP formation from enzyme-bound ADP + P_i is close to zero. (From Parsons, D. F., 1963. *Science* **140**:985.)

observation indicated that the formation of enzyme-bound ATP does not require energy. The experiments that followed, by Boyer, Harvey Penefsky, and others, showed clearly that the energy-requiring step in the ATP synthase was actually the release of newly synthesized ATP from the enzyme (Figure 20.23). Eventually, it would be shown that flow of protons through F_0 drives the enzyme conformational changes that result in the binding of substrates on ATP synthase, ATP synthesis, and the release of products.

20.4d The Binding Change Mechanism Describes the Events of Rotational Catalysis

Boyer proposed that these conformational changes occurred in a rotating fashion. His rotational catalysis model, the binding change mechanism (Figure 20.23), suggested that at any instant the three β subunits of F_1 existed in three different conformations, that these different states represented the three steps of ATP synthesis, and that each site stepped through the three states to make ATP. A site beginning with ADP and phosphate bound (the first state) would synthesize ATP (producing the second state) and then release ATP, leaving an empty site (the third state). In the binding change mechanism, the three catalytic sites thus cycle concertedly through the three intermediate states of ATP synthesis.

20.4e Proton Flow Through F_0 Drives Rotation of the Motor and Synthesis of ATP

How might the cycling proposed by Boyer's binding change mechanism occur? Important clues have emerged from several experiments that show that the γ -subunit rotates with respect to the $\alpha\beta$ complex. How such rotation might be linked to transmembrane proton flow and ATP synthesis is shown in Figure 20.24. The ring of c -subunits is a rotor that turns with respect to the a -subunit, a stator component consisting of five transmembrane α -helices with proton access channels on either side of the membrane. The γ -subunit is the link between the functions of F_1 and F_0 . In one complete rotation, the γ -subunit drives conformational changes in each β -subunit that lead to ATP synthesis. Each 360° rotation of the γ -subunit drives each β -subunit through all three conformational states of the binding change mechanism: ATP-bound (T), ADP- and P_i -bound (L), and open (O). Thus, three ATPs are synthesized per turn.

But how does the F_0 complex couple the events of proton transport and ATP synthesis? The a -subunit contains two half-channels, a proton inlet channel that opens to the intermembrane space, and a proton outlet channel that opens to the matrix. The c -subunits are proton carriers that transfer protons from the inlet channel to the outlet channel only by rotation of the c -ring. Each c -subunit contains a protonatable residue, Asp⁶¹. Protons flowing from the intermembrane space through the inlet half-channel protonate the Asp⁶¹ of a passing c -subunit and ride the rotor around the ring until they reach the outlet channel and flow out into the matrix.

The molecular details of this process are shown in Figure 20.24. Each c -subunit in the c -ring has an inner helix and an outer helix. Asp⁶¹ is located midway along the outer α -helix. When protonated, the Asp carboxyl faces into the adjacent subunit. Rotation of the entire outer α -helix exposes Asp⁶¹ to the outside when it is deprotonated. Arg²¹⁰, located midway on a transmembrane helix of the a -subunit, forms hydrogen bonds with Asp⁶¹ residues on two adjacent c -subunits. The half-channels of the a -subunit extend up and down from Arg²¹⁰. The inlet channel terminates in Asn²¹⁴, whereas the outlet channel terminates at Ser²⁰⁶.

Figure 20.23 The binding change mechanism for ATP synthesis by ATP synthase. This model assumes that F_1 has three interacting and conformationally distinct active sites: an open (O) conformation with almost no affinity for ligands, a loose (L) conformation with low affinity for ligands, and a tight (T) conformation with high affinity for ligands. Synthesis of ATP is initiated (step 1) by binding of ADP and P_i to an L site. In the second step, an energy-driven conformational change converts the L site to a T conformation and converts T to O and O to L. In the third step, ATP is synthesized at the T site and released from the O site. Two additional passes through this cycle produce two more ATPs and return the enzyme to its original state.

Figure 20.24 Details of proton transfer between the α -subunit and c -subunits. **(a)** Protons entering the inlet half-channel in the α -subunit are transferred to binding sites on c -subunits. Rotation of the c -ring delivers protons to the outlet half-channel in the α -subunit. Flow of protons through the structure turns the rotor and drives the cycle of conformational changes in β that synthesize ATP. **(b)** Arg²¹⁰ on the α -subunit lies between the end of the inlet half-channel (Asn²¹⁴) and the end of the outlet half-channel (Ser²⁰⁶) (PDB id = 1C17). **(c)** A view looking down into the plane of the membrane. Transported protons flow from the inlet half-channel to Asp⁶¹ residues on the c -ring, around the ring, and then into the outlet half-channel. When Asp⁶¹ is protonated, the outer helix of the c -subunit rotates clockwise to bury the protonated carboxyl group for its trip around the c -ring. Counterclockwise ring rotation then brings another protonated Asp⁶¹ to the α -subunit, where an exiting proton is transferred to the outlet half-channel.

The structure of the *c*-subunit complex is exquisitely suited for proton transport. When a proton enters the *a*-subunit inlet channel and is transferred from *a*-subunit Asn²¹⁴ to *c*-subunit Asp⁶¹, the α -helix of that *c*-subunit rotates clockwise to bury the Asp carboxyl group (Figure 20.24c). Each Asp⁶¹ remains protonated once it leaves the *a*-subunit interface because the hydrophobic environment of the membrane interior makes deprotonation (and charge formation) highly unfavorable. However, when a protonated Asp residue approaches the *a*-subunit outlet channel, the proton is transferred to Ser²⁰⁶ and exits through the outlet channel. The *a*-subunit Arg²¹⁰ side chain orients adjacent Asp⁶¹ groups and promotes transfers of entering protons from *a*-subunit Asn²¹⁴ to Asp⁶¹ and transfers of exiting protons from Asp⁶¹ to *a*-subunit Ser²⁰⁶. Arg²¹⁰, because it is protonated, also prevents direct proton transfer from Asn²¹⁴ to Ser²⁰⁶, which would circumvent ring rotation and motor function.

ATP synthesis occurs in concert with rotation of the *c*-ring, because the γ -subunit is anchored to the rotating *c*-ring and rotates with it. Rotation causes the γ -subunit to turn relative to the three β -subunit nucleotide sites of F₁, changing the conformation of each in sequence, so ADP is first bound, then phosphorylated, then released, according to Boyer's binding change mechanism.

20.4f How Many Protons Are Required to Make an ATP? It Depends on the Organism

The bioenergetic cost of making an ATP varies widely among organisms. In prokarya, chloroplasts, and fungi, ATP synthases have evolved a range of *c*-ring sizes from 10 to 15 subunits. Since one turn of the *c*-ring produces 3 ATP, the cost of making an ATP varies from 3.3 (10/3) to 5 (15/3) protons. On the other hand, evidence indicates that all vertebrates and all or most invertebrates contain *c*-rings with only eight subunits. Thus, the approximately 50,000 vertebrates and two million invertebrates on earth require 8/3 or 2.7 protons to make one ATP. Vertebrate and invertebrate ATP synthases are the most efficient that have been found.

Why might the number of *c* subunits vary? It is logical to assume an inverse relationship between the number of *c* subunits in an organism's F₁F₀-ATP synthase and the strength of the proton-motive force. (Proton-motive force is a term used to describe the free energy difference, ΔG , for protons across a membrane [see equation 20.12].) If the proton-motive force is small, more H⁺ would have to traverse the membrane via the *c*-subunit ring to deliver enough energy to drive ATP synthesis, and of course, if the proton-motive force is large, fewer protons (and fewer *c* subunits) would be needed. The highly evolved human species needs only eight protons to accomplish one turn of the ATP synthase rotor, whereas most other organisms require more than eight.

20.4g The Mitchell Model Has Been Confirmed in a Reconstitution Experiment

When Mitchell first described his chemiosmotic hypothesis in 1961, little evidence existed to support it and it was met with considerable skepticism by the scientific community. Eventually, however, considerable evidence accumulated to support this model. It is now clear that the electron-transport chain generates a proton gradient, and careful measurements have shown that ATP is synthesized when a pH gradient is applied to mitochondria that cannot carry out electron transport. Even more relevant is a simple but crucial experiment reported in 1974 by Efraim Racker and Walther Stoeckenius, which provided specific confirmation of the Mitchell hypothesis. In this experiment, the bovine mitochondrial ATP synthase was reconstituted in simple lipid vesicles with bacteriorhodopsin, a light-driven proton pump from *Halobacterium halobium*. As shown in Figure 20.25, upon illumination, bacteriorhodopsin pumped protons into these vesicles, and the resulting proton gradient was sufficient to drive ATP synthesis by the ATP synthase. Because the only two kinds of proteins present were one that produced a proton gradient and one that used such a gradient to make ATP, this experiment essentially verified Mitchell's chemiosmotic hypothesis.

Figure 20.25 The reconstituted vesicles containing ATP synthase and bacteriorhodopsin used by Stoeckenius and Racker to confirm the Mitchell chemiosmotic hypothesis. (Note that both proteins are in reverse inside-out orientation relative to their normal orientation in biological membranes.)

20.4h Inhibitors of Oxidative Phosphorylation Reveal Insights About the Mechanism

Many details of electron transport and oxidative phosphorylation mechanisms have been gained from studying the effects of particular electron transport and oxidative phosphorylation inhibitors (Figure 20.26). The sites of inhibition by these agents are indicated in Figure 20.27.

Inhibitors of Complexes I, II, and III Block Electron Transport Rotenone is a common insecticide that strongly inhibits the NADH–UQ reductase. Rotenone is obtained from the roots of several species of plants. Indigenous communities from certain parts of the world have made a practice of beating the roots of trees along riverbanks to release rotenone into the water, where it paralyzes fish and makes them easy prey. Amytal and other barbiturates also inhibit Complex I. All these substances appear to inhibit reduction of coenzyme Q and the oxidation of the Fe-S clusters of NADH–UQ reductase.

Cyanide, Azide, and Carbon Monoxide Inhibit Complex IV Complex IV, the cytochrome *c* oxidase, is specifically inhibited by cyanide, azide, and carbon monoxide (Figure 20.27). Cyanide and azide bind tightly to the ferric form of cytochrome *a*₃, whereas

Figure 20.26 The structures of several inhibitors of electron transport and oxidative phosphorylation.

Figure 20.27 The sites of action of several inhibitors of electron transport and/or oxidative phosphorylation.

Dinitrophenol**Dicumarol****Carbonyl cyanide-*p*-trifluoromethoxyphenyl hydrazone**

Figure 20.28 Structures of several uncouplers, molecules that dissipate the proton gradient across the inner mitochondrial membrane and thereby destroy the tight coupling between electron transport and the ATP synthase reaction.

(a) Dinitrophenol; (b) Dicumarol; (c) Carbonyl cyanide-*p*-trifluoromethoxyphenyl hydrazone—best known as FCCP; for Fluoro carbonyl cyanide phenylhydrazone.

carbon monoxide binds only to the ferrous form. The inhibitory actions of cyanide and azide at this site are very potent, whereas the principal toxicity of carbon monoxide arises from its affinity for the iron of hemoglobin. Herein lies an important distinction between the poisonous effects of cyanide and carbon monoxide. Because animals (including humans) carry a large number of hemoglobin molecules, they must inhale a large quantity of carbon monoxide to die from it. These same organisms, however, possess comparatively few molecules of cytochrome a_3 . Consequently, a limited exposure to cyanide can be lethal. The sudden action of cyanide attests to the organism's constant and immediate need for the energy supplied by electron transport.

Oligomycin Is an ATP Synthase Inhibitor One of the best-studied inhibitors of ATP synthase is oligomycin. Oligomycin is a polyketide antibiotic that acts directly on ATP synthase by binding at the interface between the α -subunit and the c -subunit rotor. Oligomycin also blocks the movement of protons through F_0 .

20.4i Uncouplers Disrupt the Coupling of Electron Transport and ATP Synthase

Another important class of reagents affects ATP synthesis, but in a manner that does not involve direct binding to any of the proteins of the electron-transport chain or the F_1F_0 -ATPase. These agents are known as **uncouplers** because they disrupt the tight coupling between electron transport and the ATP synthase. Uncouplers act by dissipating the proton gradient across the inner mitochondrial membrane created by the electron-transport system. Typical examples include 2,4-dinitrophenol, dicumarol, and carbonyl cyanide-*p*-trifluoromethoxyphenyl hydrazone (perhaps better known as fluorocarbonyl cyanide phenylhydrazone, or FCCP) (Figure 20.28). These compounds share two common features: hydrophobic character and a dissociable proton. As uncouplers, they function by carrying protons across the inner membrane. Their tendency is to acquire protons on the cytosolic surface of the membrane (where the proton concentration is high) and carry them to the matrix side, thereby destroying the proton gradient that couples electron transport and the ATP synthase. In mitochondria treated with uncouplers, electron transport continues and protons are driven out through the inner membrane. However, they leak back in so rapidly via the uncouplers that ATP synthesis does not occur. Instead, the energy released in electron transport is dissipated as heat.

20.4j ATP-ADP Translocase Mediates the Movement of ATP and ADP Across the Mitochondrial Membrane

ATP, the cellular energy currency, must exit the mitochondria to carry energy throughout the cell, and ADP must be brought into the mitochondria for reprocessing. Neither of these processes occurs spontaneously because the highly charged ATP and ADP molecules do not readily cross biological membranes. Instead, these processes are mediated by a single transport system, the **ATP-ADP translocase**. This protein tightly couples the exit of ATP with the entry of ADP so that the mitochondrial nucleotide levels remain approximately constant. For each ATP transported out, one ADP is transported into the matrix. The translocase is the most abundant protein in the inner mitochondrial membrane and accounts for approximately 14% of the total mitochondrial membrane protein. It is a homodimer of 30 kDa subunits. The structure of the bovine translocase consists of six transmembrane α -helices. The helices are all tilted with respect to the membrane, and the first, third, and fifth helices are bent or kinked at proline residues in the middle of the membrane (Figure 20.29).

Transport occurs via a single nucleotide-binding site, which alternately faces the matrix and the intermembrane space. It binds ATP on the matrix side, reorients to face the outside, and exchanges ATP for ADP, with subsequent rearrangement to face the matrix side of the inner membrane. Transport of ATP and ADP is regulated by phosphorylation of Tyr¹⁹⁴ on transmembrane helix number 5 (Figure 20.29). The relatively

Human Biochemistry

Endogenous Uncouplers—Novel Proteins with Many Beneficial Effects

Certain cold-adapted animals, hibernating animals, and newborn animals generate large amounts of heat by uncoupling oxidative phosphorylation. These organisms have a type of fat known as brown adipose tissue, so called for the color imparted by the many mitochondria this adipose tissue contains. The inner membrane of brown adipose tissue mitochondria contains large amounts of an endogenous protein called *thermogenin* (literally, “heat maker”) or *uncoupling protein 1* (UCP1). UCP1 creates a passive proton channel through which protons flow from the cytosol to the matrix and UCP1 is a universal temperature regulator for animals. Mice that lack UCP1 cannot maintain their body temperature in cold conditions, whereas normal animals produce larger amounts of UCP1 when they are cold adapted.

Two other uncoupling proteins, UCP2 and UCP3, show 60% sequence identity with UCP1 and, like UCP1, they can also dissipate the mitochondrial proton gradient, but they do so in the service of very different physiological functions. UCP2 is found mainly in kidney, pancreas, spleen, immune cells, and the central nervous system, and it is involved in a variety of processes, including regulation of food intake, insulin secretion, and immunity. In particular, it plays a role in regulation of the generation of *reactive oxygen species* (ROS), which include hydrogen peroxide, hypochlorite ion, hydroxyl radical, and superoxide anion (see figure).

Mitochondrial ROS production correlates exponentially with mitochondrial proton-motive force (Equation 20.12 and Section 20.3). (The larger the proton-motive force, the more likely that the respiratory electron carriers will donate electrons to oxygen to form ROS.) Dissipation of the proton-motive force by UCP2 thus attenuates ROS formation and reduces oxidative stress, which has been linked to diabetes and atherosclerosis. On the other hand, UCP3 may play a similar role in attenuation of ROS during fatty

acid oxidation. It also appears to be essential for adaptation to fasting.

Certain plants use the heat of uncoupled proton transport for a special purpose. Skunk cabbage and related plants contain floral spikes that are maintained as much as 20° above ambient temperature in this way. The warmth of the spikes serves to vaporize odiferous molecules, which attract insects that fertilize the flowers. Red tomatoes have very small mitochondrial membrane proton gradients compared with green tomatoes—evidence that uncouplers are more active in red tomatoes.

large size and charge of the ATP and ADP substrates, compared to the relatively small size of the translocase itself, may require large conformation changes during transport. Export of ATP by the translocase is coupled to the ATP/ADP ratio and the proton-motive force across the inner mitochondrial membrane, ensuring that the energy needs of the cell will be met.

Outward Movement of ATP Is Favored over Outward ADP Movement The charge on ATP at pH 7.2 or so is about -4 , and the charge on ADP at the same pH is about -3 . Thus, net exchange of an ATP (out) for an ADP (in) results in the net movement of one negative charge from the matrix to the cytosol. (This process is equivalent to the movement of a proton from the cytosol to the matrix.) Recall that the inner membrane is positive outside (see Figure 20.19), and it becomes clear that outward movement of ATP is favored over outward ADP transport, ensuring that ATP will be transported out (Figure 20.29). Inward movement of ADP is favored over inward movement of ATP for the same reason. Thus, the membrane electrochemical potential itself controls the specificity of the ATP–ADP translocase. However, the electrochemical potential is

Figure 20.29 The bovine ATP–ADP translocase (PDB id = 2C3E). **(a)** a ribbon structure and the path of the protein across the membrane. **(b)** Outward transport of ATP (via the ATP–ADP translocase) is favored by the membrane electrochemical potential.

diminished by the ATP–ADP translocase cycle and therefore operates with an energy cost to the cell. The cell must compensate by passing yet more electrons down the electron-transport chain.

What is the cost of ATP–ADP exchange relative to the energy cost of ATP synthesis itself? We already noted that moving one ATP out and one ADP in is the equivalent of one proton moving from the cytosol to the matrix. Synthesis of an ATP results from the movement of approximately three protons from the cytosol into the matrix through F₀. Altogether, this means that approximately four protons are transported into the matrix per ATP synthesized. Thus, approximately one-fourth of the energy derived from the respiratory chain (electron transport and oxidative phosphorylation) is expended as the electrochemical energy devoted to mitochondrial ATP–ADP transport.

20.5 | What Is the P/O Ratio for Mitochondrial Oxidative Phosphorylation?

The **P/O ratio** is the number of molecules of ATP formed in oxidative phosphorylation per two electrons flowing through a defined segment of the electron-transport chain. In spite of intense study of this ratio, its actual value remains a matter of contention.

The P/O ratio depends on the ratio of H⁺ transported out of the matrix per 2 e⁻ passed from NADH to O₂ in the electron-transport chain and on the number of H⁺ that pass through the ATP synthase to synthesize an ATP. The latter number depends on the number of c-subunits in the F₀ ring of the synthase. As noted in Table 20.2, the number of c-subunits in the ATP synthase ranges from 8 to 15, depending on the organism. This would correspond to ratios of H⁺ consumed per ATP from about 2.7 to 5, respectively, since each rotation of the ATP synthase rotor drives the formation of three ATP. Adding one H⁺ for the action of the ATP–ADP translocase raises these values to about 3.7 and 6, respectively.

Assuming 10 H^+ are transported out of the matrix per $2 e^-$ passed from NADH to O_2 through the electron-transport chain, and 3.7 H^+ are transported into the matrix per ATP synthesized (and translocated), then the mitochondrial P/O ratio is $10/3.7$, or 2.7, for the case of electrons entering the electron-transport chain as NADH.

$$\frac{\text{P}}{\text{O}} = \left(\frac{1 \text{ ATP}}{3.7 \text{ H}^+} \right) \left(\frac{10 \text{ H}^+}{2 e^- [\text{NADH} \rightarrow \frac{1}{2} \text{O}_2]} \right) = \frac{10}{3.7} = 2.7$$

This is somewhat lower than earlier estimates, which placed the P/O ratio at three for mitochondrial oxidation of NADH. For the portion of the chain from succinate to O_2 , the $\text{H}^+/2e^-$ ratio is 6 (as noted previously), and the P/O ratio in this case would be $6/3.7$, or 1.6; earlier estimates placed this number at 2. The consensus of more recent experimental measurements of P/O ratios for these two cases has been closer to the values of 2.7 and 1.6. Many chemists and biochemists, accustomed to the integral stoichiometries of chemical and metabolic reactions, were once reluctant to accept the notion of nonintegral P/O ratios. At some point, as we learn more about these complex coupled processes, it may be necessary to reassess the numbers.

20.6 | How Are the Electrons of Cytosolic NADH Fed into Electron Transport?

Most of the NADH used in electron transport is produced in the mitochondrial matrix, an appropriate site because NADH is oxidized by Complex I on the matrix side of the inner membrane. Furthermore, the inner mitochondrial membrane is impermeable to NADH. Recall, however, that NADH is produced in glycolysis by glyceraldehyde-3-P dehydrogenase in the cytosol. If this NADH were not oxidized to regenerate NAD^+ , the glycolytic pathway would cease to function due to NAD^+ limitation. Eukaryotic cells have a number of **shuttle systems** that harvest the electrons of cytosolic NADH for delivery to mitochondria without actually transporting NADH across the inner membrane.

20.6a The Glycerophosphate Shuttle Ensures Efficient Use of Cytosolic NADH

In the **glycerophosphate shuttle pathway**, two different **glycerophosphate dehydrogenases**, one in the cytosol and one on the outer face of the mitochondrial inner membrane, work together to carry electrons into the mitochondrial matrix (see Figure 20.30). NADH produced in the cytosol transfers its electrons to dihydroxyacetone phos-

Figure 20.30 The glycerophosphate shuttle (also known as the glycerol phosphate shuttle) couples the cytosolic oxidation of NADH with mitochondrial reduction of $[\text{FAD}]$.

phate, thus reducing it to glycerol-3-phosphate. This metabolite is reoxidized by the FAD^+ -dependent mitochondrial membrane enzyme to reform dihydroxyacetone phosphate and enzyme-bound FADH_2 . The two electrons of $[\text{FADH}_2]$ are passed directly to UQ, forming UQH_2 . Thus, via this shuttle, cytosolic NADH can be used to produce mitochondrial $[\text{FADH}_2]$ and, subsequently, UQH_2 . As a result, cytosolic NADH oxidized via this shuttle route yields only 1.6 molecules of ATP. The cell pays with a potential ATP molecule for the convenience of getting cytosolic NADH into the mitochondria. Although this may seem wasteful, there is an important payoff. The glycerophosphate shuttle is essentially irreversible, and even when NADH levels are very low relative to NAD^+ , the cycle operates effectively.

20.6b The Malate–Aspartate Shuttle Is Reversible

The second electron shuttle system, called the **malate–aspartate shuttle**, is shown in Figure 20.31. Oxaloacetate is reduced in the cytosol, acquiring the electrons of NADH (which is oxidized to NAD^+). Malate is transported across the inner membrane, where it is reoxidized by malate dehydrogenase, converting NAD^+ to NADH in the matrix. This mitochondrial NADH readily enters the electron-transport chain.

Figure 20.31 The malate (oxaloacetate)–aspartate shuttle, which operates across the inner mitochondrial membrane. In this shuttle process, electrons from cytosolic NADH are carried by malate across the inner mitochondrial membrane to produce NADH in the matrix.

The oxaloacetate produced in this reaction cannot cross the inner membrane and must be transaminated to form aspartate, which can be transported across the membrane to the cytosolic side. Transamination in the cytosol recycles aspartate back to oxaloacetate. In contrast to the glycerol phosphate shuttle, the malate–aspartate cycle is reversible, and it operates as shown in Figure 20.31 only if the NADH/NAD⁺ ratio in the cytosol is higher than the ratio in the matrix. Because this shuttle produces NADH in the matrix, the full 2.7 ATPs per NADH are recovered.

20.6c The Net Yield of ATP from Glucose Oxidation Depends on the Shuttle Used

The complete route for the conversion of the metabolic energy of glucose to ATP has now been described in Chapters 18 through 20. Assuming appropriate P/O ratios, the number of ATP molecules produced by the complete oxidation of a molecule of glucose can be estimated. Keeping in mind that P/O ratios must be viewed as approximate, for all the reasons previously cited, this text assumes the values of 2.7 and 1.6 for the mitochondrial oxidation of NADH and succinate, respectively. In eukaryotic cells, the combined pathways of glycolysis, the TCA cycle, electron transport, and oxidative phosphorylation then yield a net of approximately 32 to 34 molecules of ATP per molecule of glucose oxidized, depending on the shuttle route used (Table 20.3).

Table 20.3 Yield of ATP from Glucose Oxidation

Pathway	ATP Yield per Glucose	
	Glycerol–Phosphate Shuttle	Malate–Aspartate Shuttle
<i>Glycolysis: glucose to pyruvate (cytosol)</i>		
Phosphorylation of glucose	–1	–1
Phosphorylation of fructose-6-phosphate	–1	–1
Dephosphorylation of 2 molecules of 1,3-BPG	+2	+2
Dephosphorylation of 2 molecules of PEP	+2	+2
Oxidation of 2 molecules of glyceraldehyde-3-phosphate yields 2 NADH		
<i>Pyruvate conversion to acetyl-CoA (mitochondria)</i>		
2 NADH		
<i>Citric acid cycle (mitochondria)</i>		
2 molecules of GTP from 2 molecules of succinyl-CoA	+2	+2
Oxidation of 2 molecules each of isocitrate, α -ketoglutarate, and malate yields 6 NADH		
Oxidation of 2 molecules of succinate yields 2 [FADH ₂]		
<i>Oxidative phosphorylation (mitochondria)</i>		
2 NADH from glycolysis yield 1.6 ATPs each if NADH is oxidized by glycerol–phosphate shuttle; 2.7 ATP by malate–aspartate shuttle	+3.2	+5.4
Oxidative decarboxylation of 2 pyruvate to 2 acetyl-CoA: 2 NADH produce 2.7 ATPs each	+5.4	+5.4
2 [FADH ₂] from each citric acid cycle produce 1.6 ATPs each	+3.2	+3.2
6 NADH from citric acid cycle produce 2.7 ATPs each	+16.2	+16.2
<i>Net Yield</i>	32.0	34.2

Note: These P/O ratios of 2.7 and 1.6 for mitochondrial oxidation of NADH and [FADH₂] are consensus values. Because they may not reflect actual values and because these ratios may change depending on metabolic conditions, these estimates of ATP yield from glucose oxidation are approximate.

The net stoichiometric equation for the oxidation of glucose, using the glycerol phosphate shuttle, is

Because the 2 NADH formed in glycolysis are *transported* by the glycerol phosphate shuttle in this case, they each yield only 1.6 ATP, as already described. On the other hand, if these 2 NADH take part in the malate–aspartate shuttle, each yields 2.7 ATP, giving a total (in this case) of 34.2 ATP formed per glucose oxidized. Most of the ATP—28 out of 32 or 30 out of 34—is produced by oxidative phosphorylation; only 4 ATP molecules result from direct synthesis during glycolysis and the TCA cycle.

The situation in bacteria is somewhat different. Prokaryotic cells need not carry out ATP–ADP exchange. Thus, bacteria have the potential to produce as many as 38 ATP per glucose.

20.6d 3.5 Billion Years of Evolution Have Resulted in a Very Efficient System

How much energy does a eukaryotic cell extract from the glucose molecule? Taking a value of 50 kJ/mol for the hydrolysis of ATP under cellular conditions (see Chapter 3), the production of 34 ATPs per glucose oxidized yields 1700 kJ/mol of glucose. The cellular oxidation (combustion) of glucose yields $\Delta G = -2937$ kJ/mol. The overall efficiency for the pathways of glycolysis, the TCA cycle, electron transport, and oxidative phosphorylation is $1700/2937 \times 100\% = 58\%$.

20.7 | How Do Mitochondria Mediate Apoptosis?

Mitochondria are not only the home of the TCA cycle and oxidative phosphorylation but also are a crossroads for several cell-signaling pathways. Mitochondria take up Ca^{2+} ions released from the endoplasmic reticulum, thus helping control intracellular Ca^{2+} signals. They produce reactive oxygen species (ROS), including oxygen ions, free radicals and peroxides, that play signaling roles in cells, although ROS can also cause cellular damage. Mitochondria also participate in the programmed death of cells, a process known as **apoptosis** (the second “p” is silent in this word).

Apoptosis is a mechanism through which certain cells are eliminated from higher organisms. It is central to the development and homeostasis of multicellular organisms, and it is the route by which unwanted or harmful cells are eliminated. Under normal circumstances, apoptosis is suppressed through compartmentation of the involved activators and enzymes. Mitochondria play a major role in this subcellular partitioning of the apoptotic activator molecules. One such activator is cytochrome *c*, which normally resides in the intermembrane space, bound tightly to a lipid chain of cardiolipin in the membrane (Figure 20.32). A variety of triggering agents, including Ca^{2+} , ROS, certain lipid molecules, a family of **caspases** (proteases with a catalytic Cys residue that cleave next to Asp residues in targets), and certain protein kinases, can induce the opening of pores in the mitochondrial membrane. For example, using hydrogen peroxide as a substrate, cytochrome *c* can oxidize its bound cardiolipin chain, releasing itself from the membrane. When the outer membrane is made permeable by other apoptotic signals, cytochrome *c* can enter the cytosol. This is termed **mitochondrial outer membrane permeabilization (MOMP)**.

Permeabilization events, which occur at points where outer and inner mitochondrial membranes are in contact, involve association of the ATP–ADP translocase in the inner membrane and the **voltage-dependent anion channel (VDAC)** in the outer membrane. This interaction leads to the opening of protein-permeable pores. Cytochrome *c*, as well as several other proteins, can pass through these pores. Pore formation is carefully regulated by the BCL-2 family of proteins, which includes both proapoptotic

members (proteins known as BAX, BID, and BAD) and antiapoptotic members (BCL-2 itself, as well as BCL-X_L and BCL-W). The BCL-2 proteins also activate a series of events that trigger **autophagy**, a catabolic process involving the degradation of the cell's own components through the lysosomal machinery. The cell's choice of apoptosis or autophagy is regulated in part by a membrane protein called *RAGE*, the *receptor for advanced glycation endproducts*.

Figure 20.32 The role of mitochondria in apoptosis. **(a)** Cytochrome *c* is anchored at the inner mitochondrial membrane by association with cardiolipin (diphosphatidylglycerol). The peroxidase activity of cytochrome *c* oxidizes a cardiolipin lipid chain, releasing cytochrome *c* from the membrane. **(b)** The opening of pores in the outer membrane, induced by a variety of triggering agents, releases cytochrome *c* to the cytosol, where it initiates the events of apoptosis.

20.7a Cytochrome *c* Triggers Apoptosome Assembly

How is the release of cytochrome *c* translated into the activation of the death cascade, a point of no return for the cell? The answer lies in the assembly, in the cytosol, of a signaling platform called the **apoptosome** (Figures 20.32 and 20.33). The function of the apoptosome is to activate a cascade of proteases called **caspases**. (The “c” in “caspase” is for cysteine and “asp” is for aspartic acid. Caspases have Cys at the active site and cleave their peptide substrates after Asp residues.) The apoptosome is a wheel-shaped, heptameric platform that looks like (and in some ways behaves like) an earth-orbiting space station. It is assembled from seven subunits of the **apoptotic protease-activating factor 1 (Apaf-1)**, a multidomain protein. Apaf-1 contains an ATPase domain (which prefers dATP over ATP in some organisms), a *caspase-recruitment domain (CARD)*, and a *WD40 repeat* domain. Normally (before the death-signaling cytochrome *c* is released from mitochondria), these three domains are folded against each other (Figure 20.33b), with dATP tightly bound, and Apaf-1 is locked in an inactive monomeric state. Binding of cytochrome *c* to the WD40 domain, followed by dATP hydrolysis, converts Apaf-1 to an extended conformation. Then, exchange of dADP for a new molecule of dATP prompts assembly of the heptameric platform (Figure 20.33), which goes on to activate the death-dealing caspase cascade.

Mitochondria-mediated apoptosis is the mode of cell death for many neurons in the brain during strokes and other brain-trauma injuries. When a stroke occurs, the neurons at the site of oxygen deprivation die within minutes by a nonspecific process of necrosis, but cells adjacent to the immediate site of injury die more slowly by apoptosis. These latter cells have been saved by a variety of therapeutic interventions that suppress apoptosis in laboratory studies, raising the hope that strokes and other neurodegenerative conditions may someday be treated clinically in similar ways.

Figure 20.33 (a) Apaf-1 is a multidomain protein, consisting of an N-terminal CARD, a nucleotide-binding and oligomerization domain (NOD), and several WD40 domains. (b) Binding of cytochrome *c* to the WD40 domains and ATP hydrolysis unlocks Apaf-1 to form the semiopen conformation. Nucleotide exchange leads to oligomerization and apoptosome formation. (c) A model of the apoptosome, a wheellike structure with molecules of cytochrome *c* bound to the WD40 domains, which extend outward like spokes.

Foundational Biochemistry Things You Should Know after Reading Chapter 20.

- Electrons from glycolysis and the TCA cycle, stored in the form of reduced coenzymes (NADH and FADH₂), pass through the electron transport chain, generating a proton gradient that is used to make ATP.
- Electron transport and oxidative phosphorylation take place in the inner membranes of mitochondria and in the plasma membranes of prokaryotes.
- Mitochondria are surrounded by a simple and porous outer membrane as well as a more complex inner membrane.
- Mitochondria are constantly remodeled by fission and fusion of the mitochondrial membranes.
- Electrons move spontaneously from more negative to more positive reduction potentials, passing through the four complexes of the electron transport chain.
- Complex I of the electron transport chain collects a pair of electrons from NADH and passes them to ubiquinone, inducing conformational changes that pump four protons from the matrix to the intermembrane space.
- Complex II of the electron transport chain oxidizes succinate, collecting a pair of electrons from FADH₂ and passing them to ubiquinone, with no attendant transport of protons across the inner membrane.
- Complex III of the electron transport chain mediates electron transport from hydrophobic ubiquinone to water-soluble cytochrome *c*, in a multi-step pathway called the Q cycle. Two electrons through this cycle pump four protons across the mitochondrial inner membrane.
- Complex IV of the electron transport chain transfers electrons from cytochrome *c* to oxygen, reducing it to water. One pair of electrons passing through this complex transport two protons across the mitochondrial inner membrane. Oxygen is the terminal acceptor of electrons in the electron transport chain.
- The complexes of the electron transport chain function as supercomplexes (also known as respirasomes) in the inner mitochondrial membrane.
- Peter Mitchell's chemiosmotic hypothesis proposed that protons are driven across the inner mitochondrial membrane by electron transport and that the resulting proton gradient would drive the synthesis of ATP.
- The free energy change for movement of protons across the inner mitochondrial membrane is sufficient to drive the synthesis of ATP by the ATP synthase.
- The F₁F₀-ATP synthase is an enzyme, a proton pump, and a rotating molecular motor that drives the synthesis of ATP.
- The three catalytic β -sites of the F₁ complex of the ATP synthase normally exist in three different conformations that represent the steps of ATP synthesis—one with ATP bound, one with ADP bound and one empty, as predicted by Paul Boyer's binding change mechanism and as confirmed by John Walker's structural studies.
- Proton flow through the F₀ unit drives rotation of the *c*-ring of the ATP synthase, inducing conformational changes that drive the synthesis of ATP in the F₁ unit.
- Reconstituted vesicles containing ATP synthase and bacteriorhodopsin were used by Walter Stoeckenius and Efraim Racker to synthesize ATP upon exposure to light, confirming the Mitchell hypothesis.
- Inhibitors of Complexes I–IV of the electron transport chain block electron transport.
- Uncouplers, whether proteins, or small hydrophobic molecules with dissociable protons, disrupt the coupling of electron transport and ATP synthesis.
- The ATP–ADP translocase mediates the movement of ATP and ADP across the inner mitochondrial membrane.
- The P/O ratio for electrons entering the electron transport chain from NADH is approximately 2.7. The P/O ratio for electrons entering as succinate/FADH₂ is approximately 1.6.
- Electrons from cytosolic NADH can be fed into the electron transport chain via the glycerophosphate shuttle or the malate-aspartate shuttle, the latter being more efficient.
- The combined pathways of glycolysis, the TCA cycle, electron transport and oxidative phosphorylation yield 32 to 34 ATP per glucose oxidized in eukaryotes.
- Apoptosis is triggered by oxidation of cardiolipin in the mitochondrial membrane, which leads to release of cytochrome *c* to the cytosol. This triggers assembly of apoptosomes and activation of caspases that lead to apoptosis, the programmed death of cells.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. Understanding Redox Couples For the following reaction,

determine which of the redox couples is the electron acceptor and which is the electron donor under standard-state conditions. Calculate the value of $\Delta \mathcal{E}_0'$, and determine the standard-state free energy change for the reaction in the thermodynamically favored direction.

2. Reduction/Oxidation Potentials (Integrates with Chapter 3) Refer to Table 3.3 listing the standard reduction potentials of some biochemical compounds.

- For each pair listed, indicate which compound is most likely to be reduced.
 - UQ or fumarate
 - NAD⁺ or FAD
 - pyruvate or cytochrome *c* (Fe³⁺)

- For each pair listed, indicate which compound is most likely to be oxidized.

- FMNH₂ or succinate
- H₂O or UQH₂
- malate or α -ketoglutarate

3. Determining the Redox Potential of the Glyceraldehyde-3-Phosphate Dehydrogenase Reaction Calculate the value of $\Delta \mathcal{E}_0'$ for the glyceraldehyde-3-phosphate dehydrogenase reaction, and calculate the free energy change for the reaction under standard-state conditions.

4. Understanding the pH Dependence of NAD⁺ Reduction For the following redox reaction,

suggest an equation (analogous to Equation 3.33) that predicts the pH dependence of this reaction, and calculate the reduction potential for this reaction at pH 8.

5. Understanding an Antidote for Cyanide Poisoning Sodium nitrite (NaNO₂) is used by emergency medical personnel as an antidote for

cyanide poisoning (for this purpose, it must be administered immediately). Based on the discussion of cyanide poisoning in Section 20.4, suggest a mechanism for the lifesaving effect of sodium nitrite.

6. Assessing the Mechanism of Uncoupler Action A wealthy investor has come to you for advice. She has been approached by a biochemist who seeks financial backing for a company that would market dinitrophenol and dicumarol as weight-loss medications. The biochemist has explained to her that these agents are uncouplers and that they would dissipate metabolic energy as heat. The investor wants to know if you think she should invest in the biochemist's company. How do you respond?

7. Assessing the [ATP]/[ADP][P_i] Ratio and ATP Synthesis Assuming that 3 H⁺ are transported per ATP synthesized in the mitochondrial matrix, the membrane potential difference is 0.18 V (negative inside), and the pH difference is 1 unit (acid outside, basic inside), calculate the largest ratio of [ATP]/[ADP][P_i] under which synthesis of ATP can occur.

8. Analyzing the Succinate Dehydrogenase Reaction Of the dehydrogenase reactions in glycolysis and the TCA cycle, all but one use NAD⁺ as the electron acceptor. The lone exception is the succinate dehydrogenase reaction, which uses covalently bound FAD of a flavoprotein as the electron acceptor. The standard reduction potential for this bound FAD is in the range of 0.003 to 0.091 V (see Table 3.3). Compared with the other dehydrogenase reactions of glycolysis and the TCA cycle, what is unique about succinate dehydrogenase? Why is bound FAD a more suitable electron acceptor in this case?

9. Analyzing the Succinate Dehydrogenase Reaction (Integrates with Chapter 3) The conversion of succinate into fumarate uses FAD as the oxidizing agent. Use the $\mathcal{E}_o'$ values given in Table 3.3 to calculate:

- $\Delta G^\circ'$ for this reaction.
- $\Delta G^\circ'$ for this reaction if NAD⁺ was used as the oxidizing agent.

10. Analysis of the NADH-CoQ Reductase Reaction

- What is the standard free energy change ($\Delta G^\circ'$) for the reduction of coenzyme Q by NADH as carried out by Complex I (NADH-coenzyme Q reductase) of the electron-transport pathway if $\mathcal{E}_o'$ (NAD⁺/NADH) = -0.320 V and $\mathcal{E}_o'$ (CoQ/CoQH₂) = +0.060 V.
- What is the equilibrium constant (K_{eq}) for this reaction?
- Assume that (1) the actual free energy release accompanying the NADH-coenzyme Q reductase reaction is equal to the amount released under standard conditions (as calculated in part a), (2) this energy can be converted into the synthesis of ATP with an efficiency = 0.75 (that is, 75% of the energy released upon NADH oxidation is captured in ATP synthesis), and (3) the oxidation of one equivalent of NADH by coenzyme Q leads to the phosphorylation of one equivalent of ATP.

Under these conditions, what is the maximum ratio of [ATP]/[ADP] attainable by oxidative phosphorylation when [P_i] = 1 mM? (Assume $\Delta G^\circ'$ for ATP synthesis = +30.5 kJ/mol.)

11. Determining the Impact of the Succinate Dehydrogenase Reaction on Oxidative Phosphorylation Consider the oxidation of succinate by molecular oxygen as carried out via the electron-transport pathway

- What is the standard free energy change ($\Delta G^\circ'$) for this reaction if $\mathcal{E}_o'$ (Fum/Succ) = +0.031 V and $\mathcal{E}_o'$ ($\frac{1}{2}\text{O}_2/\text{H}_2\text{O}$) = +0.816 V?
- What is the equilibrium constant (K_{eq}) for this reaction?
- Assume that (1) the actual free energy release accompanying succinate oxidation by the electron-transport pathway is equal to the amount released under standard conditions (as calculated in part a), (2) this energy can be converted into the synthesis of ATP with an efficiency = 0.7 (that is, 70% of the energy released upon succinate oxidation is captured in ATP synthesis), and

(3) the oxidation of one succinate leads to the phosphorylation of two equivalents of ATP.

Under these conditions, what is the maximum ratio of [ATP]/[ADP] attainable by oxidative phosphorylation when [P_i] = 1 mM? (Assume $\Delta G^\circ'$ for ATP synthesis = +30.5 kJ/mol.)

12. Determining the Effects of NADH Oxidation on Oxidative Phosphorylation Consider the oxidation of NADH by molecular oxygen as carried out via the electron-transport pathway

- What is the standard free energy change ($\Delta G^\circ'$) for this reaction if $\mathcal{E}_o'$ (NAD⁺/NADH) = -0.320 V and $\mathcal{E}_o'$ (O₂/H₂O) = +0.816 V.
- What is the equilibrium constant (K_{eq}) for this reaction?
- Assume that (1) the actual free energy release accompanying NADH oxidation by the electron-transport pathway is equal to the amount released under standard conditions (as calculated in part a), (2) this energy can be converted into the synthesis of ATP with an efficiency = 0.75 (that is, 75% of the energy released upon NADH oxidation is captured in ATP synthesis), and (3) the oxidation of one NADH leads to the phosphorylation of three equivalents of ATP.

Under these conditions, what is the maximum ratio of [ATP]/[ADP] attainable by oxidative phosphorylation when [P_i] = 2 mM? (Assume $\Delta G^\circ'$ for ATP synthesis = +30.5 kJ/mol.)

13. Determining the Effect of the Cytochrome Oxidase Reaction on Oxidative Phosphorylation Write a balanced equation for the reduction of molecular oxygen by reduced cytochrome *c* as carried out by Complex IV (cytochrome oxidase) of the electron-transport pathway.

- What is the standard free energy change ($\Delta G^\circ'$) for this reaction if

$$\Delta \mathcal{E}_o' \text{ cyt } c(\text{Fe}^{3+})/\text{cyt } c(\text{Fe}^{2+}) = +0.254 \text{ volts and } \mathcal{E}_o' \left(\frac{1}{2}\text{O}_2/\text{H}_2\text{O} \right) = 0.816 \text{ volts}$$

- What is the equilibrium constant (K_{eq}) for this reaction?
- Assume that (1) the actual free energy release accompanying cytochrome *c* oxidation by the electron-transport pathway is equal to the amount released under standard conditions (as calculated in part a), (2) this energy can be converted into the synthesis of ATP with an efficiency = 0.6 (that is, 60% of the energy released upon cytochrome *c* oxidation is captured in ATP synthesis), and (3) the reduction of one molecule of O₂ by reduced cytochrome *c* leads to the phosphorylation of two equivalents of ATP.

Under these conditions, what is the maximum ratio of [ATP]/[ADP] attainable by oxidative phosphorylation when [P_i] = 3 mM? (Assume $\Delta G^\circ'$ for ATP synthesis = +30.5 kJ/mol and T = 298 K.)

14. Understanding the Energetics of the Lactate Dehydrogenase Reaction

The standard reduction potential for (NAD⁺/NADH) is -0.320 V, and the standard reduction potential for (pyruvate/lactate) is -0.185 V.

- What is the standard free energy change ($\Delta G^\circ'$) for the lactate dehydrogenase reaction:

- What is the equilibrium constant (K_{eq}) for this reaction?
- If [pyruvate] = 0.05 mM and [lactate] = 2.9 mM and ΔG for the lactate dehydrogenase reaction = -15 kJ/mol in erythrocytes, what is the [NAD⁺]/[NADH] ratio under these conditions?

15. Analyzing the Lactate Dehydrogenase Action (Integrates with Chapter 3)

The conversion of pyruvate into lactate uses NAD⁺ as the oxidizing agent. Use the $\mathcal{E}_o'$ values given in Table 3.3 to calculate:

- $\Delta G^\circ'$ for this reaction.
- $\Delta G^\circ'$ for this reaction if FAD was used as the oxidizing agent.

- 16. Assessing Proton Transport and Free Energy Change in Bacterial ATP Synthesis** Assume that the free energy change (ΔG) associated with the movement of 1 mole of protons from the outside to the inside of a bacterial cell is -23 kJ/mol and 3 H^+ must cross the bacterial plasma membrane per ATP formed by the bacterial F_1F_0 -ATP synthase. ATP synthesis thus takes place by the coupled process:

- If the overall free energy change ($\Delta G_{\text{overall}}$) associated with ATP synthesis in these cells by the coupled process is -21 kJ/mol , what is the equilibrium constant (K_{eq}) for the process?
 - What is $\Delta G_{\text{synthesis}}$, the free energy change for ATP synthesis, in these bacteria under these conditions?
 - The standard free energy change for ATP hydrolysis ($\Delta G^{\circ}_{\text{hydrolysis}}$) is -30.5 kJ/mol . If $[\text{P}_i] = 2 \text{ mM}$ in these bacterial cells, what is the $[\text{ATP}]/[\text{ADP}]$ ratio in these cells?
- 17. *b* Cytochromes in Complex III** As discussed in Section 20.2d, the two *b* cytochromes of Complex III contain the same heme molecule but with very different reduction potentials (-0.1 V versus $+0.05 \text{ V}$). Explain what causes this difference in reduction potential.
- 18. Describing the Path of Electrons Through the Q Cycle of Complex III** Describe in your own words the path of electrons through the Q cycle of Complex III.
- 19. Describing the Path of Electrons Through Complex IV** Describe in your own words the path of electrons through the copper and iron centers of Complex IV.
- 20. Oxidation of Water** Because of its high reduction potential, the reduction of O_2 to H_2O serves as a potent terminal electron acceptor system for the electron transport chain. Is it possible for H_2O to be reoxidized to O_2 or, in other words, is it possible for oxygen in water to lose its electrons?
- 21. Understanding Oxidation of Unsaturated Lipids** In the course of events triggering apoptosis, a fatty acid chain of cardiolipin undergoes peroxidation to release the associated cytochrome *c*. Lipid peroxidation occurs at a double bond. Suggest a mechanism for the reaction of hydrogen peroxide with an unsaturation in a lipid chain, and identify a likely product of the reaction.
- 22. Determining the Number of Protons in a Typical Mitochondrion** In problem 20 at the end of Chapter 19, you might have calculated the number of molecules of oxaloacetate in a typical mitochondrion. What about protons? A typical mitochondrion can be thought of as a cylinder $1 \mu\text{m}$ in diameter and $2 \mu\text{m}$ in length. If the pH in the matrix is 7.8, how many protons are contained in the mitochondrial matrix?
- 23. Understanding the Unique Requirement for FAD in the Succinate Dehydrogenase Reaction** Considering that all other dehydrogenases of glycolysis and the TCA cycle use NADH as the electron donor, why does succinate dehydrogenase, a component of the TCA cycle and the electron-transfer chain, use FAD as the electron acceptor from succinate, rather than NAD^+ ? Note that there are two justifications for the choice of FAD here—one based on energetics and one based on the mechanism of electron transfer for FAD versus NAD^+ .
- 24. Anaerobic Respiration** Anaerobic organisms do not use oxygen as the terminal acceptor for electron transport. Other reduction reactions, shown below, drive metabolism in anaerobic organisms. Write stoichiometric equations for these reduction reactions:
- $\text{Fe}^{3+} \rightarrow \text{Fe}^{2+}$
 - $\text{SO}_4^{2-} \rightarrow \text{HS}^-$
 - $\text{NO}_3^- \rightarrow \text{N}_2$
 - $\text{S} \rightarrow \text{HS}^-$

- 25. Understanding the Mechanism of the ATP Synthase** Based on your reading in this chapter on the F_1F_0 -ATPase, what would you conclude about the mechanism of ATP synthesis:

- The reaction proceeds by nucleophilic substitution via the $\text{S}_{\text{N}}2$ mechanism.
- The reaction proceeds by nucleophilic substitution via the $\text{S}_{\text{N}}1$ mechanism.
- The reaction proceeds by electrophilic substitution via the $\text{E}1$ mechanism.
- The reaction proceeds by electrophilic substitution via the $\text{E}2$ mechanism.

26. Relating Proton Transport and Free Energy Changes in Mitochondria

Imagine that you are working with isolated mitochondria and you manage to double the ratio of protons outside to protons inside. In order to maintain the overall ΔG at its original value (whatever it is), how would you have to change the mitochondria membrane potential?

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

- Using the PSafe model for Complex I of the electron transport chain: Describe the interactions of different arms of the L-shape. Describe Nqo1's Rossman fold. Determine the specific interactions of each residue of the catalytic binding site with NADH.
- Using the PSafe model for ADP-ATP translocase, explain the formation of the kinked α -helices.

Think-Pair-Share Question

The electron transport/oxidative phosphorylation pathway may seem like a drawn-out and overly complicated process with room for improvement or simplification. Consider this set of questions to argue that the system as it exists may be the best of all possible worlds.

- A single pair of electrons from NADH induces proton transport in complexes I, III and IV creating the proton motive force that drives the synthesis of ATP. Why not add more complexes in the electron transport system? Why could an expanded system consisting of more complexes that could induce much more proton transport leading to a stronger proton motor force and the synthesis of more ATP from a single NADH be catastrophic to the cell? (Hint: revisit "Human Biochemistry: Endogenous Uncouplers—Novel Proteins with Many Beneficial Effects").
- Why do cells not use a direct reduction of oxygen by NADH at the active site of a complex IV-like protein according to the following equation: $2\text{NADH} + 2\text{H}^+ + \text{O}_2 \rightarrow 2\text{NAD}^+ + 2\text{H}_2\text{O}$? Such a setup would eliminate the need for proton pumping or electron transport.
- Imagine an inverse electron/proton transport system in which the electron transport/oxidative phosphorylation process involves the movement of protons through multiple complexes inside the mitochondrial inner membrane and the transport of electrons across the mitochondrial inner membrane towards the intermembrane space. What would be the driving force for this proton transport through the various complexes? What kind of features would such a system need to contain? Would it be as efficient and functional as the existing system?

Photosynthesis

21

Richard Hamilton Smith/Corbis

◀ Field of goldenrod.

*In a sun-flecked lane,
Beside a path where cattle trod,
Blown by wind and rain,
Drawing substance from air and sod;
In ruggedness, it stands aloof,
The ragged grass and puerile leaves,
Lending a hand to fill the woof
In the pattern that beauty weaves.
What mystery this, hath been wrought;
Beauty from sunshine, air, and sod!
Could we thus gain the ends we sought—
Tell us thy secret, Goldenrod.*

Rosa Staubus
Oklahoma pioneer (1886–1966)

Essential Questions

Photosynthesis is the primary source of energy for all life forms (except chemolithotrophic prokaryotes). Much of the energy of photosynthesis is used to drive the synthesis of organic molecules from atmospheric CO₂. **How is solar energy captured and transformed into metabolically useful chemical energy? How is the chemical energy produced by photosynthesis used to create organic molecules from carbon dioxide?**

The vast majority of energy consumed by living organisms stems from solar energy captured by the process of photosynthesis. Only chemolithotrophic prokaryotes are independent of this energy source. Of the 1.5×10^{22} kJ of energy reaching the earth each day from the sun, 1% is absorbed by photosynthetic organisms and transduced into chemical energy.¹ This energy, in the form of biomolecules, becomes available to other members of the biosphere through food chains. The transduction of solar, or light, energy into chemical energy is often expressed in terms of **carbon dioxide fixation**, in which hexose is formed from carbon dioxide and oxygen is evolved:

Estimates indicate that more than 2×10^{11} tons of carbon dioxide are fixed globally per year, of which one-third is fixed in the oceans, primarily by photosynthetic marine microorganisms.

Although photosynthesis is traditionally equated with CO₂ fixation, light energy (or rather the chemical energy derived from it) drives all endergonic processes in phototrophic cells. The assimilation of inorganic forms of nitrogen and sulfur into organic molecules represents two other metabolic conversions closely coupled to light energy in green plants. Our previous considerations of aerobic metabolism (Chapters 18 through 20) presented

¹Of the remaining 99%, two-thirds is absorbed by the earth and oceans, thereby heating the planet; the remaining one-third is lost as light reflected back into space.

Key Questions

- 21.1 What Are the General Properties of Photosynthesis?
- 21.2 How Is Solar Energy Captured by Chlorophyll?
- 21.3 What Kinds of Photosystems Are Used to Capture Light Energy?
- 21.4 What Is the Molecular Architecture of Photosynthetic Reaction Centers?
- 21.5 What Is the Quantum Yield of Photosynthesis?
- 21.6 How Does Light Drive the Synthesis of ATP?
- 21.7 How Is Carbon Dioxide Used to Make Organic Molecules?
- 21.8 How Does Photorespiration Limit CO₂ Fixation?

cellular respiration (precisely the reverse of Equation 21.1) as the central energy-releasing process in life. It necessarily follows that the formation of hexose from carbon dioxide and water, the products of cellular respiration, must be endergonic. The necessary energy comes from light. Note that in the carbon dioxide fixation reaction described, light is used to drive a chemical reaction against its thermodynamic potential.

21.1 What Are the General Properties of Photosynthesis?

Organisms capable of photosynthesis are very diverse, ranging from simple prokaryotic forms to the largest organisms of all, *Sequoia gigantea*, the giant redwood trees of California. Despite this diversity, we find certain generalities regarding photosynthesis.

21.1a Photosynthesis Occurs in Membranes

One universal attribute is that *photosynthesis occurs in membranes*. In photosynthetic prokaryotes, the photosynthetic membranes fill up the cell interior; in photosynthetic eukaryotes, the photosynthetic membranes are localized in large organelles known as **chloroplasts** (Figures 21.1 and 21.2). Chloroplasts are one member in a family of related plant-specific organelles known as **plastids**. Chloroplasts themselves show a range of diversity, from the single, spiral chloroplast that gives *Spirogyra* its name to the multitude of ellipsoidal plastids typical of higher plant cells (Figure 21.3).

Characteristic of all chloroplasts, however, is the organization of the inner membrane system, the so-called **thylakoid membrane**. The thylakoid membrane is organized into paired folds that extend throughout the organelle, as shown in Figure 21.2. These paired folds, or **lamellae**, give rise to flattened sacs or discs, **thylakoid vesicles** (from the Greek *thylakos*, meaning “sack”), which occur in stacks called **grana**. A single stack, or **granum**, may contain dozens of thylakoid vesicles, and different grana are joined by lamellae that run through the soluble portion, or **stroma**, of the organelle. Chloroplasts thus possess three membrane-bound aqueous compartments: the intermembrane space, the stroma, and the interior of the thylakoid vesicles, the so-called **thylakoid space** (also known as the **thylakoid lumen**). This third compartment serves an important function in the transduction of light energy into ATP formation. The thylakoid membrane has a highly characteristic lipid composition and, like the inner membrane of the mitochondrion, is impermeable to most ions and molecules. Chloroplasts, like their mitochondrial counterparts, possess DNA, RNA, and ribosomes and consequently display a considerable amount of autonomy. However, many critical chloroplast components are encoded by nuclear genes, so autonomy is far from absolute.

James Dennis/Phototake

Figure 21.2 Schematic of an idealized chloroplast.

Figure 21.3 Chloroplast structures. (a) The spiral chloroplasts (green) of *Spirogyra*, a fresh-water alga. (b) The chloroplasts of a higher plant cell are seen here as the dark, oval-shaped membrane-rich organelles distributed around the cell periphery. Note the multiple chloroplasts around the cell's periphery.

21.1b Photosynthesis Consists of Both Light Reactions and Dark Reactions

If a chloroplast suspension is illuminated in the absence of carbon dioxide, oxygen is released. Furthermore, if the illuminated chloroplasts are now placed in the dark and supplied with CO_2 , net hexose synthesis can be observed (Figure 21.4). Thus, the release of oxygen can be temporally separated from CO_2 fixation and also has a light dependency that CO_2 fixation lacks. The **light reactions** of photosynthesis, of which O_2 evolution is only one part, are associated with the thylakoid membranes. In contrast, the light-independent reactions, or so-called **dark reactions**, notably CO_2 fixation, are located in the stroma. A concise summary of the photosynthetic process is that radiant electromagnetic energy (light) is transformed by a specific photochemical system located in the thylakoids to yield chemical energy in the form of reducing potential (NADPH) and high-energy phosphate (ATP). NADPH and ATP can then be used to drive the endergonic process of hexose formation from CO_2 by a series of enzymatic reactions found in the stroma (see Equation 21.3).

Figure 21.4 The light-dependent and light-independent reactions of photosynthesis.

21.1c Water Is the Ultimate Electron Donor for Photosynthetic NADP⁺ Reduction

In green plants, water serves as the ultimate electron donor for the photosynthetic generation of reducing equivalents. The reaction sequence

describes the process, where $nh\nu$ symbolizes light energy (n is some number of photons of energy $h\nu$, where h is Planck's constant and ν is the frequency of the light). Light energy is necessary to make the unfavorable reduction of NADP⁺ by H₂O ($\Delta\mathcal{E}_o' = -1.136 \text{ V}$; $\Delta G^{\circ'} = +219 \text{ kJ/mol NADP}^+$) thermodynamically favorable. Thus, the light energy input, $nh\nu$, must exceed $219 \text{ kJ/mol NADP}^+$. The stoichiometry of ATP formation depends on the pattern of photophosphorylation operating in the cell at the time and on the ATP yield in terms of the chemiosmotic ratio, ATP/H⁺, as we will see later. Nevertheless, the stoichiometry for the metabolic pathway of CO₂ fixation can be written with certainty:

A More Generalized Equation for Photosynthesis In 1931, a comparative study of photosynthesis in bacteria led C. B. van Niel to a more general formulation of the overall reaction:

In photosynthetic bacteria, H₂A is variously H₂S (in photosynthetic green and purple bacteria (reaction (21.5))), isopropanol (in *Rhodospseudomonas* species, reaction (21.6)), or some similar oxidizable substrate. [(CH₂O) symbolizes a carbohydrate unit.]

In cyanobacteria and the eukaryotic photosynthetic cells of algae and higher plants, H₂A is H₂O, as implied earlier, and 2 A is O₂. The accumulation of O₂ to constitute 21% of the earth's atmosphere is the direct result of eons of global oxygenic photosynthesis.

21.2 | How Is Solar Energy Captured by Chlorophyll?

Photosynthesis depends on the photoreactivity of **chlorophyll**. Chlorophylls are magnesium-containing substituted tetrapyrroles whose basic structure is reminiscent of heme, the iron-containing porphyrin (see Chapters 5 and 20). Chlorophylls differ from heme in a number of properties: Magnesium instead of iron is coordinated in the center of the planar conjugated ring structure; a long-chain alcohol, **phytol**, is esterified to a pyrrole ring substituent; and the methine bridge linking pyrroles III and IV is substituted and crosslinked to ring III, leading to the formation of a fifth five-membered ring, labeled V. The structures of chlorophyll *a* and *b* are shown in Figure 21.5a.

Chlorophylls are excellent light absorbers because of their aromaticity. That is, they possess delocalized π electrons, whose orbitals lie above and below the planar ring structure. The energy differences between electronic states in these π orbitals correspond to the energies of visible light photons. When light energy is absorbed, an electron is promoted to a higher orbital, enhancing the potential for transfer of this electron to a suitable acceptor. Loss of such a photoexcited electron to an acceptor is an oxidation–reduction reaction. The net result is the transduction of light energy into the chemical energy of a redox reaction.

21.2a Chlorophylls and Accessory Light-Harvesting Pigments Absorb Light of Different Wavelengths

The absorption spectra of chlorophylls *a* and *b* (Figure 21.5b) differ somewhat. Plants that possess both chlorophylls can harvest a wider spectrum of incident energy. Other pigments in photosynthetic organisms, so-called **accessory light-harvesting pigments** (Figure 21.6), increase the possibility for absorption of incident light (the light that strikes the chloroplast surface), of wavelengths not absorbed by the chlorophylls. Carotenoids and phycocyanobilins, like chlorophyll, possess many conjugated double

Figure 21.5 The (a) structures and (b) absorption spectra of chlorophyll *a* and *b*. The phytyl side chain of ring IV provides a hydrophobic tail to anchor the chlorophyll in membrane protein complexes.

bonds and thus absorb visible light. Carotenoids have two primary roles in photosynthesis—light harvesting and photoprotection through destruction of reactive oxygen species that arise as byproducts of photoexcitation.

21.2b The Light Energy Absorbed by Photosynthetic Pigments Has Several Possible Fates

Each photon represents a quantum of light energy. A quantum of light energy absorbed by a photosynthetic pigment has four possible fates (Figure 21.7):

1. **Loss as heat.** The energy can be dissipated as heat through redistribution into atomic vibrations within the pigment molecule.
2. **Loss as light.** Energy of excitation reappears as **fluorescence** (light emission); a photon of fluorescence is emitted as the e^- drops down to a lower orbital. This fate is common only in saturating light intensities. For thermodynamic reasons, the photon of fluorescence has a longer wavelength and hence lower energy than the quantum of excitation.
3. **Resonance energy transfer.** The excitation energy can be transferred by resonance energy transfer to a neighboring molecule if the energy level difference between the two corresponds to the quantum of excitation energy. In this process, the energy transferred raises an electron in the receptor molecule to a higher energy state as the photoexcited e^- in the original absorbing molecule returns to ground state. This so-called *Förster resonance energy transfer* is the mechanism whereby quanta of light falling anywhere within an array of pigment molecules can be transferred ultimately to specific photochemically reactive sites.
4. **Energy transduction.** The energy of excitation, in raising an electron to a higher energy orbital, dramatically changes the standard reduction potential, $\mathcal{E}_0'$, of the pigment such that it becomes a much more effective electron donor. That is, the excited-state species, by virtue of having an electron at a higher energy level through light absorption, has become a more potent electron donor. Reaction of this excited-state electron donor with an electron acceptor situated in its vicinity leads to the transformation, or **transduction**, of light energy (photons) to chemical energy (reducing power, the potential for electron-transfer reactions). *Transduction of light energy into chemical energy, the photochemical event, is the essence of photosynthesis.*

Figure 21.7 Possible fates of the quantum of light energy absorbed by photosynthetic pigments.

21.2c The Transduction of Light Energy into Chemical Energy Involves Oxidation–Reduction

The diagram presented in Figure 21.8 illustrates the fundamental transduction of light energy into chemical energy (an oxidation–reduction reaction) that is the basis of photosynthesis. Chlorophyll (Chl) resides in a membrane in close association with molecules competent in e^- transfer, symbolized here as A and B. Chl absorbs a

Figure 21.8 Model for light absorption by chlorophyll and transduction of light energy into an oxidation–reduction reaction. The scheme shows a photon of light initiating a series of one-electron transfer events. **I:** Photoexcitation of Chl creates Chl*. **II:** Electron transfer from Chl* to A yields oxidized Chl (Chl⁺) and reduced A (A⁻). **III:** An electron-transfer pathway from A⁻ to NADP⁺ leads to NADPH formation and restoration of oxidized A (A). **IV:** Chl⁺ accepts an electron from B, restoring Chl and generating oxidized B (B⁺). **V:** B⁺ is reduced back to B by an electron originating in H₂O. Water oxidation is the source of O₂ formation.

Chemistry in History

Emmett Chapelle

Dr. Emmett Chapelle (1925–2019) was an African American educated in the segregated public schools of Phoenix, AZ. After high school graduation in 1942, he enlisted in the U.S. Army and was wounded twice while serving with the 92nd Infantry Division in Italy. After the war, despite facing segregation and social adversity, he received an associate's degree in electrical engineering from Phoenix College and a Bachelor of Science in Biology at the University of California, Berkeley in 1950. Following a teaching stint in Tennessee, he earned his Master of Biology from the University of Washington.

During the early years of the space race, Dr. Chapelle was credited for the inclusion of single-celled algae on spacecrafts as highly efficient, potentially edible, and renewable oxygen sources. Dr. Chapelle also invented a method for the detection of ATP based on the light-emitting reaction of fireflies. In this reaction, the firefly enzyme luciferase acts on its substrate luciferin to produce light, provided ATP is present. All known organisms contain ATP, so he knew that he could use this reaction to test for the presence of life. His revolutionary method is still in use today for the detection of microbes in food and water and the testing of extraterrestrial soils for microscopic life.

photon of light, becoming activated to Chl^* in the process. Electron transfer from Chl^* to A leads to oxidized Chl ($\text{Chl}^{\cdot+}$, a **cationic free radical**) and reduced A (A^- in the diagram). Subsequent oxidation of A^- eventually culminates in reduction of NADP^+ to NADPH. The **electron hole** in oxidized Chl ($\text{Chl}^{\cdot+}$) is filled by transfer of an electron from B to $\text{Chl}^{\cdot+}$, restoring Chl and creating B^+ . B^+ is restored to B by an e^- donated by water. O_2 is the product of water oxidation. Note that the system is restored to its original state once NADPH is formed and H_2O is oxidized. Proton translocations accompany these light-driven electron-transport reactions. Such H^+ translocations establish a chemiosmotic gradient across the photosynthetic membrane that can drive ATP synthesis.

21.2d Photosynthetic Units Consist of Many Chlorophyll Molecules but Only a Single Reaction Center

In the early 1930s, Robert Emerson and William Arnold investigated the relationship between the amount of incident light energy, the amount of chlorophyll present, and the amount of oxygen evolved by illuminated algal cells. Emerson and Arnold were seeking to determine the **quantum yield of photosynthesis**: the number of electrons transferred per photon of light. Their studies gave an unexpected result: When algae were illuminated with very brief light flashes that could excite every chlorophyll molecule at least once, only one molecule of O_2 was evolved per 2400 chlorophyll molecules. This result implied that not all chlorophyll molecules are photochemically reactive, and it led to the concept that photosynthesis occurs in functionally discrete units.

Chlorophyll serves two roles in photosynthesis. It is involved in light harvesting and the transfer of light energy to photoreactive sites by exciton transfer, and it participates directly in the photochemical events whereby light energy becomes chemical energy. A **photosynthetic unit** (Figure 21.9) can be envisioned as an antenna of several hundred light-harvesting chlorophyll molecules (*green*) plus a special pair of photochemically reactive chlorophyll *a* molecules called the **reaction center** (*orange*). The purpose of the vast majority of chlorophyll in a photosynthetic unit is to harvest light incident within the unit and funnel it, via resonance energy transfer, to the reaction center chlorophyll dimers that are photochemically active. Most chlorophyll thus acts as a large light-collecting antenna, and it is at the reaction centers that the photochemical event occurs. Oxidation of chlorophyll leaves a **cationic free radical**, $\text{Chl}^{\cdot+}$, whose properties as an electron acceptor have important consequences for photosynthesis. Note that the Mg^{2+} ion does not change in valence during these redox reactions.

Figure 21.9 Schematic of a photosynthetic unit. The green disks represent individual chlorophyll molecules.

21.3 What Kinds of Photosystems Are Used to Capture Light Energy?

All photosynthetic cells contain some form of photosystem. Photosynthetic bacteria have only one photosystem; furthermore, they lack the ability to use light energy to split H_2O and release O_2 . Cyanobacteria, green algae, and higher plants are *oxygenic phototrophs* because they can generate O_2 from water. Oxygenic phototrophs have two distinct photosystems: **photosystem I (PSI)** and **photosystem II (PSII)**. Type I photosystems use ferredoxins as terminal electron acceptors; type II photosystems use quinones as terminal electron acceptors. PSI is defined by reaction center chlorophylls with maximal red light absorption at 700 nm; PSII uses reaction centers that exhibit maximal red light absorption at 680 nm. The reaction center Chl of PSI is referred to as **P700** because it absorbs light of 700 nm wavelength; the reaction center Chl of PSII is called **P680** for analogous reasons. Both P700 and P680 are chlorophyll *a* dimers situated within specialized protein complexes. A distinct property of PSII is its role in light-driven O_2 evolution. Interestingly, the photosystems of photosynthetic bacteria are type II photosystems that resemble eukaryotic PSII more than PSI, even though these bacteria lack O_2 -evolving capacity.

21.3a Chlorophyll Exists in Plant Membranes in Association with Proteins

Isolated thylakoid membranes can be dissolved by detergent treatment, releasing complexes containing both chlorophylls and protein. These chlorophyll–protein complexes represent integral components of the thylakoid membrane, and their organization reflects their roles as either **light-harvesting complexes (LHC)**, **PSI complexes**, or **PSII complexes**. All chlorophyll is apparently localized within these three macromolecular assemblies.

21.3b PSI and PSII Participate in the Overall Process of Photosynthesis

What are the roles of the two photosystems, and what is their relationship to each other? PSI provides reducing power in the form of NADPH. PSII splits water, producing O_2 , and feeds the electrons released into an electron-transport chain that couples PSII to PSI. Electron transfer between PSII and PSI pumps protons for chemiosmotic ATP synthesis. As summarized by Equation 21.2, photosynthesis involves the reduction of NADP^+ using electrons derived from water and activated by light, $h\nu$. ATP is generated in the process. The standard reduction potential for the $\text{NADP}^+/\text{NADPH}$ couple is -0.32 V . Thus, a strong reductant with an $\mathcal{E}_o'$ more negative than -0.32 V is required to reduce NADP^+ under standard conditions. By similar reasoning, a very strong oxidant is required to oxidize water to oxygen because $\mathcal{E}_o'(\frac{1}{2}\text{O}_2/\text{H}_2\text{O})$ is $+0.82\text{ V}$. Separation of the oxidizing and reducing aspects of Equation 21.2 is accomplished in nature by devoting PSI to NADP^+ reduction and PSII to water oxidation. PSI and PSII are linked via an electron-transport chain so that the weak reductant generated by PSII can provide an electron to reduce the weak oxidant side of P700 (Figure 21.10). Thus, *electrons flow from H_2O to NADP^+ , driven by light energy absorbed at the reaction*

Figure 21.10 Roles of the two photosystems, PSI and PSII.

centers. Oxygen is a by-product of the **photolysis**, literally “light-splitting,” of water. Accompanying electron flow is production of a proton gradient and ATP synthesis (see Section 21.6). This light-driven phosphorylation is termed *photophosphorylation*.

21.3c The Pathway of Photosynthetic Electron Transfer Is Called the Z Scheme

Photosystems I and II contain unique complements of electron carriers, and these carriers mediate the stepwise transfer of electrons from water to NADP^+ . When the individual redox components of PSI and PSII are arranged as an e^- transport chain according to their standard reduction potentials, the zigzag result resembles the letter Z laid sideways (Figure 21.11). The various electron carriers are indicated as follows: Mn complex is the manganese-containing oxygen-evolving complex; D is its e^- acceptor and the immediate e^- donor to P680^+ ; Q_A and Q_B represent special plastoquinone molecules (see Figure 21.13), and PQ, the plastoquinone pool; Fe-S stands for the Rieske iron–sulfur center, and *cyt f*, cytochrome *f*. PC is the abbreviation for plastocyanin, the immediate e^- donor to P700^+ ; and F_A , F_B , and F_X represent the membrane-associated **ferredoxins** downstream from A_0 (a specialized Chl *a*) and A_1 (a specialized PSI quinone). Fd is the soluble ferredoxin pool that serves as the e^- donor to the flavoprotein (Fp), called **ferredoxin– NADP^+ reductase (FNR)**, which catalyzes reduction of NADP^+ to NADPH. $\text{Cyt}(b_6)_\text{N},(b_6)_\text{P}$ symbolizes the cytochrome b_6 moieties of the cytochrome b_6f complex.

Ferredoxin (Fd) A generic term for small proteins possessing iron–sulfur clusters that participate in various electron-transfer reactions.

The Z scheme of the linear flow of electrons from H_2O to NADP^+ is accomplished by three **membrane-spanning supramolecular complexes** composed of intrinsic and extrinsic polypeptides (shown as shaded boxes bounded by solid black lines in Figure 21.11). These complexes are the PSII complex, the cytochrome b_6f complex, and the PSI complex. The PSII complex is aptly described as a light-driven **water : plastoquinone oxidoreductase**; it is the enzyme system responsible for photolysis of water, and as such, it contains the **oxygen-evolving complex**, or **OEC**. The OEC of PSII is a metal cluster containing four Mn atoms, one Ca atom, and five O atoms, with four associated H_2O molecules. As P680 undergoes four cycles of light-induced oxidation, four protons and four electrons are removed from two of the water molecules and their O atoms are joined to form O_2 . A tyrosyl side chain of the PSII complex (see following discussion) mediates electron transfer between the Mn_4CaO_5 cluster and P680. The O_2 -evolving reaction requires Cl^- ions in addition to the Mn_4CaO_5 cluster.

Protons (H^+) accumulate in the chloroplast lumen when PSII catalyzes light-driven H_2O oxidation. Further along the linear electron transfer pathway, additional protons are translocated from the stroma into the lumen by the electron transfer reactions within the cytochrome b_6f complex. Light-driven accumulation of H^+ in the lumen is the driving force for ATP synthesis (Figure 21.11), and the process is thus termed **photophosphorylation**.

An alternative to the Z-scheme linear electron flow (LEF) from water to NADP^+ occurs when electrons flow in a circle from photoexcited P700^* back to itself via the cytochrome b_6f complex, filling the electron hole in P700^+ . In this **cyclic electron flow (CEF)** (the dashed arrow in Figure 21.11), the electron from P700^* passes primarily through Fd and FNR to reach the b_6f complex, which then catalyzes electron transfer into P700^+ . Of the three membrane-spanning supramolecular complexes, CEF requires just the participation of PSI and the cytochrome b_6f complex. Since PSII is not involved, no O_2 is evolved, and since the electron from P700 returns to it, no NADP^+ is reduced. However, since electrons passing through the b_6f complex cause the translocation of H^+ into the lumen, cyclic electron flow can drive ATP synthesis, a process called **cyclic photophosphorylation**.

21.3d Oxygen Evolution Requires the Accumulation of Four Oxidizing Equivalents in PSII

When isolated chloroplasts that have been held in the dark are illuminated with very brief flashes of light, O_2 evolution reaches a peak on the third flash and every fourth flash thereafter (Figure 21.12a). The oscillation in O_2 evolution dampens over repeated flashes and converges to an average value. These data are interpreted to mean that the

Figure 21.11 The Z scheme of photosynthesis. **(a)** The Z scheme is a diagrammatic representation of photosynthetic electron flow from H_2O to $NADP^+$. The energy relationships can be derived from the $\mathcal{E}_o'$ scale beside the Z diagram. Energy input as light is indicated by two broad arrows, one photon appearing in P680 and the other in P700. P680* and P700* represent photoexcited states. The three supramolecular complexes (PSI, PSII, and the cytochrome b_6/f complex) are in shaded boxes. Proton translocations that establish the proton-motive force driving ATP synthesis are illustrated as well. **(b)** The functional relationships among PSII, the cytochrome b_6/f complex, PSI, and the photosynthetic CF₁CF₀-ATP synthase within the thylakoid membrane. The functional relationships for photosynthetic electron transport through PSII, cytochrome b_6/f , and PSI are based on 4 photons (2 per photosystem) driving the passage of an electron pair from water to $NADP^+$. ATP synthesis is based on an H^+/ATP ratio of 14/3.

Figure 21.12 Oxygen evolution requires the accumulation of four oxidizing equivalents in PSII. **(a)** O_2 evolution after brief light flashes. **(b)** A simple model for the cycling of the PSII reaction center through five different oxidation states, S_0 to S_4 . One e^- is removed photochemically at each light flash, moving the reaction center successively through S_1 , S_2 , S_3 , and S_4 . S_4 decays spontaneously to S_0 by oxidizing 2 H_2O to O_2 .

Figure 21.13 The structures of plastoquinone A and its reduced form, plastoquinol (or plastoquinol). Plastoquinone A has nine isoprene units and is the most abundant plastoquinone in plants and algae.

P680 reaction center complex cycles through five different oxidation states, numbered S_0 to S_4 . One electron and one proton are removed photochemically in each step. When S_4 is attained, an O_2 molecule is released (Figure 21.12b) as PSII returns to oxidation state S_0 and two new water molecules bind. (The reason the first pulse of O_2 release occurred on the third flash [Figure 21.12a] is that the PSII reaction centers in the isolated chloroplasts were already poised at S_1 reduction level.)

21.3e Electrons Are Taken from H_2O to Replace Electrons Lost from P680

The events intervening between H_2O and P680 involve D , the name assigned to a specific protein tyrosine residue that mediates e^- transfer from H_2O via the Mn complex to $P680^+$ (see Figure 21.11). The oxidized form of D is a tyrosyl free radical species, $D^{\cdot+}$. To begin the cycle, an exciton of energy excites P680 to $P680^*$, whereupon $P680^*$ transfers an electron to a nearby Chl a molecule, which is the direct electron acceptor from $P680^*$. This Chl a then reduces a molecule of **pheophytin** (Pheo in Figure 21.11). Pheophytin is like chlorophyll a , except two H^+ replace the centrally coordinated Mg^{2+} ion. Loss of an electron from $P680^*$ creates $P680^+$, the electron acceptor for D . Electrons flow from Pheo via specialized molecules of **plastoquinone** (Q in Figure 21.11), to a pool of plastoquinone (PQ) within the membrane. Because of its lipid nature, plastoquinone is mobile within the membrane and hence serves to shuttle electrons from the PSII supramolecular complex to the cytochrome b_6f complex. Alternate oxidation–reduction of plastoquinone to its hydroquinone form involves the uptake of protons (Figure 21.13). The asymmetry of the thylakoid membrane is designed to exploit this proton uptake and release so that protons (H^+) accumulate within the lumen of thylakoid vesicles, establishing an electrochemical gradient. Note that plastoquinone is an analog of coenzyme Q, the mitochondrial electron carrier (see Chapter 20).

21.3f Electrons from PSII Are Transferred to PSI via the Cytochrome b_6f Complex

The cytochrome b_6f or **plastoquinol:plastocyanin oxidoreductase** is a large (210 kDa) multimeric protein possessing 26 transmembrane α -helices. This membrane protein complex is structurally and functionally homologous to the cytochrome bc_1 complex (Complex III) of mitochondria (see Chapter 20). It includes the two heme-containing electron transfer proteins for which it is named, as well as *iron–sulfur clusters*, which also participate in electron transport. The purpose of this complex is to mediate the transfer of electrons from PSII to PSI and to pump protons across the thylakoid membrane via a plastoquinone-mediated Q cycle, analogous to that found in mitochondrial e^- transport (see Chapter 20). Cytochrome f (f from the Latin *folium*, meaning “foliage”) is a c -type cytochrome, with a reduction potential of +0.365 V. Cytochrome b_6 in two forms (low- and high-potential) participates in the oxidation of plastoquinol and the Q cycle of the b_6f complex. Thus, the role of the cytochrome b_6f complex is directly analogous to the role of mitochondrial Complex III: Using the energy of an oxidation–reduction reaction to create a proton gradient across a membrane. The cytochrome b_6f complex also serves in the alternative cyclic electron flow pathway.

21.3g Plastocyanin Transfers Electrons from the Cytochrome b_6f Complex to PSI

Plastocyanin (PC in Figure 21.11) is an electron carrier capable of diffusion along the inside of the thylakoid and migration in and out of the membrane, aptly suited to its role in shuttling electrons between the cytochrome b_6f complex and PSI. Plastocyanin is a low-molecular-weight (10.4 kDa) protein containing a single copper atom. PC functions as a single-electron carrier ($\mathcal{E}_0' = +0.32$ V) as its copper atom undergoes alternate oxidation–reduction between the cuprous (Cu^+) and cupric (Cu^{2+}) states.

Structure of the cyanobacterial cytochrome b_6f complex depicting the heme groups of cytochromes b_6N , b_6P , and f (red) and the iron-sulfur clusters (blue; PDB id = 1BF5). The upper bundle of α -helices defines the transmembrane domain.

Thus, the role of plastocyanin is directly analogous to the role of mitochondrial cytochrome c : It mediates electron transfer between two membrane protein complexes. PSI is a light-driven **plastocyanin:ferredoxin oxidoreductase**. When P700, the specialized chlorophyll a dimer of PSI, is excited by light and oxidized by transferring its e^- to an adjacent chlorophyll a molecule that serves as its immediate e^- acceptor, $P700^+$ is formed. (The standard reduction potential for the $P700^+/P700$ couple is about +0.45 V.) $P700^+$ readily gains an electron from plastocyanin.

The immediate electron acceptor for $P700^+$ is a special molecule of chlorophyll. This unique Chl a (A_0) rapidly passes the electron to a specialized quinone (A_1), which in turn passes the e^- to the first in a series of *membrane-bound ferredoxins*. This Fd series ends with a soluble form of ferredoxin, Fd_s , which serves as the immediate electron donor to the flavoprotein that catalyzes $NADP^+$ reduction, namely, ferredoxin: $NADP^+$ reductase.

21.4 | What Is the Molecular Architecture of Photosynthetic Reaction Centers?

What molecular architecture couples the absorption of light energy to rapid electron-transfer events, in turn coupling these e^- transfers to proton translocations so that ATP synthesis is possible? Part of the answer to this question lies in the membrane-associated nature of the photosystems. A major breakthrough occurred in 1984, when Johann Deisenhofer, Hartmut Michel, and Robert Huber reported the first X-ray crystallographic analysis of a membrane protein. To the great benefit of photosynthesis research, this protein was the reaction center from the photosynthetic purple bacterium *Rhodospseudomonas viridis*. This research earned these three scientists the 1988 Nobel Prize in Chemistry.

21.4a The *R. viridis* Photosynthetic Reaction Center Is an Integral Membrane Protein

R. viridis is a photosynthetic prokaryote with a single photosystem that resembles PSII (even though it lacks an OEC and the capacity to oxidize water). The reaction center (145 kDa) of the *R. viridis* photosystem is localized in the plasma membrane of these photosynthetic bacteria and is composed of four different polypeptides, designated *L* (273 amino acid residues), *M* (323 residues), *H* (258 residues), and *cytochrome*

Figure 21.14 The *R. viridis* reaction center (RC). (a) Diagram of the RC showing light activation and path of e^- transfer. (b) Molecular graphic of the *R. viridis* RC including M (yellow), L (blue), H (orange), and the cytochrome (green). (c) Deletion of the *R. viridis* RC protein chains reveals the spatial relationship between its heme, chlorophyll, and quinone prosthetic groups. The iron atom is represented by a sphere (PDB id = 1PRC). (d) The cytochrome subunit is membrane-associated via a diacylglycerol moiety on its N-terminal Cys residue.

(333 amino acid residues) (Figure 21.14a). *L* and *M* each consist of five membrane-spanning α -helical segments; *H* has one such helix, the majority of the protein forming a globular domain in the cytoplasm (Figure 21.14b). The cytochrome subunit contains four heme groups; the N-terminal amino acid of this protein is cysteine. This cytochrome is anchored to the periplasmic face of the membrane via the hydrophobic chains of two fatty acid groups that are esterified to a glyceryl moiety joined via a thioether bond to the Cys (Figure 21.14d). *L* and *M* each bear two *bacteriochlorophyll* molecules (the bacterial version of Chl) and one *bacteriopheophytin*. *L* also has a bound quinone molecule, Q_A . Together, *L* and *M* coordinate an Fe atom. The photochemically active species of the *R. viridis* reaction center, **P870**, is composed of two bacteriochlorophylls, one contributed by *L* and the other by *M*.

21.4b Photosynthetic Electron Transfer by the *R. viridis* Reaction Center Leads to ATP Synthesis

The prosthetic groups of the *R. viridis* reaction center (P870, BChl, BPheo, and the bound quinones) are fixed in a spatial relationship to one another that favors photosynthetic e^- transfer (Figure 21.14a,c). Photoexcitation of P870 (creation of P870*) leads to e^- loss (P870 $^+$) via electron transfer to the nearby bacteriochlorophyll (BChl). The e^- is then transferred via the *L* bacteriopheophytin (BPheo) to Q_A , which is also an *L* prosthetic group. The corresponding site on *M* is occupied by a loosely bound quinone, Q_B , and electron transfer from Q_A to Q_B takes place. An interesting aspect of the system is that *no* electron transfer occurs through *M*, even though it has components apparently symmetric to and identical to the *L* e^- transfer pathway.

The reduced quinone formed at the Q_B site is free to diffuse to a neighboring *cytochrome bc₁* membrane complex, where its oxidation is coupled to H^+ translocation and, hence, ultimately to ATP synthesis (Figure 21.15).

Cytochrome c₂, a periplasmic protein, serves to cycle electrons back to P870 $^+$ via the four hemes of the reaction center cytochrome subunit. A specific tyrosine residue of *L* (Tyr¹⁶²) is situated between P870 and the closest cytochrome heme. This Tyr is the immediate e^- donor to P870 $^+$ and completes the light-driven electron transfer cycle.

Figure 21.15 Photophosphorylation. Photoexcitation of the *R. viridis* RC leads to reduction of a quinone, Q, to form QH₂. Oxidation of QH₂ by the cytochrome *bc*₁ complex leads to H⁺ translocation for ATP synthesis by the *R. viridis* F₁F₀-ATP synthase.

21.4c The Molecular Architecture of PSII Resembles the *R. viridis* Reaction Center Architecture

Some have argued that PSII is the most important enzyme system in the history of life. Its appearance in cyanobacteria about 2.5 billion years ago dramatically altered the trajectory of evolution. PSII accomplishes the light-driven formation of O₂ from two H₂O, and it is directly responsible for all of the oxygen in the atmosphere. The availability of molecular oxygen for highly exergonic oxidative reactions allowed the evolution of energy-intensive organisms such as animals. So animals exist because of PSII.

Type II photosystems of higher plants, green algae, and cyanobacteria contain more than 20 subunits and are considerably more complex than the *R. viridis* reaction center. Interestingly, both type II and type I photosystems show significant similarity to the *R. viridis* reaction center, thus establishing a strong evolutionary connection between reaction centers.

PSII from the thermophilic cyanobacterium *Thermosynechococcus elongatus* is representative of Type II photosystems across all photosynthetic organisms, even higher plants. Such conservation fits well with the evolutionary origin of chloroplasts from cyanobacteria. PSII is a homodimeric structure. Each monomer has a mass of almost 350 kDa and 23 different protein subunits, the 4 largest being the reaction center pair of subunits (**D1** and **D2**) and 2 chlorophyll-containing inner antenna subunits (**CP43** and **CP47**) that bracket D1 and D2 (Figure 21.16). Together, CP43 and CP47 have a total of 26 Chl *a* molecules, and exciton energy is collected and transferred from them to P680. Collectively, the protein subunits in a PSII monomer have at least 34 transmembrane

α -helical segments, 22 of which are found in the D1-D2-CP43-CP47 core structure. D1 and D2 each have five membrane-spanning α -helices. Structurally and functionally, these two subunits are a direct counterpart of the *L* and *M* subunits of the *R. viridis* reaction center. P680 consists of a pair of Chl *a* molecules, with D1 and D2 each contributing one. D1 and D2 each have two other Chl *a* molecules, one near each P680 (**Chl_{D1}** and **Chl_{D2}**, respectively) and another that interacts with CP43/CP47 (Chl_{Z-D1} and Chl_{Z-D2}, respectively) (Figure 21.16). Two equivalents of pheophytin (Pheo) are located on D1 and D2. The tyrosine species D is Tyr¹⁶¹ in the D1 amino acid sequence. Complexed to D2 is a tightly bound plastoquinone molecule, Q_A. Electrons flow from P680* to Chl_{D1} and on to Pheo_{D1}. Pheo_{D1} then transfers the electron to Q_A on D2, where it then moves to a second plastoquinone situated in the Q_B site on D1 (Figure 21.16). Electron transfer from Q_A and Q_B is assisted by the iron atom located between them. Each plastoquinone that enters the Q_B site accepts two electrons derived from water and two H⁺ from the stroma before it is released into the membrane as the hydroquinone PQH₂. Thus, two photons are required to reduce each PQ that enters the Q_B site. The stoichiometry of the electron transfer reaction catalyzed by PSII can be written as

Note, however, that the four protons added to the two PQ to form two PQH₂ arise from the stromal side of the photosynthetic membrane, as four protons released from the two water molecules appear on the luminal side of the membrane. Net proton transfer across the membrane is 1 H⁺/hν for the PSII reaction.

Figure 21.16 Molecular architecture of the *T. elongatus* PSII dimer. **(a)** The arrow shows the path of electron transfer from P680* to Chl_{D1} to Pheo_{D1} to Q_A on D2 and then, via the Fe atom, to Q_B on D1. The Tyr¹⁶¹ residue of D1, (Y_Z), is situated between P680 and the Mn₄CaO₅ cluster (OEC). **(b)** Structure of *T. elongatus* PSII (PDB id = 3BZ1), including chlorophylls of the reaction center and electron-transfer path (green), pheophytins (blue), and the OEC (brick red). (Adapted from Barber, J., 2003. Photosystem II: The engine of life. *Quarterly Review of Biophysics* 36:71–89.)

Electrons withdrawn from water are the source of the electrons needed to restore oxidized P680 (P680^+) back to the P680 state for another cycle of light-driven electron transport. The oxidation of two H_2O molecules results in O_2 formation and is carried out by the oxygen evolving complex (OEC) located on the luminal side of the PSII D1 subunit. These electrons pass from the OEC to P680^+ via Tyr^{161} (also known as Y_Z) of the D1 subunit. The water-binding site of the OEC is a cluster of four manganese, one calcium, and five oxygen atoms (Mn_4CaO_5); an associated Cl^- ion is essential to water oxidation. Protons liberated upon oxidation of these H_2O molecules are passed directly into the thylakoid lumen, where they contribute to the proton gradient generated by photosynthetic electron transport.

21.4d How Does PSII Generate O_2 from H_2O ?

PSII catalyzes what is probably the most thermodynamically difficult reaction in nature, the light-driven oxidation of water to molecular oxygen. The protons and electrons released in this reaction are used to reduce NADP^+ to NADPH and to establish a proton gradient across the photosynthetic membrane that can be tapped to drive chemiosmotic ATP synthesis (see Figure 21.20). Accumulation of molecular oxygen in the atmosphere as a byproduct of the photo-oxidation of water has transformed the planet since the evolutionary appearance of this reaction some 2 billion years ago in cyanobacteria. How does PSII evolve oxygen?

The Structure of the Oxygen-Evolving Complex The architecture of the *Thermosynechococcus* photosynthetic OEC reveals a large globular protein domain juxtaposed on the luminal side of the D1 subunit of PSII (Figure 21.16). The active site of the OEC is identifiable by the Mn_4CaO_5 cluster, as shown in Figure 21.17. This metal cluster is held by Glu^{189} , Asp^{342} , His^{332} , and His^{337} of the PSII D1 subunit and Glu^{354} of CP43. The chloride ion (Cl^-) required for O_2 evolution is believed to be a Ca^{2+} ligand. Note also that Tyr^{161} (Y_Z) is situated near the metal cluster, ideally poised to serve in electron transfer between H_2O and P680^+ . When four e^- have been removed from the cluster (one from each Mn atom) through e^- transfer to PSII via Tyr^{161} , two H_2O molecules provide the four e^- needed to re-reduce the Mn atoms, and O_2 is evolved. One O atom in O_2 comes from the O5 atom of the cluster; the other one comes from either W2 or W3. The four H^+ released contribute to the proton gradient.

Figure 21.17 Structure of the PSII oxygen-evolving complex (OEC). Four Mn atoms (purple) and one Ca atom (green) form the water-splitting metal cluster of the OEC. Bridging O atoms are red. The four water molecules held by the Mn_4CaO_5 cluster (aqua) are labeled W1–W4. O5, the O atom shared by the Ca atom and Mn atoms 3 and 4, along with an O atom from either the W2 or W3 water molecule, give rise to the molecule of O_2 generated by the OEC. Those amino acid side chains of D1 responsible for binding the Mn_4CaO_5 cluster are also shown (PDB id = 4UB6). (Adapted from Figure 2 in Suga, M., et al., 2015. Native structure of photosystem II at 1.95 Å resolution viewed by femtosecond X-ray pulses. *Nature* **517**:99–103.)

21.4e The Molecular Architecture of PSI Resembles the *R. viridis* Reaction Center and PSII Architecture

As with the *T. elongatus* PSII structure, the structure of *T. elongatus* PSI is representative of Type I photosystems across all photosynthetic organisms that possess them, including representatives in the plant kingdom. These PSI structures complete our view of reaction center architecture and confirm the fundamental similarities in organization that exist in these energy-transducing integral membrane proteins. Because of direct correlations with eukaryotic PSI, this cyanobacterial PSI provides a general model for all P700-dependent photosystems.

T. elongatus PSI exists as a cloverleaf-shaped trimeric structure. Each monomer (356 kDa) consists of 12 different protein subunits and 127 cofactors: 96 chlorophyll *a* molecules, 2 phylloquinones, 3 Fe_4S_4 clusters, 22 carotenoids, and 4 lipids that are an intrinsic part of the protein complex (Figure 21.18). All of the electron-transferring prosthetic groups essential to PSI function are localized to just three polypeptides: **PsaA**, **PsaB**, and **PsaC**. PsaA and PsaB (83 kDa each) compose the reaction center heterodimer, a structural pattern now seen as universal in photosynthetic reaction centers. PsaA and PsaB each have 11 transmembrane α -helices, with the 5 most C-terminal α -helices of each serving as the scaffold for the reaction center photosynthetic electron-transfer apparatus. PsaC interacts with the stromal face of the PsaA–PsaB heterodimer. PsaC carries two of the Fe_4S_4 clusters, F_A and F_B , and interacts with **PsaD**. Together they provide a docking site for ferredoxin. The electron-transfer system of PSI consists of three pairs of chlorophyll molecules: **P700** (a heterodimer of Chl *a* and an epimeric form, Chl *a'*) and two additional Chl *a* pairs (symbolized by A_0) that mediate e^- transfer to the quinone acceptor. The *T. elongatus* quinone acceptor (A_1) is **phylloquinone** (also known as vitamin K_1). The **Fx** Fe_4S_4 cluster bridges PsaA and PsaB; two of its four cysteine ligands come from PsaA, the other two from PsaB. Photochemistry begins with exciton absorption at P700, creating P700^* , which has the most negative reduction potential known in nature. Almost instantaneous electron transfer and charge separation (to form $\text{P700}^+ : A_0^-$) is followed by transfer of the electron from A_0 to A_1 , then to F_A , to F_B , and then on to a ferredoxin molecule located at the stromal side of the membrane. The positive charge at P700^+ and the e^- at F_A/F_B represent a charge separation across the membrane, an energized condition created by light. Plastocyanin (or in cyanobacteria, a luminal cytochrome designated *cytochrome c_6*) delivers an electron to fill the electron hole in P700^+ .

Figure 21.19 View of the plant PSI-LHC1 supercomplex, from the stromal side of the thylakoid membrane, including Chl molecules (*green*) and carotenoids and lipids (*red*). The 16 protein subunits are shown as ribbon diagrams in the background, with the positions of the green plant-specific subunits PsaG, PsaH, and PsaK, as well as the LHC1-4 subunits indicated. (PDB id = 3LW5).

21.4f How Do Green Plants Carry Out Photosynthesis?

Higher plant photosystems follow the structural and functional pattern first revealed in the bacterial RC and recapitulated in the cyanobacterial PSI and PSII. With new structural information for the higher plant PSI (from *Pisum sativum*, garden pea) and PSII (from spinach), the fundamental organization pattern for photosystems seen earlier is confirmed for higher plants. Further, the structure of a plant membrane protein supercomplex consisting of the PSI reaction center and its light-harvesting antenna **LHC1** (light-harvesting complex 1) has been described. This supercomplex exists as a monomer composed of 16 distinct protein subunits and 232 prosthetic groups, including 156 chlorophylls, 2 phylloquinones, and 3 Fe_4S_4 clusters (Figure 21.19). The four LHC1 subunits form an arc around one side of the PSI RC. A second light-harvesting complex (LHC2) binds to another side. This plant PSI system, like all photosystems, is remarkably efficient, showing a quantum efficiency of nearly one (one electron transferred per photon falling anywhere within the supercomplex). The many Chl and other light-harvesting molecules of the supercomplex form an integrated network for highly efficient transfer of light energy into P700. Indeed, plant and algal photosystems I and II in nature always exist as supramolecular complexes, with the photosystem surrounded by its particular LHCs. The architecture of the LHCs around photosystems is variable from species to species.

21.5 | What Is the Quantum Yield of Photosynthesis?

The quantum yield of photosynthesis can be defined as the amount of product formed per equivalent of light input. In terms of exciton delivery to reaction center Chl dimers and subsequent e^- transfer, the quantum yield of photosynthesis typically approaches the theoretical limit of one. The quantum yield of photosynthesis can also be expressed

as the ratio of CO_2 fixed or O_2 evolved per photon absorbed. Interestingly, Figure 21.11b indicates an overall stoichiometry of seven H^+ contributed to the proton gradient across the thylakoid membrane for each pair of electrons moving from H_2O to NADP^+ : two into the lumen upon oxidation of a water molecule, four into the lumen from oxidation of PQH_2 by the cytochrome b_6f complex, and one H^+ disappearing from the stroma as NADP^+ is reduced to NADPH . More appropriately, 4 $h\nu$ per photosystem (8 quanta) total would drive the evolution of 1 O_2 , the reduction of 2 NADP^+ , and a contribution of 14 H^+ to the proton gradient.

21.5a The H^+ /ATP Ratio Determines ATP Yield per Quantum

The H^+ /ATP ratio depends on the number of c -subunits in the F_1F_0 -ATP synthase possessed by a cell or organism (chloroplast F_1F_0 -ATP synthase is termed CF_1CF_0 -ATP synthase, C = chloroplast, see below). As we have seen, the number of c -subunits in ATP synthase can vary from organism to organism. Chloroplast CF_1CF_0 -ATP synthase has 14 c -subunits; thus, 3 ATP are formed per 14 H^+ , so 3 ATP would be synthesized in chloroplasts from an input of 8 quanta.

The energy of a photon depends on its wavelength, according to the equation $E = h\nu = hc/\lambda$, where E is energy, c is the speed of light, and λ is its wavelength. Expressed in molar terms, an einstein is the amount of energy in Avogadro's number of photons: $E = Nhc/\lambda$. Light of 700 nm wavelength is the longest-wavelength and the lowest-energy light acting in the eukaryotic photosystems. An einstein of 700 nm light is equivalent in energy to approximately 170 kJ. Eight einsteins of this light, 1360 kJ, theoretically generate 2 moles of NADPH , 3 moles of ATP, and 1 mole of O_2 .

21.5b Calculation of the Photosynthetic Energy Requirements for Hexose Synthesis Depends on $\text{H}^+/h\nu$ and ATP/H^+ Ratios

The fixation of carbon dioxide to form hexose, the dark reactions of photosynthesis, requires considerable energy. The overall stoichiometry of this process (see Equation 21.3) involves 12 NADPH and 18 ATPs. Thus, the ATP/NADPH ratio for CO_2 fixation is 1.5. To generate 12 equivalents of NADPH and 18 equivalents of ATP necessitates the input of 48 einsteins of light, minimally 170 kJ each, or 8160 kJ, from which one mole of hexose would be synthesized. The standard free energy change, ΔG° , for hexose formation from carbon dioxide and water (the exact reverse of cellular respiration) is +2870 kJ/mol. Note that many assumptions underlie these calculations, including assumptions about the ATP/H^+ ratio, the H^+/e^- ratio, and ultimately, the relationship between quantum input and overall yields of NADPH and ATP.

21.6 | How Does Light Drive the Synthesis of ATP?

Light-driven ATP synthesis, or photophosphorylation, is a fundamental part of the photosynthetic process. The conversion of light energy to chemical energy results in electron-transfer reactions, which lead to the generation of reducing power (reduced quinones or NADPH). Coupled with these electron transfers, protons are driven across the thylakoid membranes from the stromal side to the luminal side. These proton translocations occur in a manner analogous to the proton translocations accompanying mitochondrial electron transport that provide the driving force for oxidative phosphorylation (see Chapter 20). Figure 21.11 indicates that proton translocations can occur at a number of sites. For example, protons are produced in the thylakoid lumen upon photolysis of water by PSII. The oxidation–reduction events as electrons pass through the plastoquinone pool and the Q cycle are another source of proton translocations. The proton transfer accompanying NADP^+ reduction also can be envisioned as protons being taken from the stromal side of the thylakoid vesicle. The current view is that three protons are translocated for each electron that flows

from H_2O to NADP^+ . Because this electron transfer requires two photons, one falling at PSII and one at PSI, the overall yield is 1.5 protons per quantum of light.

21.6a The Mechanism of Photophosphorylation Is Chemiosmotic

The thylakoid membrane is asymmetrically organized, or sided, like the mitochondrial membrane. It also shares the property of being a barrier to the passive diffusion of H^+ ions. Photosynthetic electron transport thus establishes an electrochemical gradient, or proton-motive force, across the thylakoid membrane with the interior, or lumen, side accumulating H^+ ions relative to the stroma of the chloroplast. Like oxidative phosphorylation, the mechanism of photophosphorylation is chemiosmotic.

A proton-motive force of approximately -250 mV is needed to achieve ATP synthesis. This proton-motive force, Δp , is composed of a membrane potential, $\Delta\psi$, and a pH gradient, ΔpH (see Chapter 20). The proton-motive force is defined as the free energy difference, ΔG , divided by $\mathcal{F}$, Faraday's constant:

$$\Delta p = \Delta G/\mathcal{F} = \Delta\psi - (2.3 RT/\mathcal{F})\Delta\text{pH} \quad (21.7)$$

In chloroplasts, the value of $\Delta\psi$ is typically -50 to -100 mV and the pH gradient is equivalent to about 3 pH units, so $-(2.3 RT/\mathcal{F})\Delta\text{pH} = -170$ mV. This situation contrasts with the mitochondrial proton-motive force, where the membrane potential contributes relatively more to Δp than does the pH gradient.

21.6b CF_1CF_0 -ATP Synthase Is the Chloroplast Equivalent of the Mitochondrial F_1F_0 -ATP Synthase

The transduction of the electrochemical gradient into the chemical energy represented by ATP is carried out by the chloroplast ATP synthase, which is highly analogous to the mitochondrial F_1F_0 -ATP synthase. The chloroplast enzyme complex is called **CF_1CF_0 -ATP synthase**. Like the mitochondrial complex, CF_1CF_0 -ATP synthase is a heteromultimer of α -, β -, γ -, δ -, ϵ -, a -, b -, and c -subunits (see Chapter 20), consisting of a knoblike structure some 9 nm in diameter (CF_1) attached to a stalked base (CF_0) embedded in the thylakoid membrane. The mechanism of action of CF_1CF_0 -ATP synthase in coupling ATP synthesis to the collapse of the pH gradient is similar to that of the mitochondrial ATP synthase described in Chapter 20. However, spinach chloroplast CF_1CF_0 ATP synthase has 14 c -subunits in its F_0 rotor, whereas the ATP synthase from the cyanobacterium *Spirulina platensis* has 15 c -subunits. Thus, one turn of the spinach F_0 c -subunit ring would require 14 H^+ , and one turn of the *S. platensis* rotor, 15. All proton-translocating ATP synthases have 3 ATP-synthesizing sites, so the H^+/ATP ratio for spinach chloroplasts is 14/3 or 4.67; the H^+/ATP ratio for the *S. platensis* enzyme is 5. The mechanism of photophosphorylation is summarized schematically in Figure 21.20. The structure of the spinach chloroplast CF_1CF_0 -ATP synthase c -subunit assembly is shown in Figure 21.21.

21.6c Photophosphorylation Can Occur in Either a Noncyclic or a Cyclic Mode

Photosynthetic electron transport, which pumps H^+ into the thylakoid lumen, can occur in two modes, linear or cyclic, both of which lead to the establishment of a transmembrane proton-motive force. Thus, both modes are coupled to ATP synthesis and are considered alternative mechanisms of photophosphorylation, even though they are distinguished by differences in their electron-transfer pathways. Noncyclic photophosphorylation is illustrated in Figure 21.20, where electrons activated by quanta at PSII and PSI flow from H_2O to NADP^+ , with concomitant establishment of the proton-motive force driving ATP synthesis. Note that in noncyclic photophosphorylation, O_2 is evolved and NADP^+ is reduced.

Figure 21.20 The mechanism of photophosphorylation. Photosynthetic electron transport establishes a proton gradient that is tapped by the CF_1CF_0 -ATP synthase to drive ATP synthesis. The value, $4.7 \text{ H}^+/\text{ATP}$, is the estimated ratio for the spinach chloroplast CF_1CF_0 -ATP synthase.

Figure 21.21 The c -subunit assembly of the spinach chloroplast CF_1CF_0 -ATP synthase consists of a cylindrical array of 14 identical subunits. Each subunit reversibly binds an H^+ through protonation/deprotonation of its Glu^{61} side chain (PDB id = 2W5J).

21.6d Cyclic Photophosphorylation Generates ATP but Not NADPH or O_2

In cyclic photophosphorylation, the electron hole in P700^+ created by electron loss from P700 is filled *not* by an electron derived from H_2O via PSII but by a cyclic pathway in which the photoexcited electron returns ultimately to P700^+ , as described earlier in Section 21.3c and illustrated in Figure 21.22. In a representative higher plant (barley

Figure 21.22 The pathway of cyclic photophosphorylation by PSI. See text for a discussion of the $H^+/h\nu$ ratio. (Adapted from Arnon, D. I., 1984. The discovery of photosynthetic phosphorylation. *Trends in Biochemical Sciences* 9:258–262.)

[*Hordeum vulgare*]), the 29-subunit NADH dehydrogenase-like (NDH) counterpart of FNR mediates cyclic electron transfer through association with PSI to form a super-complex composed of two PSI-LHC1 complexes per NDH.

Proton translocations accompany these cyclic electron transfer events so that ATP synthesis can be achieved. In cyclic photophosphorylation, ATP is the sole product of energy conversion. No NADPH is generated, and because PSII is not involved, no oxygen is evolved. Cyclic photophosphorylation theoretically yields two H^+ per e^- ($2 H^+/h\nu$) from the operation of the cytochrome b_6f complex. Thus, cyclic photophosphorylation provides a mechanism for supplementing ATP production. Estimates indicate that cyclic photophosphorylation may contribute about 10% of total chloroplast ATP synthesis and thereby elevate the ATP/NADPH ratio.

21.7 | How Is Carbon Dioxide Used to Make Organic Molecules?

As we began this chapter, we saw that photosynthesis traditionally is equated with the process of CO_2 fixation, that is, the net synthesis of carbohydrate from CO_2 . Indeed, the capacity to perform net accumulation of carbohydrate from CO_2 distinguishes the phototrophic (and autotrophic) organisms from heterotrophs. Although animals possess enzymes capable of linking CO_2 to organic acceptors, they cannot achieve a net accumulation of organic material by these reactions. For example, fatty acid biosynthesis is primed by covalent attachment of CO_2 to acetyl-CoA to form malonyl-CoA. Nevertheless, this “fixed CO_2 ” is liberated in the very next reaction, so no net CO_2 incorporation occurs.

Elucidation of the pathway of CO_2 fixation represents one of the earliest applications of radioisotope tracers to the study of biology. In 1945 Melvin Calvin and his colleagues at the University of California, Berkeley, were investigating photosynthetic CO_2 fixation in *Chlorella*. Using $^{14}CO_2$, they traced the incorporation of radio-

Figure 21.23 Molecular graphic of ribulose biphosphate carboxylase. The enzyme consists of 8 equivalents each of two subunits. Clusters of four small subunits (orange and red) are located at each end of the symmetric octamer formed by the *L* subunits (light and dark green). The active sites are revealed in the ribbon diagram by bound ribulose-1,5-bisphosphate (yellow; PDB id = 1RXO).

active ^{14}C into organic products and found that the earliest labeled product was **3-phosphoglycerate** (see Figure 17.14). Although this result suggested that the CO_2 acceptor was a two-carbon compound, further investigation revealed that, in reality, two equivalents of 3-phosphoglycerate were formed following addition of CO_2 to a five-carbon (pentose) sugar:

21.7a Ribulose-1,5-Bisphosphate Is the CO_2 Acceptor in CO_2 Fixation

The five-carbon CO_2 acceptor was identified as **ribulose-1,5-bisphosphate (RuBP)**, and the enzyme catalyzing this key reaction of CO_2 fixation is **ribulose biphosphate carboxylase/oxygenase**, or, in the jargon used by workers in this field, **rubisco**. The name *ribulose biphosphate carboxylase/oxygenase* reflects the fact that rubisco catalyzes the reaction of either CO_2 or, alternatively, O_2 with RuBP. Rubisco is found in the chloroplast stroma. It is a very abundant enzyme, constituting more than 15% of the total chloroplast protein. Given the preponderance of plant material in the biosphere, rubisco is probably the world's most abundant protein. Rubisco in higher plants is a 550 kDa heteromultimeric ($\alpha_8\beta_8$) complex consisting of eight identical large subunits (55 kDa) and eight small subunits (15 kDa) (Figure 21.23). The large subunit is the catalytic unit of the enzyme. It binds both substrates (CO_2 and RuBP) and Mg^{2+} (a divalent cation essential for enzymatic activity). The small subunit modulates the catalytic efficiency of the enzyme, increasing k_{cat} more than 100-fold. The rubisco large subunit is encoded by a gene within the chloroplast DNA, whereas the small subunit is encoded by a multigene family in the nuclear DNA. Assembly of active rubisco heteromultimers occurs within chloroplasts following transit of the small subunit polypeptide across the chloroplast membrane. Unlike most proteins, the large subunits of rubisco do not readily fold into structures that spontaneously assemble with the small subunits to form the functional holoenzyme. Instead, formation of L_8S_8 rubisco molecules requires specific chaperones to achieve its hexadecameric final state.

21.7b 2-Carboxy-3-Keto-Arabinol Is an Intermediate in the Ribulose-1,5-Bisphosphate Carboxylase Reaction

The addition of CO_2 to ribulose-1,5-bisphosphate results in the formation of an enzyme-bound intermediate, **2-carboxy-3-keto-arabinol** (Figure 21.24, II). This intermediate arises when CO_2 adds to the enediol intermediate generated from ribulose-1,5-bisphosphate. Hydrolysis of the $\text{C}_2\text{—C}_3$ bond of the intermediate generates two molecules of 3-phosphoglycerate. The CO_2 ends up as the carboxyl group of one of the two molecules.

Figure 21.24 The ribulose biphosphate carboxylase reaction. Mg^{2+} at the active site aids in stabilizing the 2,3-enediol transition state (II) for CO_2 addition and in facilitating the carbon–carbon bond cleavage that leads to product formation.

21.7c Ribulose-1,5-Bisphosphate Carboxylase Exists in Inactive and Active Forms

Rubisco exists in three forms: an inactive form, designated *E*; a carbamylated, but inactive, form, designated *EC*; and an active form, *ECM*, which is carbamylated and has Mg^{2+} at its active sites as well. Carbamylation of rubisco takes place by addition of CO_2 to its Lys^{201} $\epsilon\text{-NH}_2$ groups (to give $\epsilon\text{-NH-COO}^-$ derivatives). The CO_2 molecules used to carbamylate Lys residues do not become substrates. The carbamylation reaction occurs spontaneously at slightly alkaline pH (pH 8). Carbamylation of rubisco completes the formation of a binding site for the Mg^{2+} that participates in the catalytic reaction. Once Mg^{2+} binds to *EC*, rubisco achieves its active *ECM* form. Activated rubisco displays a K_m for CO_2 of 10 to 20 μM . The relative abundance of CO_2 in the atmosphere is low, about 0.04%. The concentration of CO_2 dissolved in aqueous solutions equilibrated with air is about 10 μM .

Substrate RuBP binds much more tightly to the inactive *E* form of rubisco ($K_D = 20 \text{ nM}$) than to the active *ECM* form (K_m for RuBP = 20 μM). Thus, RuBP is also a potent inhibitor of rubisco activity. Release of RuBP from the active site of rubisco is mediated by **rubisco activase**, a member of the AAA + ATPase family of proteins involved in conformational remodeling of other proteins. Rubisco activase is a *regulatory protein*; it binds to *E*-form rubisco near its catalytic site and, in an ATP-dependent reaction, promotes the release of RuBP. Rubisco then becomes activated by carbamylation and Mg^{2+} binding. Rubisco activase itself is activated in an indirect manner by light. Thus, light is the ultimate activator of rubisco. Even when activated, rubisco is a remarkably inefficient enzyme, catalyzing the carboxylation of only 2 to 5 RuBP molecules per second. Thus, plants must produce large amounts of it to meet their CO_2 fixation needs.

21.7d CO_2 Fixation into Carbohydrate Proceeds via the Calvin–Benson Cycle

The immediate product of CO_2 fixation, 3-phosphoglycerate, must undergo a series of transformations before the net synthesis of carbohydrate is realized. Among carbohydrates, hexoses (particularly glucose) occupy center stage. Glucose-1-P units are the building blocks for both cellulose and starch synthesis. These plant polymers constitute the most abundant organic material in the living world, and thus, the central focus on glucose-1-P as the ultimate end product of CO_2 fixation is amply justified. Also, sucrose ($\alpha\text{-D-glucopyranosyl-(1}\rightarrow\text{2)-}\beta\text{-D-fructofuranoside}$), the major carbon form translocated out of leaves to other plant tissues, is synthesized from G-1-P. In nonphotosynthetic tissues, sucrose is metabolized via glycolysis and the TCA cycle to produce ATP.

The set of reactions that transforms 3-phosphoglycerate into hexose is named the **Calvin–Benson cycle** (often referred to simply as the Calvin cycle) for its discoverers. The reaction series is indeed cyclic because not only must carbohydrate appear as an end product, but the five-carbon acceptor, RuBP, must be regenerated to provide for continual CO_2 fixation. Balanced equations that schematically represent this situation are

Each number in parentheses represents the number of carbon atoms in a compound, and the number preceding the parentheses indicates the stoichiometry of the reaction. Thus, 6(1), or 6 CO_2 , condense with 6(5) or 6 RuBP to give 12 3-phosphoglycerates. These twelve 3-PG are the primary products of CO_2 fixation and they can be used for a wide variety of purposes. The Calvin cycle describes their fate as precursors to hexose synthesis, whereby the 12(3)s are rearranged to form one hexose 1(6) and regenerate the six 5-carbon (RuBP) acceptors.

21.7e
Rubisco and the Enzymes of the Calvin Cycle Serve Three Metabolic Purposes

Rubisco and the Calvin cycle enzymes serve three important ends:

1. Rubisco constitutes the predominant CO₂ fixation enzyme in nature.
2. The Calvin cycle enzymes accomplish the reduction of 3-phosphoglycerate, the primary product of CO₂ fixation, to glyceraldehyde-3-phosphate so that carbohydrate synthesis becomes feasible.
3. The Calvin cycle enzymes catalyze reactions that transform three-carbon compounds into four-, five-, six-, and seven-carbon compounds.

Most of the enzymes mediating the reactions of the Calvin cycle also participate in either glycolysis (see Chapter 18) or the pentose phosphate pathway (see Chapter 22). The aim of the Calvin scheme is to account for hexose formation from 3-phosphoglycerate. In the course of this metabolic sequence, the NADPH and ATP produced in the light reactions are consumed, as indicated earlier in Equation 21.3.

The overall series of reactions starts with *ribulose biphosphate carboxylase* catalyzing formation of 3-phosphoglycerate from CO₂ and RuBP and concludes with **ribulose-5-phosphate kinase** (also called *phosphoribulose kinase*), which forms RuBP (Figure 21.25 and Table 21.1). The carbon balance is given at the right side of Table 21.1. Several features of the reactions in this table merit discussion. Note that a total of 18 equivalents of ATP consumed in hexose formation are expended (reactions 2 and 15): 12 to form 12 equivalents of 1,3-bisphosphoglycerate from 3-phosphoglycerate by a reversal of the normal glycolytic reaction catalyzed by **3-phosphoglycerate kinase** and six to phosphorylate Ru-5-P to regenerate 6 RuBP. All 12 NADPH equivalents are used in reaction 3. Plants possess an **NADPH-specific glyceraldehyde-3-phosphate dehydrogenase**, which contrasts with its glycolytic counterpart in its specificity for NADP over NAD and in the direction in which the reaction normally proceeds.

Table 21.1 The Calvin Cycle Series of Reactions		
Reactions 1 through 15 constitute the cycle that leads to the formation of one equivalent of glucose. The enzyme catalyzing each step, a concise reaction, and the overall carbon balance are given. Numbers in parentheses show the numbers of carbon atoms in the substrate and product molecules. Prefix numbers indicate in a stoichiometric fashion how many times each step is carried out in order to provide a balanced net reaction.		
1. Ribulose biphosphate carboxylase: 6 CO ₂ + 6 H ₂ O + 6 RuBP	→ 12 3-PG	6(1) + 6(5) → 12(3)
2. 3-Phosphoglycerate kinase: 12 3-PG + 12 ATP	→ 12 1,3-BPG + 12 ADP	12(3) → 12(3)
3. NADP ⁺ -glyceraldehyde-3-P dehydrogenase: 12 1,3-BPG + 12 NADPH + 12 H ⁺	→ 12 NADP ⁺ + 12 G-3-P + 12 P _i	12(3) → 12(3)
4. Triose-P isomerase: 5 G-3-P	→ 5 DHAP	5(3) → 5(3)
5. Aldolase: 3 G-3-P + 3 DHAP	→ 3 FBP	3(3) + 3(3) → 3(6)
6. Fructose biphosphatase: 3 FBP + 3 H ₂ O	→ 3 F-6-P + 3 P _i	3(6) → 3(6)
7. Phosphoglucoisomerase: 1 F-6-P	→ 1 G-6-P	1(6) → 1(6)
8. Phosphoglucomutase: 1 G-6-P	→ GLUCOSE-1-P The remainder of the pathway involves regenerating six RuBP acceptors (= 30 C) from the leftover two F-6-P (12 C), four G-3-P (12 C), and two DHAP (6 C).	1(6) → 1(6)
9. Transketolase: 2 F-6-P + 2 G-3-P	→ 2 Xu-5-P + 2 E-4-P	2(6) + 2(3) → 2(5) + 2(4)
10. Aldolase: 2 E-4-P + 2 DHAP	→ 2 sedoheptulose-1,7-bisphosphate (SBP)	2(4) + 2(3) → 2(7)
11. Sedoheptulose biphosphatase: 2 SBP + 2 H ₂ O	→ 2 S-7-P + 2 P _i	2(7) → 2(7)
12. Transketolase: 2 S-7-P + 2 G-3-P	→ 2 Xu-5-P + 2 R-5-P	2(7) + 2(3) → 4(5)
13. Phosphopentose epimerase: 4 Xu-5-P	→ 4 Ru-5-P	4(5) → 4(5)
14. Phosphopentose isomerase: 2 R-5-P	→ 2 Ru-5-P	2(5) → 2(5)
15. Phosphoribulose kinase: 6 Ru-5-P + 6 ATP	→ 6 RuBP + 6 ADP	6(5) → 6(5)
Net: 6 CO ₂ + 18 ATP + 12 NADPH + 12 H ⁺ + 11 H ₂ O	→ glucose-1-P + 18 ADP + 17 P _i + 12 NADP ⁺	6(1) → 1(6)

Figure 21.25 The Calvin-Benson cycle of reactions. The line thickness and number (in a blue circle) associated with the arrow at each step indicates the number of molecules reacting in a turn of the cycle that produces one molecule of glucose. Reactions are numbered as in Table 21.1.

21.7f The Calvin Cycle Reactions Can Account for Net Hexose Synthesis

When carbon rearrangements are balanced to account for net hexose synthesis, five of the glyceraldehyde-3-phosphate molecules are converted to dihydroxyacetone phosphate (DHAP). Three of these DHAPs then condense with three glyceraldehyde-3-P via the aldolase reaction to yield three hexoses in the form of fructose-1,6-bisphosphate (Figure 21.25). (Recall that the ΔG° for the aldolase reaction in the glycolytic direction is +23.9 kJ/mol. Thus, the aldolase reaction running in reverse in the Calvin cycle would be thermodynamically favored under standard-state conditions.) Taking one FBP to glucose-1-P, the desired product of this scheme, leaves 30 carbons, distributed as 2 fructose-6-phosphates, 4 glyceraldehyde-3-phosphates, and 2 DHAP. These 30 Cs are reorganized into 6 RuBP by reactions 9 through 15. Step 9 and steps 12 through 14 involve carbohydrate rearrangements like those in the pentose phosphate pathway (see Chapter 22). Reaction 11 is mediated by **sedoheptulose-1,7-bisphosphatase**. This phosphatase is unique to plants; it generates sedoheptulose-7-P, the seven-carbon sugar serving as the transketolase substrate. Likewise, **phosphoribulose kinase** carries out the unique plant function of providing RuBP from Ru-5-P (reaction 15). The net conversion accounts for the fixation of 6 equivalents of carbon dioxide into 1 hexose at the expense of 18 ATP and 12 NADPH.

21.7g The Carbon Dioxide Fixation Pathway Is Indirectly Activated by Light

Plant cells contain mitochondria and can carry out cellular respiration (glycolysis, the citric acid cycle, and oxidative phosphorylation) to provide energy in the dark. Futile cycling of carbohydrate to CO_2 by glycolysis and the citric acid cycle in one direction and CO_2 to carbohydrate by the CO_2 fixation pathway in the opposite direction is thwarted through regulation of the Calvin cycle (Figure 21.26). In this regulation the activities of key Calvin cycle enzymes are coordinated with the output of photosynthesis. In effect, these enzymes respond indirectly to **light activation**. Thus, when light energy is available to generate ATP and NADPH for CO_2 fixation, the Calvin cycle proceeds. In the dark, when ATP and NADPH cannot be produced by photosynthesis, fixation of CO_2 ceases. The light-induced changes in the chloroplast, which regulate key Calvin cycle enzymes, include (1) *changes in stromal pH*, (2) *generation of reducing power*, and (3) *Mg^{2+} efflux from the thylakoid lumen*.

Figure 21.26 Light regulation of CO_2 fixation prevents a substrate cycle between cellular respiration and hexose synthesis by CO_2 fixation.

Figure 21.27 Light-induced pH changes in chloroplast compartments. These pH changes modulate the activity of key Calvin cycle enzymes.

Light Induces pH Changes in Chloroplast Compartments As discussed in Section 21.6, illumination of chloroplasts leads to light-driven pumping of protons into the thylakoid lumen, which causes pH changes in both the stroma and the thylakoid lumen (Figure 21.27). The stromal pH rises, typically to pH 8. Because rubisco and rubisco activase are more active at pH 8, CO_2 fixation is activated as stromal pH rises. *Fructose-1,6-bisphosphatase*, *ribulose-5-phosphate kinase*, and *glyceraldehyde-3-phosphate dehydrogenase* all have alkaline pH optima. Thus, their activities increase as a result of the light-induced pH increase in the stroma.

Light Energy Generates Reducing Power Illumination of chloroplasts initiates photosynthetic electron transport, which generates reducing power in the form of reduced ferredoxin. In turn, Fd_{red} leads to reduced thioredoxin via *ferredoxin–thioredoxin reductase* (FTR; Figure 21.28). Thioredoxin is a small (12 kDa) protein possessing in its reduced state a pair of sulfhydryls ($-\text{SH HS}-$), which upon oxidation form a disulfide bridge ($-\text{S}-\text{S}-$). Several Calvin cycle enzymes have pairs of cysteine residues that are involved in a disulfide–sulfhydryl transition between an inactive ($-\text{S}-\text{S}-$) and an active ($-\text{SH HS}-$) form. These enzymes include *fructose-1,6-bisphosphatase* (residues Cys¹⁷⁴ and Cys¹⁷⁹), *NADP⁺-malate dehydrogenase* (residues Cys¹⁰ and Cys¹⁵), and *ribulose-5-phosphate kinase* (residues Cys¹⁶ and Cys⁵⁵). Thus, light activates these key enzymes through this ferredoxin-dependent, thioredoxin-mediated pathway (Figure 21.28).

Figure 21.28 The pathway for light-regulated reduction of Calvin cycle enzymes. Light-generated reducing power (Fd_{red} = reduced ferredoxin) provides e^- for reduction of thioredoxin (T) by FTR.

Light Induces Movement of Mg^{2+} Ions from the Thylakoid Vesicles into the Stroma When light-driven proton pumping across the thylakoid membrane occurs, a concomitant efflux of Mg^{2+} ions from vesicles into the stroma is observed. This efflux of Mg^{2+} somewhat counteracts the charge accumulation due to H^+ influx and is one reason why the membrane potential change in response to proton pumping is less in chloroplasts than in mitochondria (see Equation 21.7). Both *ribulose biphosphate carboxylase* and *fructose-1,6-bisphosphatase* are Mg^{2+} -activated enzymes, and Mg^{2+} flux into the stroma as a result of light-driven proton pumping stimulates the CO₂ fixation pathway at these key steps. Activity measurements have indicated that fructose biphosphatase may be the rate-limiting step in the Calvin cycle. The recurring theme of fructose biphosphatase as the target of the light-induced changes in the chloroplasts implicates this enzyme as a key point of control in the Calvin cycle.

21.7h Protein–Protein Interactions Mediated by an Intrinsically Unstructured Protein Also Regulate Calvin–Benson Cycle Activity

The 8.5 kDa chloroplast protein CP12 is an intrinsically unstructured protein (see Chapter 6) that interacts with ribulose-5-P kinase (R5PK) and glyceraldehyde-3-P dehydrogenase (GAPDH) to form a complex. When complexed with CP12, R5PK and GAPDH are relatively inactive. Note that the first of these enzymes is ATP-dependent and the second is NADPH-dependent. Thus, formation of this complex constrains the use of ATP and NADPH, the principal products of the light reactions of photosynthesis. Reduced thioredoxin, formed when PSI is illuminated, interacts with CP12, leading to the dissociation of the GAPDH–CP12–R5PK complex. Uncomplexed R5PK and GAPDH are inherently more active, and operation of the Calvin–Benson cycle is enhanced.

21.8 | How Does Photorespiration Limit CO₂ Fixation?

As indicated in section 21.7a, ribulose biphosphate carboxylase/oxygenase catalyzes an alternative reaction in which O₂ replaces CO₂ as the substrate added to RuBP (Figure 21.29a). The *ribulose-1,5-bisphosphate oxygenase* reaction diminishes plant productivity because it leads to loss of RuBP, the essential CO₂ acceptor. The K_m for O₂ in this oxygenase reaction is about 200 μM . Given the relative abundance of CO₂ and O₂ in the atmosphere and their relative K_m values in these rubisco-mediated reactions, the ratio of carboxylase to oxygenase activity in vivo is about three or four to one.

The products of ribulose biphosphate oxygenase activity are *3-phosphoglycerate* and *phosphoglycolate*. Dephosphorylation and oxidation convert phosphoglycolate to **glyoxylate**, the α -keto acid of glycine (Figure 21.29b). Transamination yields glycine. In mitochondria, two glycines from photorespiration are converted into one serine and CO₂. This step is the source of the CO₂ evolved during photorespiration. Transamination of glyoxylate to glycine by the product serine yields hydroxypyruvate; reduction of hydroxypyruvate yields glycerate, which can be phosphorylated to 3-phosphoglycerate. 3-Phosphoglycerate can fuel resynthesis of ribulose biphosphate by the Calvin cycle (see Figure 21.25).

Figure 21.29 The oxygenase reaction of rubisco.
(a) The reaction of ribulose biphosphate carboxylase with O_2 and ribulose biphosphate yields 3-phosphoglycerate and phosphoglycolate.
(b) Conversion of two phosphoglycolates to serine + CO_2 .

Other fates of phosphoglycolate are also possible, including oxidation to CO_2 , with the released energy being dissipated as heat. Obviously, agricultural productivity is dramatically lowered by this phenomenon, which, because it is a light-related uptake of O_2 and release of CO_2 , is termed **photorespiration**. As we shall see, certain plants, particularly tropical grasses, have evolved means to circumvent photorespiration. These plants are more efficient users of light for carbohydrate synthesis.

21.8a Tropical Grasses Use the Hatch–Slack Pathway to Capture Carbon Dioxide for CO_2 Fixation

Tropical grasses are less susceptible to the effects of photorespiration, as noted earlier. Studies using $^{14}CO_2$ as a tracer indicated that the first organic intermediate labeled in these plants was not a three-carbon compound but a four-carbon compound. Hal Hatch and Roger Slack, two Australian biochemists, first discovered this

C-4 product of CO₂ fixation, and the C-4 pathway of CO₂ incorporation is named the **Hatch–Slack pathway** after them. The C-4 pathway is not an alternative to the Calvin cycle series of reactions or even a net CO₂ fixation scheme. Instead, it functions as a CO₂ delivery system, carrying CO₂ from the relatively oxygen-rich surface of the leaf to interior cells, where oxygen is lower in concentration and, hence, less effective in competing with CO₂ in the rubisco reaction. Thus, the C-4 pathway is a means of avoiding photorespiration by sheltering the rubisco reaction in a cellular compartment away from high [O₂]. The C-4 compounds serving as CO₂ transporters are malate or *aspartate*.

Compartmentation of these reactions to prevent photorespiration involves the interaction of two cell types: *mesophyll cells* and *bundle sheath cells*. The mesophyll cells take up CO₂ at the leaf surface, where O₂ is abundant, and use it to carboxylate phosphoenolpyruvate to yield OAA in a reaction catalyzed by **PEP carboxylase** (Figure 21.30). This four-carbon dicarboxylic acid is then either reduced to malate by an **NADPH-specific malate dehydrogenase** or transaminated to give *aspartate* in the mesophyll cells. The 4-C CO₂ carrier (malate or aspartate) is then transported to the bundle sheath cells, where it is decarboxylated to yield CO₂ and a 3-C product. The CO₂ is then fixed into organic carbon by the Calvin cycle localized within the bundle sheath cells, and the 3-C product is returned to the mesophyll cells, where it is reconverted to PEP in preparation to accept another CO₂ (Figure 21.30). Plants that use the C-4 pathway are termed **C4 plants**, in contrast to those plants with the conventional pathway of CO₂ uptake (**C3 plants**).

Intercellular Transport of Each CO₂ via a C-4 Intermediate Costs 2 ATPs The transport of each CO₂ requires the expenditure of two high-energy phosphate bonds. The energy of these bonds is expended in the phosphorylation of pyruvate to PEP (phosphoenolpyruvate) by the plant enzyme **pyruvate-P_i dikinase**; the products are PEP, AMP, and pyrophosphate (PP_i). This represents a unique phosphotransferase reaction in that

Figure 21.30 Essential features of the compartmentation and biochemistry of the Hatch–Slack pathway of carbon dioxide uptake in C4 plants.

both the β - and γ -phosphates of a single ATP are used to phosphorylate the two substrates, pyruvate and P_i . The reaction mechanism involves an enzyme phosphohistidine intermediate. The γ -phosphate of ATP is transferred to P_i , whereas formation of E-His-P occurs by addition of the β -phosphate from ATP:

Pyruvate- P_i dikinase is regulated by reversible phosphorylation of a threonine residue, the nonphosphorylated form being active. Interestingly, ADP is the phosphate donor in this interconvertible regulation. Despite the added metabolic expense of two phosphodiester bonds for each equivalent of carbon dioxide taken up, CO_2 fixation is more efficient in C4 plants, provided that light intensities and temperatures are both high. (As temperature rises, photorespiration in C3 plants rises and efficiency of CO_2 fixation falls.) Tropical grasses that are C4 plants include sugarcane, maize, and crabgrass. In terms of photosynthetic efficiency, cultivated fields of sugarcane represent the pinnacle of light-harvesting efficiency. Approximately 8% of the incident light energy on a sugarcane field appears as chemical energy in the form of CO_2 fixed into carbohydrate. This efficiency compares dramatically with the estimated photosynthetic efficiency of 0.2% for uncultivated plant areas. Research on photorespiration is actively pursued in hopes of enhancing the efficiency of agriculture by controlling this wasteful process. Synthetic biology research focused on dramatically increasing plant productivity would help provide enough food for the growing global population. Such initiatives include (1) improving rubisco's catalytic activity and specificity for CO_2 ; (2) metabolic engineering plants to limit the deleterious effects of photorespiration; and (3) the transformation of C3 plants into C4 plants. Rice, a very important food source for much of humanity, is a C3 plant. Converting rice to a C4 plant would significantly enhance its yield.

21.8b Cacti and Other Desert Plants Capture CO_2 at Night

In contrast to C4 plants, which have separated CO_2 uptake and fixation into distinct cells to minimize photorespiration, succulent plants native to semiarid and tropical environments separate CO_2 uptake and fixation in time. Carbon dioxide (as well as O_2) enters the leaf through microscopic pores known as **stomata**, and water vapor escapes from plants via these same openings. In nonsucculent plants, the stomata are open during the day, when light can drive photosynthetic CO_2 fixation, and closed at night. Succulent plants, such as the *Cactaceae* (cacti) and *Crassulaceae*, cannot open their stomata during the heat of day because any loss of precious H_2O in their arid habitats would doom them. Instead, these plants open their stomata to take up CO_2 only at night, when temperatures are lower and water loss is less likely. This carbon dioxide is immediately incorporated into PEP to form OAA by PEP carboxylase; OAA is then reduced to malate by malate dehydrogenase and stored within vacuoles until morning. During the day, the malate is released from the vacuoles and decarboxylated to yield CO_2 and a 3-C product. The CO_2 is then fixed into organic carbon by rubisco and the reactions of the Calvin cycle. Because this process involves the accumulation of organic acids (OAA, malate) and is common to succulents of the *Crassulaceae* family, it is referred to as *crassulacean acid metabolism*, and plants capable of it are called *CAM plants*.

Foundational Biochemistry Things You Should Know after Reading Chapter 21.

- The vast majority of energy used by living organisms can be traced to solar energy captured by photosynthesis.
- Photosynthesis is often expressed in terms of CO₂ fixation into carbohydrates.
- The capture of light energy in photosynthesis occurs in membranes.
- Chloroplasts are plant organelles devoted principally to photosynthesis.
- The capture of light energy during photosynthesis is localized to the inner membrane of chloroplasts, the thylakoid membrane.
- Chloroplasts possess an inner compartment not found in mitochondria, the thylakoid lumen.
- Photosynthesis consists of light-dependent (light) reactions and light-independent (dark) reactions.
- The light reactions are responsible for O₂ evolution, NADPH reduction, and ATP synthesis and are associated with the chloroplast thylakoid membranes.
- The dark reactions carry out the ATP- and NADPH-dependent process of CO₂ fixation and occur in the stroma of the chloroplast.
- Water is the ultimate electron donor for photosynthetic NADP⁺ reduction.
- All of the O₂ in the earth's atmosphere was produced by photosynthesis.
- Photosynthesis depends on the photoreactivity of chlorophyll (Chl).
- When light energy is absorbed by Chl, an electron in this pigment is excited to a higher orbital, making the loss of this electron by an oxidation-reduction reaction more likely.
- Chlorophylls and accessory light-harvesting pigments absorb light of differing wavelengths, allowing photosynthetic organisms to capture energy across the visible light spectrum.
- Light energy absorbed by photosynthetic pigments has several possible fates—loss as heat, loss through fluorescence, resonance energy transfer to a neighboring pigment molecule, or transduction into the chemical energy of an oxidation-reduction reaction.
- Photosynthetic units consist of many Chl molecules but only a single reaction-center Chl dimer.
- Oxygenic phototrophs have two Chl-based photosystems, PSI and PSII.
- P700 is the PSI reaction-center Chl dimer.
- P60 is the PSII reaction-center Chl dimer.
- Chl exists in photosynthetic membranes in association with proteins.
- The Chl-containing protein complexes are PSI, PSII, and light-harvesting complexes (LHCs).
- PSI and PSII participate in photosynthesis, with PSII catalyzing the light-driven oxidation of water to O₂ and the generation of a weak reductant, and PSI catalyzing the light-driven reduction of NADP⁺.
- Together, PSI and PSII carry out the light-driven transfer of electrons from H₂O to NADP⁺, a process known as linear electron flow (LEF).
- Cyclic electron flow (CEF) in photosynthesis occurs when the electron lost from light-activated P700* returns to it via the cytochrome *b₆f* complex.
- Transfer of reducing equivalents through the cytochrome *b₆f* complex leads to proton translocations that contribute to ATP synthesis.
- Synthesis of ATP by means of a proton gradient established by light-driven electron transport is called photophosphorylation.
- The pathway of photosynthetic electron transfer is called the Z scheme.
- Three membrane-spanning supramolecular complexes achieve the Z scheme of electron transfer: PSII, cytochrome *b₆f* and PSI.
- Plastoquinone and plastocyanin mediate the transfer of electrons from PSII to cytochrome *b₆f* and from cytochrome *b₆f* to PSI, respectively.
- O₂ evolution requires the accumulation of four oxidizing equivalents in PSII.
- Electrons taken from H₂O replace electrons lost upon photo-oxidation of P680.
- X-ray crystallographic solution of the *Rhodospseudomonas viridis* reaction center (RC) established the molecular architecture of reaction centers.
- The *R. viridis* RC is an integral membrane protein containing a reaction-center bacteriochlorophyll dimer (P870), bacteriochlorophyll, bacteriopheophytin, quinone, cytochromes, and a Fe atom.
- The molecular architectures of PSII and PSI resemble the molecular architecture of the *R. viridis* RC.
- The oxygen-evolving complex (OEC) of PSII possesses four Mn²⁺, one Ca²⁺, and five O atoms.
- The plant PSI complex has a quantum efficiency that is near-perfect: Essentially every photon of light absorbed leads to the transfer of an electron.
- The quantum yield of photosynthesis is expressed in terms of O₂ evolution, H⁺ translocation, NADP⁺ reduction and ATP synthesis.
- The photosynthetic energy requirements for hexose synthesis depend on the H⁺/*hν* and the ATP/H⁺ ratios.
- The mechanism of photophosphorylation, like oxidative phosphorylation, is chemiosmotic.
- CF₁CF₀-ATP synthase is the chloroplast equivalent of mitochondrial F₁F₀-ATP synthase.
- The chloroplast ATP synthase *c*-subunit rotor has 14 *c*-subunits, so the H⁺/ATP ratio for ATP synthesis in chloroplasts = 14/3 = 4.67.
- Photophosphorylation can occur in either a noncyclic or a cyclic mode.
- Noncyclic photophosphorylation yields ATP, O₂, and NADPH.
- Cyclic photophosphorylation yields only ATP.
- Ribulose-1,5-bisphosphate is the CO₂ acceptor in the Calvin–Benson carbon dioxide fixation pathway.
- Ribulose bisphosphate carboxylase/oxygenase (rubisco) catalyzes the formation of two 3-phosphoglycerate molecules from ribulose-1,5-bisphosphate + CO₂.
- 2-Carboxy-3-keto-arabinitol is the key intermediate in the rubisco reaction.
- Rubisco exists in an inactive state that is activated through carbamoylation of Lys²⁰¹, coordination of Mg²⁺, and removal of tightly bound substrate by rubisco activase.

- The Calvin–Benson cycle accounts for the vast preponderance of CO₂ fixation in the biosphere, carbohydrate synthesis, and the production of four-, five-, six-, and seven-carbon sugars.
- The conversion of 6 CO₂ to 1 hexose requires 12 NADPH and 18 ATP.
- The Calvin–Benson cycle is indirectly activated by light through light-driven pH changes in the chloroplast compartments, reduction of disulfides in key enzymes to pairs of —SH groups, and Mg²⁺ movement from the thylakoid lumen into the stroma.
- Protein–protein interactions mediated by an intrinsically unstructured protein (IUP) also regulate the Calvin–Benson cycle activity.
- Photorespiration limits CO₂ fixation through the wasteful consumption of RuBP by the oxygenase activity of rubisco.
- Tropical grasses use the Hatch–Slack pathway to capture carbon dioxide for CO₂ fixation.
- In tropical grasses, carbon dioxide capture occurs in mesophyll cells and fixation occurs in bundle sheath cells.
- Pyruvate-P_i kinase is a key enzyme in PEP synthesis for CO₂ capture.
- Cacti and other succulent plants of arid climates capture CO₂ at night.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Mg²⁺ in Chlorophyll** Give a possible explanation as to why Mg²⁺, and not Fe²⁺, is in the center of chlorophyll?
- P700* Has the Most Negative Standard Reduction Potential Found in Nature** In photosystem I, P700 in its ground state has an $\mathcal{E}_0' = +0.4$ V. Excitation of P700 by a photon of 700-nm light alters the $\mathcal{E}_0'$ of P700* to -0.6 V. What is the efficiency of energy capture in this light reaction of P700?
- PSII Has the Most Positive Standard Reduction Potential Found in Nature** What is the $\mathcal{E}_0'$ for the light-generated primary oxidant of photosystem II if the light-induced oxidation of water (which leads to O₂ evolution) proceeds with a ΔG° of -25 kJ/mol?
- Equating the Energy of an Oxidation–Reduction Potential Difference and the Energy for ATP Synthesis** (Integrates with Chapters 3 and 20.) Assuming that the concentrations of ATP, ADP, and P_i in chloroplasts are 3, 0.1, and 10 mM, respectively, what is the ΔG for ATP synthesis under these conditions? Photosynthetic electron transport establishes the proton-motive force driving photophosphorylation. What redox potential difference is necessary to achieve ATP synthesis under the foregoing conditions, assuming 1.3 ATP equivalents are synthesized for each electron pair transferred?
- The Q Cycle in Photosynthesis** (Integrates with Chapter 20.) Write a balanced equation for the Q cycle as catalyzed by the cytochrome *b₆f* complex of chloroplasts.
- The Relative Efficiency of ATP Synthesis in Noncyclic Versus Cyclic Photophosphorylation** If noncyclic photosynthetic electron transport leads to the translocation of $7\text{ H}^+/2\text{e}^-$ and cyclic photosynthetic electron transport leads to the translocation of $2\text{ H}^+/\text{e}^-$, what is the relative photosynthetic efficiency of ATP synthesis (expressed as the number of photons absorbed per ATP synthesized) for noncyclic versus cyclic photophosphorylation? (Assume that the CF₁CF₀–ATP synthase yields 3 ATP/14 H⁺.)
- ΔpH and $\Delta\psi$ in the Chloroplast Proton-Motive Force** (Integrates with Chapter 20.) In mitochondria, the membrane potential ($\Delta\psi$) contributes relatively more to Δp (proton-motive force) than does the pH gradient (ΔpH). The reverse is true in chloroplasts. Why do you suppose that the proton-motive force in chloroplasts can depend more on ΔpH than mitochondria can? Why is ($\Delta\psi$) less in chloroplasts than in mitochondria?
- The Role of Tyr¹⁶¹ in PSII** Predict the consequences of a Y161F mutation in the amino acid sequence of the D1 subunit of PSII.
- H⁺/ATP Ratio in Photosynthetic Bacteria** (Integrates with Chapter 20.) Calculate (in einsteins and in kJ/mol) how many photons would be required by the *Rhodospseudomonas viridis* photophosphorylation system to synthesize 3 ATPs. (Assume that the *R. viridis* F₁F₀–ATP synthase *c*-subunit rotor contains 12 *c*-subunits and that the *R. viridis* cytochrome *bc*₁ complex translocates $2\text{ H}^+/\text{e}^-$.)
- The Standard-State Free Energy Change for NADP-Glyceraldehyde-3-P Dehydrogenase** (Integrates with Chapters 18 and 20.) Calculate ΔG° for the NADP⁺-specific glyceraldehyde-3-P dehydrogenase reaction of the Calvin–Benson cycle.
- Photosynthesis of Glucose** Write a balanced equation for the synthesis of a glucose molecule from ribulose-1,5-bisphosphate and CO₂ that involves the first three reactions of the Calvin cycle and subsequent conversion of the two glyceraldehyde-3-P molecules into glucose.
- Tracing the Fate of CO₂ During Photosynthesis** ¹⁴C-labeled carbon dioxide is administered to a green plant, and shortly thereafter the following compounds are isolated from the plant: 3-phosphoglycerate, glucose, erythrose-4-phosphate, sedoheptulose-1,7-bisphosphate, and ribose-5-phosphate. In which carbon atoms will radioactivity be found?
- Fate of C¹⁸O₂ in the Calvin–Benson Cycle** If the Calvin–Benson cycle proceeded in the presence of C¹⁸O₂ (assuming both oxygens are labeled), in what intermediates or products would the oxygen isotopes appear?
- ROS and Photosynthesis** Is it possible for reactive oxygen species (ROS) to be generated through the photosynthesis process?
- Regulation of CO₂ Fixation During Photosynthesis** The photosynthetic CO₂ fixation pathway is regulated in response to specific effects induced in chloroplasts by light. What is the nature of these effects, and how do they regulate this metabolic pathway?
- Uncoupling in Chloroplasts?** What would happen if the photosynthetically driven proton translocation was uncoupled from ATP synthesis in chloroplasts?
- The Formation of Phosphoglycerate During Photorespiration** Write a balanced equation for the conversion of phosphoglycolate to glyceralate-3-P by the reactions of photorespiration. Does this balanced equation demonstrate that photorespiration is a wasteful process?
- The Source of the Oxygen Atoms in Photosynthetic O₂ Evolution** The overall equation for photosynthetic CO₂ fixation is

$$6\text{ CO}_2 + 6\text{ H}_2\text{O} \longrightarrow \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{ O}_2$$

All the O atoms evolved as O₂ come from water; none come from carbon dioxide. But 12 O atoms are evolved as 6 O₂, and only 6 O atoms appear as 6 H₂O in the equation. Also, 6 CO₂ have 12 O atoms, yet there are only 6 O atoms in C₆H₁₂O₆. How can you account for these discrepancies? (*Hint*: Consider the partial reactions of photosynthesis: ATP synthesis, NADP⁺ reduction, photolysis of water, and the overall reaction for hexose synthesis in the Calvin–Benson cycle.)

- 19. Alternative Oxygen-Evolving Oxidation Reactions** Consider the following alternative oxygen-evolving redox reactions:
 $\text{NO}_3^- \longrightarrow \text{NO}_2^- + \text{O}_2$ and $\text{SO}_4^{2-} \longrightarrow \text{SO}_3^{2-} + \text{O}_2$
 a. Balance these redox reactions.
 b. Explain why NO_3^- and SO_4^{2-} would be poor substitutes for H_2O in the photosynthesis process.
- 20. The Influence of *c*-Subunit Stoichiometry on the Efficiency of ATP Synthesis** The number of *c*-subunits in F_1F_0 -type ATP synthases shows some variation from organism to organism. For example, the yeast ATP synthase contains 10 *c*-subunits, the spinach CF_1CF_0 -ATP synthase has 14, and the cyanobacterium *Spirulina platensis* enzyme apparently has 15.
 a. What is the consequence of *c*-subunit stoichiometry for the H^+/ATP ratio?
 b. What is the relationship between *c*-subunit stoichiometry and the magnitude of Δp (the proton-motive force)?
- 21. The Energetics of Hydroquinone Reduction by Photosynthetic Reaction Centers** The reduction of membrane-associated quinones, such as coenzyme Q and plastoquinones, is a common feature of photosystems (see Figures 21.15, 21.20, and 21.22). Assume $\mathcal{E}_o'$ for $\text{PQ}/\text{PQH}_2 = 0.07 \text{ V}$ and the potential of the ground-state chlorophyll molecule = 0.5 V , calculate ΔG for the reduction of plastoquinone by
 a. 870 nm light.
 b. 700 nm light.
 c. 680 nm light.
- 22. The Energetics of Proton Translocation by the Cytochrome *b₆f* Complex** Plastoquinone oxidation by cytochrome *b₆f* and cytochrome *b_c1* complexes apparently leads to the translocation of $4^+/2e^-$. If $\mathcal{E}_o'$ for cytochrome *f* = 0.365 V (Table 3.3) and $\mathcal{E}_o'$ for $\text{PQ}/\text{PQH}_2 = 0.07 \text{ V}$, calculate ΔG for the coupled reaction:

$$2 h\nu + 4 \text{H}^+_{\text{in}} \longrightarrow 4 \text{H}^+_{\text{out}}$$

 (Assume a value of 23 kJ/mol for the free energy change (ΔG) associated with moving protons from inside to outside.)
- 23. The Overall Free Energy Change for Photosynthetic NADP^+ Reduction** Calculate the overall free energy change (ΔG) for noncyclic photosynthetic electron transport.

$$4 (700 \text{ nm photons}) + 4 (680 \text{ nm photons}) + 2 \text{H}_2\text{O} + 2 \text{NADP}^+ \longrightarrow \text{O}_2 + 2 \text{NADPH} + 2 \text{H}^+$$
- 24. Tyrosine Radical as Primary Electron Acceptor from the OEC** Why is a tyrosine radical, not a serine or threonine radical, better suited to be the primary electron acceptor from the oxygen evolving complex?
- 25. Why can Water be Considered Food for Plants?** In animals and humans, complex organic molecules like carbohydrates, lipids or proteins are considered food. For plants, water can be considered a food. What chemical functions do these two categories of food have in common?
- 26. Light-Harvesting by Accessory Pigments** From Figure 21.5, predict the spectral properties of accessory light-harvesting pigments found in plants.
- 27. Mg^{2+} Movements Upon Chloroplast Illumination** Draw a figure analogous to Figure 21.27, plotting $[\text{Mg}^{2+}]$ in the stroma and thylakoid lumen on the *y*-axis and *dark-light-dark* on the *x*-axis.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

- 28.** Using the ActiveModel for photosystem II, explain why dimerization occurs, and identify the residues that drive dimerization.
- 29.** Look at the Ramachandran plot in the ActiveModel for photosystem II, and determine the ϕ and ψ angles of the α -helices in photosystem II. What are typical ϕ and ψ angles for α -helices?

Think-Pair-Share Question

The transketolase reaction in the Calvin-Benson cycle (Table 21.1 and Figure 21.25) involves the reaction between a ketose and an aldose to yield a different aldose and ketose.

- a. Draw the molecules in the transketolase reaction that uses D-ribose or D-arabinose as the aldose (see Figure 7.2) and D-fructose as the ketose (see Figure 7.3). Use colored pens to illustrate the fragments of the molecules that are exchanged.
- b. For a transketolase reaction that generates D-ribose or D-fructose as a product, suggest a combination of an aldose and a ketose. Draw the molecules in this reaction and use colored pens to illustrate the fragments of the molecules that are exchanged.

(Hint: Transketolases require the ketose to have the C3 and C4 alcohol groups in threose configuration. See Figure 7.2).

Gluconeogenesis, Glycogen Metabolism, and the Pentose Phosphate Pathway

22

*Con pan y vino se anda el camino.
(With bread and wine you can walk your road.)*

Spanish proverb

iStockphoto.com/Jason Alan

◀ A basket of fresh bread. Carbohydrates such as these provide a significant portion of human caloric intake.

Essential Question

As shown in Chapters 18 and 19, the metabolism of sugars is an important source of energy for cells. Animals, including humans, typically obtain significant amounts of glucose and other sugars from the breakdown of starch in their diets. Glucose can also be supplied via breakdown of cellular reserves of glycogen (in animals) or starch (in plants). **What is the nature of gluconeogenesis, the pathway that synthesizes glucose from noncarbohydrate precursors; how is glycogen synthesized from glucose; and how are electrons from glucose used in biosynthesis?**

The ability to synthesize glucose from common metabolites is very important to most organisms. Human metabolism, for example, consumes about 160 ± 20 grams of glucose per day, about 75% of this in the brain. Body fluids carry only about 20 grams of free glucose, and glycogen stores normally can provide only about 180 to 200 grams of free glucose. Thus, the body carries only a little more than a one-day supply of glucose. If glucose is not obtained in the diet, the body must produce new glucose from noncarbohydrate precursors. The term for this activity is **gluconeogenesis**, which means the generation (*genesis*) of new (*neo*) glucose.

Furthermore, muscles consume large amounts of glucose via glycolysis, producing large amounts of pyruvate. In vigorous exercise, muscle cells become anaerobic and pyruvate is converted to lactate. Gluconeogenesis salvages this pyruvate and lactate and reconverts it to glucose.

Another pathway of glucose catabolism, the *pentose phosphate pathway*, is the primary source of NADPH, the reduced coenzyme essential to most reductive biosynthetic processes. For example, NADPH is crucial to the biosynthesis of fatty acids and amino acids. The pentose phosphate pathway also results in the production of ribose-5-phosphate, an essential component of ATP, NAD⁺, FAD, coenzyme A, and particularly DNA and RNA. This important pathway will also be considered in this chapter.

Key Questions

- 22.1 What Is Gluconeogenesis, and How Does It Operate?
- 22.2 How Is Gluconeogenesis Regulated?
- 22.3 How Are Glycogen and Starch Catabolized in Animals?
- 22.4 How Is Glycogen Synthesized?
- 22.5 How Is Glycogen Metabolism Controlled?
- 22.6 Can Glucose Provide Electrons for Biosynthesis?

22.1 | What Is Gluconeogenesis, and How Does It Operate?

This section describes the essential features of gluconeogenesis: the substrates that the pathway utilizes, which organs in animals carry out the pathway, and the four reactions that make the pathway energetically favorable and spontaneous.

22.1a The Substrates for Gluconeogenesis Include Pyruvate, Lactate, and Amino Acids

As noted above, pyruvate and lactate are the principal substrates of gluconeogenesis. In addition to pyruvate and lactate, other noncarbohydrate precursors can be used as substrates for gluconeogenesis in animals. These include most of the amino acids, as well as glycerol and all the TCA cycle intermediates. On the other hand, fatty acids are not substrates for gluconeogenesis in animals, because most fatty acids yield only acetyl-CoA upon degradation, and animals cannot carry out net synthesis of sugars from acetyl-CoA. Lysine and leucine are the only amino acids that are not substrates for gluconeogenesis. These amino acids produce only acetyl-CoA upon degradation. Note also that acetyl-CoA can be a substrate for gluconeogenesis in plants when the glyoxylate cycle is operating (see Section 19.9).

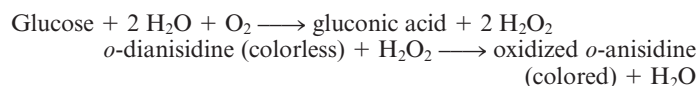

22.1b Nearly All Gluconeogenesis Occurs in the Liver and Kidneys in Animals

Interestingly, the mammalian organs that consume the most glucose, namely, brain and muscle, carry out very little glucose synthesis. The major sites of gluconeogenesis are the liver and kidneys, which account for about 90% and 10% of the body's gluconeogenic activity, respectively. Glucose produced by gluconeogenesis in the liver and

Human Biochemistry

The Chemistry of Glucose Monitoring Devices

Individuals with diabetes must measure their serum glucose concentration frequently, often several times a day. The advent of computerized, automated devices for glucose monitoring has made this necessary chore easier, far more accurate, and more convenient than it once was. These devices all use a simple chemical scheme for glucose measurement that involves oxidation of glucose to gluconic acid by glucose oxidase. This reaction produces two molecules of hydrogen peroxide per molecule of glucose oxidized. The H_2O_2 is then used to oxidize a dye, such as *o*-dianisidine, to a colored product that can be measured:

The amount of colored dye produced is directly proportional to the amount of glucose in the sample.

The patient typically applies a drop of blood (from a finger-prick*) to a plastic test strip that is then inserted into the glucose monitor. Within half a minute, a digital readout indicates the blood glucose value. Modern glucose monitors store several days of glucose measurements, and the data can be easily transferred to a computer for analysis and graphing.

Charles M. Grisham

*How does the monitor deal with getting just the right amount of blood? The blood flows up an absorbent wick by capillary action. It is impossible to overfill this device, but the monitor will give an error signal if not enough blood flows up the strip.

Careers in Chemistry

Dr. Kayunta Johnson-Winters

Dr. Kayunta Johnson-Winters is an Associate Professor at the University of Texas at Arlington and a mechanistic enzymologist with a research focus on F_{420} -dependent enzymes. She double majored in biology and chemistry at Alverno College in Milwaukee and went on to earn a Ph.D. in Biochemistry from the University of Wisconsin-Milwaukee. Dr. Johnson-Winters conducted postdoctoral research with John Enemark at the

University of Arizona on the mechanisms of sulfite oxidizing enzymes.

Her current research uses steady-state and rapid-mixing pre-steady state kinetic methods to investigate reaction intermediates of glucose-6-phosphate dehydrogenase. This enzyme and other F_{420} cofactor dependent enzymes in *Mycobacterium tuberculosis* hold promise as potential drug targets for treatment of tuberculosis.

kidneys is released into the blood and is subsequently absorbed by brain, heart, muscle, and red blood cells to meet their metabolic needs. In turn, pyruvate and lactate produced in these tissues are returned to the liver and kidneys to be used as gluconeogenic substrates.

22.1c Gluconeogenesis Is Not Merely the Reverse of Glycolysis

In some ways, gluconeogenesis is the reverse, or antithesis, of glycolysis. Glucose is synthesized, not catabolized; ATP is consumed, not produced; and NADH is oxidized to NAD^+ , rather than the other way around. However, gluconeogenesis cannot be merely the reversal of glycolysis, for two reasons. First, glycolysis is exergonic, with a ΔG° of approximately -74 kJ/mol. If gluconeogenesis were merely the reverse, it would be a strongly endergonic process and could not occur spontaneously. The energetics of the process must be augmented so that gluconeogenesis can proceed spontaneously. Second, the processes of glycolysis and gluconeogenesis must be regulated in a reciprocal fashion so that when glycolysis is active, gluconeogenesis is inhibited, and when gluconeogenesis is proceeding, glycolysis is turned off. Both of these limitations are overcome by having unique reactions within the routes of glycolysis and gluconeogenesis, rather than a completely shared pathway.

22.1d Gluconeogenesis—Something Borrowed, Something New

The complete route of gluconeogenesis is shown in Figure 22.1, side by side with the glycolytic pathway. Gluconeogenesis employs four different reactions, catalyzed by four different enzymes, for the three steps of glycolysis that are highly exergonic (and highly regulated). In essence, seven of the ten steps of glycolysis are merely reversed in gluconeogenesis. The six reactions between fructose-1,6-bisphosphate and PEP are shared by the two pathways, as is the isomerization of glucose-6-P to fructose-6-P. The three exergonic, regulated reactions—the hexokinase (glucokinase), phosphofructokinase, and pyruvate kinase reactions—are replaced by alternative reactions in the gluconeogenic pathway.

The conversion of pyruvate to PEP that initiates gluconeogenesis is accomplished by two unique reactions. **Pyruvate carboxylase** catalyzes the first, converting pyruvate to oxaloacetate. Then, **PEP carboxykinase** catalyzes the conversion of oxaloacetate to PEP. Conversion of fructose-1,6-bisphosphate to fructose-6-phosphate is catalyzed by a specific phosphatase, **fructose-1,6-bisphosphatase**. The final step to produce glucose, hydrolysis of glucose-6-phosphate, is mediated by **glucose-6-phosphatase**. Each of these steps is considered in detail in the following paragraphs. The overall conversion of pyruvate to PEP by pyruvate carboxylase and PEP carboxykinase has

Figure 22.1 The pathways of gluconeogenesis and glycolysis. Yellow boxes denote reactions unique to gluconeogenesis. Species in *blue*, *green*, and *peach-colored* shaded boxes indicate other entry points for gluconeogenesis (in addition to pyruvate).

a $\Delta G^\circ'$ close to zero but is pulled along by subsequent reactions. The conversion of fructose-1,6-bisphosphate to glucose in the last three steps of gluconeogenesis is strongly exergonic, with a $\Delta G^\circ'$ of about -30.5 kJ/mol. This sequence of two phosphatase reactions separated by an isomerization accounts for most of the free energy release that makes the gluconeogenesis pathway spontaneous.

22.1e Four Enzyme Reactions Are Unique to Gluconeogenesis

1. Pyruvate Carboxylase—A Biotin-Dependent Enzyme—Converts Pyruvate to Oxaloacetate

Initiation of gluconeogenesis occurs in the **pyruvate carboxylase reaction**—the conversion of pyruvate to oxaloacetate.

The reaction takes place in two discrete steps, involves ATP and bicarbonate as substrates, and utilizes biotin as a coenzyme and acetyl-CoA as an allosteric activator. Pyruvate carboxylase is a tetrameric enzyme (with a molecular mass of about 500 kDa). Each monomer possesses a biotin covalently linked to the ϵ -amino group of a lysine residue at the active site (Figure 22.2). The first step of the reaction involves nucleophilic attack of a bicarbonate oxygen at the γ -P of ATP to form **carbonylphosphate** (an activated form of CO_2) and ADP (Figure 22.3). Reaction of carbonylphosphate with biotin occurs rapidly to form N-carboxybiotin, liberating inorganic phosphate. The third step involves abstraction of a proton from the C-3 of pyruvate, forming a carbanion that can attack the carbon of N-carboxybiotin to form oxaloacetate.

Pyruvate Carboxylase Is Allosterically Activated by Acetyl-Coenzyme A Two particularly interesting aspects of the pyruvate carboxylase reaction are (i) allosteric activation of the enzyme by acyl-CoA derivatives and (ii) compartmentation of the reaction in the mitochondrial matrix. The carboxylation of biotin requires the presence (at an allosteric site) of acetyl-CoA or other acylated CoA derivatives. The second half of the carboxylase reaction—the attack by pyruvate to form oxaloacetate—is not affected by CoA derivatives.

Activation of pyruvate carboxylase by acetyl-CoA provides an important physiological regulation. Acetyl-CoA is the primary substrate for the TCA cycle, and oxaloacetate (formed by pyruvate carboxylase) is an important intermediate in both the TCA cycle and the gluconeogenesis pathway. If levels of ATP and/or acetyl-CoA (or other acyl-CoAs)

In most organisms, pyruvate carboxylase is a homotetramer of 130-kDa subunits, with each subunit composed of three functional domains named biotin carboxylase, carboxyl transferase, and biotin carboxyl carrier protein. Shown here is the biotin carboxylase domain of pyruvate carboxylase from *Bacillus thermodenitrificans* (PDB id = 2DZD).

Figure 22.2 Covalent linkage of biotin to an active-site lysine in pyruvate carboxylase.

Figure 22.3 A mechanism for the pyruvate carboxylase reaction. Bicarbonate must be activated for attack by the pyruvate carbanion. This activation is driven by ATP and involves formation of a carbonylphosphate intermediate—a mixed anhydride of carbonic and phosphoric acids. (*Carbonylphosphate* and *carboxyphosphate* are synonyms.)

Figure 22.4 Pyruvate carboxylase is a compartmentalized reaction. Pyruvate is converted to oxaloacetate in the mitochondria. Because oxaloacetate cannot be transported across the mitochondrial membrane, it must be reduced to malate, which is then transported to the cytosol and oxidized back to oxaloacetate before gluconeogenesis can continue.

PEP carboxykinase from *Escherichia coli* with ADP (blue), pyruvate (purple), and Mg^{2+} (orange; PDB id = 1OS1).

are low, pyruvate is directed primarily into the TCA cycle, which eventually promotes the synthesis of ATP. If ATP and acetyl-CoA levels are high, pyruvate is converted to oxaloacetate and consumed in gluconeogenesis. Clearly, high levels of ATP and CoA derivatives are signs that energy is abundant and that metabolites will be converted to glucose (and perhaps even glycogen). If the energy status of the cell is low (in terms of ATP and CoA derivatives), pyruvate is consumed in the TCA cycle. Also, as noted in Chapter 19, pyruvate carboxylase is an important anaplerotic enzyme. Its activation by acetyl-CoA leads to oxaloacetate formation, replenishing the level of TCA cycle intermediates.

Compartmentalized Pyruvate Carboxylase Depends on Metabolite Conversion and Transport The second interesting feature of pyruvate carboxylase is that it is found only in the matrix of the mitochondria. By contrast, the next enzyme in the gluconeogenic pathway, PEP carboxykinase, may be localized in the cytosol, in the mitochondria, or both. For example, rabbit-liver PEP carboxykinase is predominantly mitochondrial, whereas the rat-liver enzyme is strictly cytosolic. In human liver, PEP carboxykinase is found both in the cytosol and in the mitochondria. Pyruvate is transported into the mitochondrial matrix (Figure 22.4), where it can be converted to acetyl-CoA (for use in the TCA cycle) and then to citrate (for fatty acid synthesis). Alternatively, it may be converted directly to OAA by pyruvate carboxylase and used in gluconeogenesis. In tissues where PEP carboxykinase is found only in the mitochondria, oxaloacetate is converted to PEP, which is then transported to the cytosol for gluconeogenesis. However, in tissues that must convert some oxaloacetate to PEP in the cytosol, a problem arises. Oxaloacetate cannot be transported directly across the mitochondrial membrane. Instead, it must first be transformed into malate or aspartate for transport across the mitochondrial inner membrane (Figure 22.4). Cytosolic malate and aspartate are reconverted to oxaloacetate before continuing along the gluconeogenic route.

2. PEP Carboxykinase Converts Oxaloacetate to PEP The second reaction in the gluconeogenic pyruvate–PEP bypass is the conversion of oxaloacetate to PEP.

Production of a high-energy metabolite such as PEP requires energy. The energetic requirements are handled in two ways here. First, the CO_2 added to pyruvate in the pyruvate carboxylase step is removed in the PEP carboxykinase reaction. Decarboxylation is a favorable process and helps drive the formation of the very high-energy enol phosphate in PEP. This decarboxylation drives a reaction that would otherwise be highly endergonic. Note the inherent metabolic logic in this pair of reactions: Pyruvate carboxylase consumed an ATP to drive a carboxylation so that the PEP carboxykinase could use the decarboxylation to facilitate formation of PEP. Second, another high-energy phosphate is consumed by the carboxykinase. Mammals and various other organisms use GTP in this reaction, rather than ATP. The use of GTP here is equivalent to the consumption of an ATP, due to the activity of the **nucleoside diphosphate kinase** (see Figure 19.2). The substantial free energy of hydrolysis of GTP is crucial to the synthesis of PEP in this step. The overall ΔG for the pyruvate carboxylase and PEP carboxykinase reactions under physiological conditions in the liver is -22.6 kJ/mol . Once PEP is formed in this way, the phosphoglycerate mutase, phosphoglycerate kinase, glyceraldehyde-3-P dehydrogenase, aldolase, and triose phosphate isomerase reactions act to eventually form fructose-1,6-bisphosphate, as shown in Figure 22.1.

3. Fructose-1,6-Bisphosphatase Converts Fructose-1,6-Bisphosphate to Fructose-6-Phosphate The hydrolysis of fructose-1,6-bisphosphate to fructose-6-phosphate is catalyzed by fructose-1,6-bisphosphatase.

Like all phosphate ester hydrolyses, this is a thermodynamically favorable (exergonic) reaction under standard-state conditions ($\Delta G^{\circ'} = -16.7 \text{ kJ/mol}$). Under physiological conditions in the liver, the reaction is also exergonic ($\Delta G = -8.6 \text{ kJ/mol}$). **Fructose-1,6-bisphosphatase** is an allosterically regulated enzyme. Citrate stimulates bisphosphatase activity, but *fructose-2,6-bisphosphate* is a potent allosteric inhibitor. AMP also inhibits the bisphosphatase; the inhibition by AMP is enhanced by fructose-2,6-bisphosphate.

4. Glucose-6-Phosphatase Converts Glucose-6-Phosphate to Glucose The final step in the gluconeogenesis pathway is the conversion of glucose-6-phosphate to glucose by the action of **glucose-6-phosphatase** (Figure 22.5). This enzyme is present in the membranes of the endoplasmic reticulum of liver and kidney cells but is absent in muscle and brain. For this reason, gluconeogenesis is not carried out in muscle and brain. The glucose-6-phosphatase system includes the phosphatase itself and three transport proteins, T1, T2, and T3. The glucose-6-phosphate transporter (T1) takes glucose-6-phosphate into the endoplasmic reticulum, where it is hydrolyzed to glucose and P_i . The T2 and T3 transporters export glucose and P_i , respectively, to the cytosol, and glucose is then exported (to the circulation) by the GLUT2 transporter. The glucose-6-phosphatase reaction involves a phosphorylated enzyme intermediate, phosphohistidine (Figure 22.6). The ΔG for the glucose-6-phosphatase reaction in liver is -5.1 kJ/mol .

Coupling with Hydrolysis of ATP and GTP Drives Gluconeogenesis The net reaction for the conversion of pyruvate to glucose in gluconeogenesis is

Fructose-1,6-bisphosphatase from pig with fructose-6-phosphate (orange), AMP (blue), and Mg^{2+} (dark blue; PDB id = 1FBP).

Figure 22.5 Glucose-6-phosphatase is localized in the endoplasmic reticulum. Conversion of glucose-6-phosphate to glucose occurs following transport into the endoplasmic reticulum. Glucose-6-phosphatase and the three transporters, T1, T2, and T3, are known collectively as the glucose-6-phosphatase system.

Figure 22.6 The glucose-6-phosphatase reaction involves formation of a phosphohistidine intermediate.

The net free energy change, ΔG° , for this conversion is -37.7 kJ/mol. The consumption of a total of six nucleoside triphosphates drives this process forward. If glycolysis were merely reversed to achieve the net synthesis of glucose from pyruvate, the net reaction would be

and the overall ΔG° would be about $+74$ kJ/mol. Such a process would be highly endergonic and, therefore, thermodynamically unfeasible. Hydrolysis of four additional high-energy phosphate bonds makes gluconeogenesis thermodynamically

Human Biochemistry

Metformin—a Diabetes Drug with Multiple Actions

Diabetes, the inability to assimilate and metabolize blood glucose, afflicts millions of people. People with type 1 diabetes are unable to synthesize and secrete insulin. On the other hand, people with type 2 diabetes make sufficient insulin, but the molecular pathways that respond to insulin are defective. Many type 2 diabetic people exhibit a condition termed **insulin resistance** even before the onset of diabetes. **Metformin** (see accompanying figure) is a drug that regulates glucose homeostasis and improves sensitivity to insulin. Metformin does not act on just one cellular target, but instead works through multiple mechanisms in the body. It acts preferentially in the liver, in part because it is taken up readily by transport channels in hepatocytes (liver cells). Metformin also stimulates glucose uptake by glucose transporters in peripheral tissues, increases insulin receptor expression, increases binding of insulin to insulin receptors, stimulates tyrosine kinase activity of the insulin receptor, and inhibits gluconeogenesis and glycogenolysis in the liver. The inhibition of gluconeogenesis involves reduction in liver uptake of gluconeogenic substrates and antagonism of glucagon signaling pathways. Metformin inhibits Complex I of the electron transport system (Section 20.2b), which suppresses ATP production, increases cellular AMP and ADP, and raises the cellular AMP/ATP ratio.

Metformin also inhibits AMP deaminase, which also raises AMP levels. Elevated AMP activates AMP kinase (AMPK), the cellular energy sensor. That, in turn, promotes catabolic reactions that generate ATP and inhibit anabolic reactions, including the fructose-1,6-bisphosphatase reaction of gluconeogenesis.

Metformin also increases secretion from intestinal cells of glucagon-like peptide 1 (GLP-1), a glucose-lowering hormone that is released in response to food ingestion and that stimulates glucose-dependent secretion of insulin and inhibits glucagon release from the pancreas. Metformin also exerts antioxidant effects, reducing reactive oxygen species (ROS) in cells by several mechanisms. Finally, metformin exerts anti-inflammatory effects, preventing vascular damage and protecting against cardiovascular disease.

Gluconeogenesis inhibitors may be the next wave in diabetes therapy. Drugs that block gluconeogenesis without affecting glycolysis would need to target one of the enzymes unique to gluconeogenesis. 3-Mercaptopicolinate and hydrazine inhibit PEP carboxykinase, and **chlorogenic acid**, a natural product found in the skin of peaches, inhibits the transport activity of the glucose-6-phosphatase system (but not the glucose-6-phosphatase enzyme activity). Drugs of this type may be useful in the treatment of type 2 diabetes.

favorable. Under physiological conditions, however, gluconeogenesis is somewhat less favorable than at standard state, with an overall ΔG of -15.6 kJ/mol for the conversion of pyruvate to glucose.

Lactate Formed in Muscles Is Recycled to Glucose in the Liver A final point on the redistribution of lactate and glucose in the body serves to emphasize the metabolic interactions between organs. Vigorous exercise can lead to oxygen shortage (anaerobic conditions), and energy requirements must be met by increased levels of glycolysis. Under such conditions, glycolysis converts NAD^+ to NADH , yet O_2 is unavailable for regeneration of NAD^+ via cellular respiration. Instead, large amounts of NADH are reoxidized by the reduction of pyruvate to lactate. The lactate thus produced can be transported from muscle to the liver, where it is reoxidized by liver lactate dehydrogenase to yield pyruvate, which is converted eventually to glucose. In this way, the liver shares in the metabolic stress created by vigorous exercise. It exports glucose to muscle, which produces lactate, and lactate from muscle can be processed by the liver into new glucose. This is referred to as the Cori cycle (Figure 22.7). Liver, with a typically high NAD^+/NADH ratio (about 700), readily produces more glucose than it can use. Muscle that is vigorously exercising will enter anaerobiosis and show a decreasing NAD^+/NADH ratio, which favors reduction of pyruvate to lactate.

22.2 | How Is Gluconeogenesis Regulated?

Nearly all of the reactions of glycolysis and gluconeogenesis take place in the cytosol. If metabolic control were not exerted over these reactions, glycolytic degradation of glucose and gluconeogenic synthesis of glucose could operate simultaneously, with no net benefit to the cell and with considerable consumption of ATP. This is prevented by a sophisticated system of **reciprocal control**, which inhibits glycolysis when gluconeogenesis is active, and vice versa. Reciprocal regulation of these two pathways depends largely on the energy status of the cell. When the energy status of the cell is

Figure 22.7 The Cori cycle recycles lactate formed in muscles to glucose in the liver.

Critical Developments in Biochemistry

The Pioneering Studies of Carl and Gerty Cori

The Cori cycle is named for Carl and Gerty Cori, who received the Nobel Prize in Physiology or Medicine in 1947 for their studies of glycogen metabolism and blood glucose regulation. Carl Ferdinand Cori and Gerty Theresa Radnitz were both born in Prague (then in Austria). They earned medical degrees from the German University of Prague in 1920 and were married later that year. They joined the faculty of the Washington University School of Medicine in St. Louis in 1931. Their remarkable collaboration resulted in many fundamental advances in carbohydrate and glycogen metabolism. They were credited with the discovery of glucose-1-phosphate, also known at the time as the Cori ester.

They also showed that glucose-6-phosphate was produced from glucose-1-P by the action of phosphoglucomutase. They isolated and crystallized glycogen phosphorylase and elucidated the pathway of glycogen breakdown. In 1952, they showed that absence of glucose-6-phosphatase in the liver was the enzymatic defect in von Gierke's disease, an inherited glycogen-storage disease. Six eventual Nobel laureates received training in their laboratory. Gerty Cori was the first American woman to receive a Nobel Prize. Carl Cori said of their remarkable collaboration: "Our efforts have been largely complementary and one without the other would not have gone so far..."

low, glucose is rapidly degraded to produce needed energy. When the energy status is high, pyruvate and other metabolites are utilized for synthesis (and storage) of glucose. Moreover, when blood glucose levels are low, gluconeogenesis is active.

In glycolysis, the three regulated enzymes are those catalyzing the strongly exergonic reactions: hexokinase (glucokinase), phosphofructokinase, and pyruvate kinase. As noted earlier, the gluconeogenic pathway replaces these three reactions with corresponding reactions that are exergonic in the direction of glucose synthesis: glucose-6-phosphatase, fructose-1,6-bisphosphatase, and the pyruvate carboxylase–PEP carboxykinase pair, respectively. These are the three most appropriate sites of regulation in gluconeogenesis.

22.2a Gluconeogenesis Is Regulated by Allosteric and Substrate-Level Control Mechanisms

The mechanisms of regulation of gluconeogenesis are shown in Figure 22.8. Control is exerted at the same steps as for glycolysis, but in different ways. Glucose-6-phosphatase is not under allosteric control. However, the K_m for the substrate, glucose-6-phosphate, is considerably higher than the normal range of substrate concentrations. As a result, glucose-6-phosphatase displays a near-linear dependence of activity on substrate concentrations and is thus said to be under **substrate-level control** by glucose-6-phosphate.

Acetyl-CoA is a potent allosteric effector of glycolysis and gluconeogenesis. It allosterically inhibits pyruvate kinase (as noted in Chapter 18) and activates pyruvate carboxylase. Because it also allosterically inhibits pyruvate dehydrogenase (the enzymatic link between glycolysis and the TCA cycle), the cellular fate of pyruvate is strongly dependent on acetyl-CoA levels. A rise in [acetyl-CoA] indicates that cellular energy levels are high and that carbon metabolites can be directed to glucose synthesis and storage. When acetyl-CoA levels drop, the activities of pyruvate kinase and pyruvate dehydrogenase increase and flux through the TCA cycle increases, providing needed energy for the cell.

Fructose-1,6-bisphosphatase is another important site of gluconeogenic regulation. This enzyme is inhibited by AMP and activated by citrate. These effects by AMP and citrate are the opposites of those exerted on phosphofructokinase in glycolysis, providing another example of reciprocal regulatory effects. When AMP levels increase, gluconeogenic activity is diminished and glycolysis is stimulated. An increase in citrate concentration signals that TCA cycle activity can be curtailed and that pyruvate should be directed to sugar synthesis instead.

Fructose-2,6-Bisphosphate—Allosteric Regulator of Gluconeogenesis Emile Van Schaftingen and Henri-Géry Hers demonstrated in 1980 that fructose-2,6-bisphosphate is a potent stimulator of phosphofructokinase (see Chapter 18). Cognizant of the

Figure 22.8 The principal regulatory mechanisms in glycolysis and gluconeogenesis. Activators are indicated by plus signs and inhibitors by minus signs. Carbohydrate metabolism is also modulated by a variety of cellular signals, including the protein kinases PI3K, AKT, and AMPK, the tumor suppressor p53, and TIGAR (see A Deeper Look, “TIGAR-P53-Induced Enzyme That Mimics Fructose-2,6-Bisphosphatase”).

reciprocal nature of regulation in glycolysis and gluconeogenesis, Van Schaftingen and Hers also considered the possibility of an opposite effect—inhibition—for fructose-1,6-bisphosphatase. In 1981, they reported that fructose-2,6-bisphosphate was indeed a powerful inhibitor of fructose-1,6-bisphosphatase (Figure 22.9). Inhibition occurs in either the presence or absence of AMP, and the effects of AMP and fructose-2,6-bisphosphate are synergistic.

Cellular levels of fructose-2,6-bisphosphate are controlled by **phosphofructokinase-2 (PFK-2)**, an enzyme distinct from the phosphofructokinase (often designated PFK-1) of the glycolytic pathway, and by **fructose-2,6-bisphosphatase (F-2,6-BPase)**. (PFK-1 and PFK-2 are numbered not only in terms of their order of discovery, but also because PFK-1 phosphorylates at the 1-position and PFK-2 phosphorylates at the 2-position.) Remarkably, these two enzymatic activities are both found in the same protein molecule, which is an example of a **bifunctional**, or **tandem, enzyme** (Figure 22.10). The opposing activities of this bifunctional enzyme are themselves regulated in two ways. First, fructose-6-phosphate, the substrate of phosphofructokinase and the product of fructose-1,6-bisphosphatase, allosterically activates PFK-2 and inhibits F-2,6-BPase. Second, the phosphorylation by *cAMP-dependent protein kinase* of a single Ser (Ser³²)

Figure 22.9 Inhibition of fructose-1,6-bisphosphatase by fructose-2,6-bisphosphate in the (a) absence and (b) presence of 25 mM AMP. In (a) and (b), enzyme activity is plotted against substrate (fructose-1,6-bisphosphate) concentration. Concentrations of fructose-2,6-bisphosphate (in mM) are indicated above each curve. (c) The effect of AMP (0, 10, and 25 mM) on the inhibition of fructose-1,6-bisphosphatase by fructose-2,6-bisphosphate. Activity was measured in the presence of 10 mM fructose-1,6-bisphosphate. (Adapted from Van Schaftingen, E., and Hers, H.-G., 1981. Inhibition of fructose-1,6-bisphosphatase by fructose-2,6-bisphosphate. *Proceedings of the National Academy of Science, U.S.A.* 78:2861–2863.)

A Deeper Look

TIGAR—A p53-Induced Enzyme That Mimics Fructose-2,6-Bisphosphatase

Cellular stresses, such as oncogenesis and DNA damage, provoke the activation of target genes by the tumor suppressor p53. A principal target of p53 is **TIGAR (TP53-induced glycolysis and apoptosis regulator)**. TIGAR inhibits glycolysis, reduces cellular levels of reactive oxygen species (ROS), and protects cells from apoptosis. Hui Li and Gerwald Jogl have shown that TIGAR's structure is nearly identical to that of the fructose-2,6-bisphosphatase domain of the bifunctional PFK-2/F-2,6-BPase (see figure). TIGAR is a fructose biphosphatase that exerts its cellular effects by removing

the allosteric effector fructose-2,6-bisphosphate and also the glycolytic intermediate fructose-1,6-bisphosphate.

PFK-2 activity resides in the N-terminal portion of the protein (*left*), and the C-terminal domain (*right*) contains F-2,6-BPase activity. The PFK-2 domain has a bound ATP analog; the F-2,6-BPase has two phosphates bound (PDB id = 1BIF).

residue on the liver enzyme exerts reciprocal control of the PFK-2 and F-2,6-BPase activities. Phosphorylation inhibits PFK-2 activity (by increasing the K_m for fructose-6-phosphate) and stimulates F-2,6-BPase activity.

22.2b Substrate Cycles Provide Metabolic Control Mechanisms

If fructose-1,6-bisphosphatase and phosphofructokinase acted simultaneously, they would constitute a **substrate cycle** in which fructose-1,6-bisphosphate and fructose-6-phosphate became interconverted with net consumption of ATP:

Because substrate cycles such as this appear to operate with no net benefit to the cell, they were once regarded as metabolic quirks and were referred to as futile cycles. More recently, substrate cycles have been recognized as important devices for controlling metabolite concentrations.

The three steps in glycolysis and gluconeogenesis that differ constitute three such substrate cycles, each with its own particular metabolic *raison d'être*. Consider, for example, the regulation of the fructose-1,6-BP–fructose-6-P cycle by fructose-2,6-bisphosphate. As already noted, fructose-1,6-bisphosphatase is subject to allosteric inhibition by fructose-2,6-bisphosphate, whereas phosphofructokinase is allosterically activated by fructose-2,6-bisphosphate. The combination of these effects should permit either phosphofructokinase or fructose-1,6-bisphosphatase (but not both) to operate at any one time and should thus prevent futile cycling. For instance, in the *fasting state*, when food (that is, glucose) intake is zero, phosphofructokinase (and, therefore, glycolysis) is inactive due to the low concentration of fructose-2,6-bisphosphate. In the liver, gluconeogenesis operates to provide glucose for the brain. However, in the fed state, up to 30% of fructose-1,6-bisphosphate formed from phosphofructokinase is recycled back to fructose-6-P (and then to glucose). Because the dependence of fructose-1,6-bisphosphatase activity on fructose-1,6-bisphosphate is sigmoidal in the presence of fructose-2,6-bisphosphate (see Figure 22.9), substrate cycling occurs only at relatively high levels of fructose-1,6-bisphosphate. Substrate cycling in this case prevents the accumulation of excessively high levels of fructose-1,6-bisphosphate.

22.3 | How Are Glycogen and Starch Catabolized in Animals?

As noted earlier, well-fed adult human beings normally metabolize about 160 grams of carbohydrates each day. A balanced diet easily provides this amount, mostly in the form of starch. If too little carbohydrate is supplied by the diet, glycogen reserves in liver and muscle tissue can also be mobilized.

22.3a Dietary Starch Breakdown Provides Metabolic Energy

The reactions by which ingested starch and glycogen are digested are shown in Figure 22.11. The enzyme known as **α -amylase** is an important component of saliva and pancreatic juice. (**β -Amylase** is found in plants. The α - and β -designations for these enzymes serve only to distinguish the two and do not refer to glycosidic linkage nomenclature.) α -Amylase is an endoglycosidase that hydrolyzes $\alpha(1 \rightarrow 4)$ linkages of amylopectin and glycogen at random positions, eventually producing a mixture of maltose, maltotriose [with three $\alpha(1 \rightarrow 4)$ -linked glucose residues], and other small oligosaccharides. α -Amylase can cleave on either side of an amylopectin branch point, but activity is reduced in highly branched regions of the polysaccharide and stops four residues from any branch point.

The highly branched polysaccharides that are left after extensive exposure to α -amylase are called **limit dextrins**. These structures can be further degraded by the action of a **debranching enzyme**, which carries out two distinct reactions. The first of these, known as *oligo($\alpha(1,4 \rightarrow \alpha(1,4)$) glucanotransferase* activity, removes a trisaccharide unit and transfers this group to the end of another, nearby branch (Figure 22.12). This leaves a single glucose residue in $\alpha(1 \rightarrow 6)$ linkage to the main chain. The *$\alpha(1 \rightarrow 6)$ glucosidase* activity of the debranching enzyme then cleaves this residue from the chain, leaving a polysaccharide chain with one branch fewer. Repetition of this sequence of events leads to complete degradation of the polysaccharide.

Figure 22.11 Starch and glycogen are broken down by amylases and glucosidases. **(a)** The sites of hydrolysis of starch by α - and β -amylase are indicated. **(b)** Glycogenin is a glycosyltransferase that initiates eukaryotic glycogen synthesis from glucose. Bound UDP-glucose (blue) and Mn^{2+} ion (purple) are shown (PDB id = 1LL2).

Figure 22.12 The reactions of debranching enzyme. Transfer of a group of three $\alpha(1\rightarrow4)$ -linked glucose residues from a limit branch to another branch is followed by cleavage of the $\alpha(1\rightarrow6)$ bond of the residue that remains at the branch point.

β -Amylase is an exoglycosidase that cleaves maltose units from the free, nonreducing ends of amylopectin branches, as in Figure 22.11. Like α -amylase, however, β -amylase does not cleave either the $\alpha(1\rightarrow6)$ bonds at the branch points or the $\alpha(1\rightarrow4)$ linkages near the branch points.

22.3b Metabolism of Tissue Glycogen Is Regulated

Digestion itself is a highly efficient process in which almost 100% of ingested food is absorbed and metabolized. Digestive breakdown of starch is an unregulated process. On the other hand, tissue glycogen represents an important reservoir of potential energy, and it should be no surprise that the reactions involved in its degradation and synthesis are carefully controlled and regulated. Glycogen reserves in liver and muscle tissue are stored in the cytosol as granules exhibiting a molecular weight range from 6×10^6 to 1600×10^6 . These granular aggregates contain the enzymes required to synthesize and catabolize the glycogen as well as all the enzymes of glycolysis.

The principal enzyme of glycogen catabolism is **glycogen phosphorylase**, a highly regulated enzyme that was discussed extensively in Chapter 15. The glycogen phosphorylase reaction (Figure 22.13) involves phosphorolysis at a nonreducing end of a glycogen polymer. The standard-state free energy change for this reaction is $+3.1 \text{ kJ/mol}$, but the intracellular ratio of $[P_i]$ to $[\text{glucose-1-P}]$ approaches 100, and thus the actual ΔG in vivo is approximately -6 kJ/mol . There is an energetic advantage to the cell in this phosphorolysis reaction. If glycogen breakdown were hydrolytic and yielded glucose as a product, it would be necessary to phosphorylate the product glucose (with the expenditure of a molecule of ATP) to initiate its glycolytic degradation.

The glycogen phosphorylase reaction degrades glycogen to produce limit dextrans, which are further degraded by debranching enzyme, as already described.

Figure 22.13 The glycogen phosphorylase reaction.

22.4 | How Is Glycogen Synthesized?

Animals synthesize and store glycogen when glucose levels are high, but the synthetic pathway is not merely a reversal of the glycogen phosphorylase reaction. High levels of phosphate in the cell favor glycogen breakdown and prevent the phosphorylase reaction from synthesizing glycogen *in vivo*, despite the fact that $\Delta G^{\circ'}$ for the phosphorylase reaction actually favors glycogen synthesis. Hence, another reaction pathway must be employed in the cell for the net synthesis of glycogen. In essence, this pathway must activate glucose units for transfer to glycogen chains.

22.4a Glucose Units Are Activated for Transfer by Formation of Sugar Nucleotides

We are familiar with several examples of chemical activation as a strategy for group transfer reactions. Acetyl-CoA is an activated form of acetate; biotin and tetrahydrofolate activate one-carbon groups for transfer; and ATP is an activated form of phosphate. Luis Leloir, a biochemist in Argentina, showed in the 1950s that glycogen synthesis depended upon **sugar nucleotides**, which may be thought of as activated forms of sugar units. For example, formation of an ester linkage between the C-1 hydroxyl group and the β -phosphate of UDP activates the glucose moiety of **UDP-glucose**.

Uridine diphosphate glucose (UDPG)

Uridine diphosphate glucose (UDP-glucose).

22.4b UDP-Glucose Synthesis Is Driven by Pyrophosphate Hydrolysis

Sugar nucleotides are formed from sugar-1-phosphates and nucleoside triphosphates by specific **pyrophosphorylase** enzymes (Figure 22.14). For example, **UDP-glucose pyrophosphorylase** catalyzes the formation of UDP-glucose from glucose-1-phosphate and uridine 5'-triphosphate:

Figure 22.14 The UDP-glucose pyrophosphorylase reaction is a phosphoanhydride exchange, with a phosphoryl oxygen of glucose-1-P attacking the α -phosphorus of UTP to form UDP-glucose and pyrophosphate.

The reaction proceeds via attack by a phosphate oxygen of glucose-1-phosphate on the α -phosphorus of UTP, with departure of the pyrophosphate anion. The reaction is a reversible one, but—as is the case for many biosynthetic reactions—it is driven forward by subsequent hydrolysis of pyrophosphate:

The net reaction for sugar nucleotide formation (combining the preceding two equations) is thus

Sugar nucleotides of this type act as donors of sugar units in the biosynthesis of oligosaccharides and polysaccharides. In animals, UDP-glucose is the donor of glucose units for glycogen synthesis, but ADP-glucose is the glucose source for starch synthesis in plants.

22.4c Glycogen Synthase Catalyzes Formation of $\alpha(1 \rightarrow 4)$ Glycosidic Bonds in Glycogen

The very large glycogen polymer is built around a tiny protein core. The first glucose residue is covalently joined to the protein **glycogenin** (see Figure 22.11b) via an acetal linkage to a tyrosine—OH group on the protein. Sugar units can then be added by the action of **glycogen synthase**. The reaction involves transfer of a glucosyl unit from UDP-glucose to the C-4 hydroxyl group at a nonreducing end of a glycogen strand. The mechanism proceeds by cleavage of the C—O bond between the glucose moiety and the β -phosphate of UDP-glucose, leaving an oxonium ion intermediate, which is rapidly attacked by the C-4 hydroxyl oxygen of a terminal glucose unit on glycogen (Figure 22.15). The reaction is exergonic and has a $\Delta G^{\circ'}$ of -13.3 kJ/mol .

Glycogen synthase from *Agrobacterium tumefaciens* consists of two Rossman folds (see Chapter 16) separated by a deep cleft that includes the active site (shown here with bound ADP, purple; PDB id = 1RZU).

Figure 22.15 The glycogen synthase reaction. Cleavage of the C—O bond of UDP-glucose yields an oxonium intermediate. Attack by the hydroxyl oxygen of the terminal residue of a glycogen molecule completes the reaction.

22.4d Glycogen Branching Occurs by Transfer of Terminal Chain Segments

Glycogen is a branched polymer of glucose units. The branches arise from $\alpha(1 \rightarrow 6)$ linkages, which occur every 8 to 12 residues. As noted in Chapter 7, the branches provide multiple sites for rapid degradation or elongation of the polymer and also increase its solubility. Glycogen branches are formed by *amylo-(1,4 $\rightarrow$ 1,6)-transglycosylase*, also known as *branching enzyme*. The reaction involves the transfer of a 6 or 7 residue segment from the nonreducing end of a linear chain at least 11 residues in length to the C-6 hydroxyl of a glucose residue of the same chain or another chain (Figure 22.16). For each branching reaction, the resulting polymer has gained a new terminus at which growth can occur.

22.5 | How Is Glycogen Metabolism Controlled?

Synthesis and degradation of glycogen must be carefully controlled so that this important energy reservoir can properly serve the metabolic needs of the organism. This section describes the regulation of the synthesis and degradation of glycogen.

22.5a Glycogen Metabolism Is Highly Regulated

Glucose is the principal metabolic fuel for the brain, and the concentration of glucose in circulating blood must be maintained at about 5 mM for this purpose. Glucose derived from glycogen breakdown is also a primary energy source for muscle

Figure 22.16 Formation of glycogen branches by the branching enzyme. Six or seven residue segments of a growing glycogen chain are cleaved (Step 1) and transferred (Step 2) to the C-6 hydroxyl group of a glucose residue on the same or a nearby chain.

Human Biochemistry

Advanced Glycation End Products—A Serious Complication of Diabetes

Covalent linkage of sugars to proteins to form glycoproteins normally occurs through the action of enzymes that use sugar nucleotides as substrates. However, sugars may also react non-enzymatically with proteins. The C-1 carbonyl group of glucose forms Schiff base linkages with lysine side chains of proteins. These Schiff base adducts undergo Amadori rearrangements and subsequent oxidations to form irreversible glycation products, including carboxymethyllysine and pentosidine derivatives (see Figure 1). These **advanced glycation end products (AGEs)** can alter

the function of the protein. Such AGE-dependent changes are thought to contribute to circulation, joint, and vision problems in people with diabetes.

Nonenzymatic glycation of hemoglobin is a better diagnostic yardstick for type 2 diabetes than serum glucose levels. Red blood cells have an average life expectancy of about four months. By measuring the concentration of *glycated hemoglobin* in a patient, it is possible to determine the average glucose concentration in the blood over the past several months.

Figure 1 Sugars react nonenzymatically with amine groups on proteins to form Schiff base adducts, which they rearrange to form a variety of advanced glycation end products.

The cell surface receptor that binds advanced glycation end products (**RAGE**) is a multifunctional protein of the innate immune system that plays pivotal roles in diabetes, chronic inflammation, neurodegenerative diseases, T-lymphocyte proliferation, and cancer. RAGE is a single-transmembrane segment receptor expressed mainly in immune cells, neurons, endothelial and vascular smooth muscle cells, bone-forming cells, and a variety of cancer cells. RAGE consists of three extracellular immunoglobulin domains

(V, C1, and C2; Figure 2a, a transmembrane segment and a small cytoplasmic domain). The first two extracellular domains of RAGE form a single structural unit, termed VC1, which contains a basic patch (Figure 2b) and a hydrophobic patch. Binding of its ligands (AGE-modified proteins, amyloid- β , and S100 proteins) depends on interactions with these surfaces, particularly the large basic patch (*blue* in Figure 2b) comprised of Arg and Lys side chains. Binding of ligands induces dimerization of RAGE and

(Continued)

triggers a variety of intracellular responses related to inflammation and tumorigenesis. Understanding these cellular responses will be essential in light of the developing worldwide epidemic of type 2 diabetes.

contraction. Control of glycogen metabolism is effected via reciprocal regulation of glycogen phosphorylase and glycogen synthase. Thus, activation of glycogen phosphorylase is tightly linked to inhibition of glycogen synthase, and vice versa. Regulation involves both allosteric control and covalent modification, with the latter being under hormonal control. The regulation of glycogen phosphorylase has been discussed in detail in Section 15.5.

22.5b Glycogen Synthase Is Regulated by Covalent Modification

Glycogen synthase exists in two distinct forms that can be interconverted by the action of specific enzymes: active, dephosphorylated **glycogen synthase I** (glucose-6-P-independent) and less active, phosphorylated **glycogen synthase D** (glucose-6-P-dependent). The phosphorylated form can be allosterically activated by glucose-6-phosphate, but the unphosphorylated enzyme is insensitive to this allosteric effector (Figure 22.17). The nature of phosphorylation is complex (Figure 22.17a). At least nine serine residues on the enzyme appear to be subject to phosphorylation, each site's phosphorylation having some effect on enzyme activity. Four protein kinases are involved in phosphorylation of glycogen synthase: casein kinase, AMP-dependent protein kinase, protein kinase A, and glycogen synthase kinase 3 (GSK3).

Dephosphorylation of both glycogen phosphorylase and glycogen synthase is carried out by **phosphoprotein phosphatase-1 (PP1)**. The action of PP1 inactivates glycogen phosphorylase and activates glycogen synthase.

Figure 22.17 Binding of insulin to plasma membrane receptors in the liver and muscles triggers protein kinase cascades that stimulate glycogen synthesis. **(a)** Insulin's effects include inactivation of GSK3 and stimulation of PP1, both actions activating glycogen synthase, as well as recruitment of GLUT4 to the plasma membrane. Glucose uptake through the GLUT1 and GLUT4 transporters provides substrate for glycogen synthesis and glucose-6-phosphate, which allosterically activates the otherwise inactive form of glycogen synthase. **(b)** The structure of human GLUT1 is shown in two orientations (PDB id = 4PYP) **(c)** The metabolic effects of insulin are mediated through protein phosphorylation and second messenger modulation.

Figure 22.18 The portal vein system carries pancreatic secretions such as insulin and glucagon to the liver and then into the rest of the circulatory system.

22.5c Hormones Regulate Glycogen Synthesis and Degradation

Storage and utilization of tissue glycogen, maintenance of blood glucose concentration, and other aspects of carbohydrate metabolism are meticulously regulated by hormones, including *insulin*, *glucagon*, *epinephrine*, and the *glucocorticoids*.

Insulin Is a Response to Increased Blood Glucose The primary hormone responsible for conversion of glucose to glycogen is **insulin** (see Figure 5.8). Insulin is secreted by the β -cells in the pancreas within the **islets of Langerhans**. Secretion of insulin is a response to increased glucose in the blood. When blood glucose levels rise (after a meal, for example), insulin is secreted from the pancreas into the *pancreatic vein*, which empties into the *portal vein system* (Figure 22.18), so insulin traverses the liver before it enters the systemic blood supply. Insulin acts to rapidly lower blood glucose concentration in several ways. Insulin stimulates glycogen synthesis and inhibits glycogen breakdown in liver and muscle.

Insulin Triggers Glycogen Synthesis When Blood Glucose Rises The action of insulin when blood glucose rises is immediate and powerful. During periods between meals, typical human blood glucose levels are 70 to 90 mg/dL. Glucose levels normally rise to about 150 mg/dL within the first hour following a carbohydrate-rich meal (Figure 22.19) and then return to normal within 2 to 3 hours. (For diabetic subjects, whose insulin response is impaired, glucose levels rise after a meal to 250 mg/dL or even higher and remain high for much longer times.)

Human Biochemistry

Carbohydrate Utilization in Exercise

Animals have a remarkable ability to shift gears metabolically during periods of strenuous exercise or activity. Metabolic adaptations allow the body to draw on different sources of energy (all of which produce ATP) for different types of activity. During periods of short-term, high-intensity exercise (such as a 100 m dash), most of the required energy is supplied directly by existing stores of ATP and creatine phosphate (see figure, part a). Long-term, low-intensity exercise (such as a 10 km run or a 42.2 km marathon) is fueled almost entirely by aerobic metabolism. Between these extremes is a variety of activities (an 800 m run, for example) that rely on anaerobic glycolysis—conversion of glucose to lactate in the muscles and utilization of the Cori cycle.

For all these activities, breakdown of muscle glycogen provides much of the needed glucose. The rate of glycogen consumption

depends on the intensity of the exercise (see figure, part b). By contrast, glucose derived from gluconeogenesis makes only small contributions to total glucose consumed during exercise. During prolonged mild exercise, gluconeogenesis accounts for only about 8% of the total glucose consumed. During heavy exercise, this percentage becomes even lower.

Choice of diet has a dramatic effect on glycogen recovery following exhaustive exercise. A diet consisting mainly of protein and fat results in very little recovery of muscle glycogen, even after 5 days (see figure, part c). On the other hand, a high-carbohydrate diet provides faster restoration of muscle glycogen. Even in this case, however, complete recovery of glycogen stores takes about 2 days.

Carbohydrate utilization in exercise. **(a)** Contributions of the various energy sources to muscle activity during mild exercise. **(b)** Consumption of glycogen stores in fast-twitch muscles during light, moderate, and heavy exercise. **(c)** Rate of glycogen replenishment following exhaustive exercise. (a and c adapted from Rhodes, R., and Pflanzner, R. G., 1992. *Human Physiology*. Philadelphia: Saunders College Publishing; b adapted from Horton, E. S., and Terjung, R. L., 1988. *Exercise, Nutrition and Energy Metabolism*. New York: Macmillan.)

Insulin lowers blood glucose by triggering several cascades of reactions that result in glucose uptake and glycogen synthesis (see Figure 22.17a). An insulin-triggered protein kinase cascade increases glucose transport into muscle, liver, and adipose tissues by stimulating exocytotic processes that translocate GLUT4, a glucose transporter, from intracellular vesicles to the plasma membrane (see Figure 22.17a). Large amounts of glucose thus transported into the cell are converted to glucose-6-P, which can be directed to glycogen synthesis (by conversion to glucose-1-P). Also, glucose-6-P is the allosteric effector that activates the otherwise inactive, phosphorylated form of glycogen synthase.

Binding of insulin to the plasma membrane, in either liver or muscle cells, triggers another protein kinase cascade (see Figure 22.17a) that results in phosphorylation and inactivation of **glycogen synthase kinase 3 (GSK3)**. This kinase normally phosphorylates and inactivates glycogen synthase. Inhibition of GSK3 means that more of the cell's glycogen synthase will remain in the unphosphorylated, active state (see Figure 22.17a). Insulin also stimulates PP1, which dephosphorylates (and activates) glycogen synthase.

Several other physiological effects of insulin also serve to lower blood and tissue glucose levels (see Figure 22.17c). Insulin increases cellular utilization of glucose by inducing the synthesis of several important glycolytic enzymes, namely, glucokinase, phosphofructokinase, and pyruvate kinase. In addition, insulin acts to inhibit several enzymes of gluconeogenesis. These various actions enable the organism to respond quickly to increases in blood glucose levels.

Glucagon and Epinephrine Stimulate Glycogen Breakdown Catabolism of tissue glycogen is triggered by the actions of the hormones epinephrine and glucagon (Figure 22.20). In response to decreased blood glucose, glucagon (a 29-residue peptide) is released from the α -cells in pancreatic islets of Langerhans. This peptide hormone travels through the blood to specific receptors on liver cell membranes. (Glucagon acts on liver and adipose tissue but not other tissues.) Similarly, signals from the central nervous system cause release of *epinephrine*—also known as adrenaline—from the adrenal glands into the bloodstream. Epinephrine acts on liver and muscles. When either hormone binds to its receptor on the outside surface of the cell membrane, a cascade is initiated that activates glycogen phosphorylase and inhibits glycogen synthase (Figure 22.20). The result of these actions is tightly coordinated stimulation of glycogen breakdown and inhibition of glycogen synthesis.

The Phosphorylase Cascade Amplifies the Hormonal Signal Stimulation of glycogen breakdown involves consumption of molecules of ATP at three different steps in the hormone-sensitive adenylyl cyclase cascade (see Figure 15.18). Note that the cascade mechanism is a means of chemical amplification, because the binding of just a few molecules of epinephrine or glucagon results in the synthesis of many molecules of cyclic AMP, which, through the action of cAMP-dependent protein kinase, can activate many more molecules of phosphorylase kinase and even more molecules of phosphorylase. For example, an extracellular level of 10^{-10} to 10^{-8} M epinephrine prompts the formation of 10^{-6} M cyclic AMP, and for each protein kinase activated by cyclic AMP, approximately 30 phosphorylase kinase molecules are activated; each of these in turn can activate some 800 molecules of phosphorylase. Each of these catalyzes the formation of many molecules of glucose-1-P.

The Difference between Epinephrine and Glucagon Although both epinephrine and glucagon exert glycogenolytic effects, they do so for quite different reasons. Epinephrine is secreted as a response to anger or fear, and may be viewed as an alarm or danger signal for the organism. Called the fight-or-flight hormone, it prepares the organism for mobilization of large amounts of energy. Among the many physiological changes elicited by epinephrine, one is the initiation of the enzyme cascade, as in Figure 15.18, which leads to rapid breakdown of glycogen, inhibition of glycogen synthesis, stimulation of glycolysis, and production of energy. The burst of energy produced is the result of a 2000-fold amplification of the rate of glycolysis. A fear or anger response must include generation of energy (in the form of glucose)—both immediately in localized sites (the muscles) and eventually throughout the organism

Figure 22.19 A glucose tolerance test involves ingestion of a glucose solution followed by measurements of blood glucose for about 3 hours. Normal subjects exhibit a rise in blood glucose to about 150 mg/dL, followed by a decline to normal values over a 3-hour period. In diabetic subjects, blood glucose rises to higher values and remains high for longer periods.

Figure 22.20 Glucagon and epinephrine each activate a cascade of reactions that stimulate glycogen breakdown and inhibit glycogen synthesis in liver and muscles, respectively. The effects of these hormones on other metabolic pathways depend on the tissue. In liver, glucagon inhibits glycolysis and stimulates gluconeogenesis, facilitating export of glucose into the bloodstream. In muscles, epinephrine stimulates glycolysis to provide energy for contraction. These effects all depend on protein phosphorylations by cAMP-dependent protein kinase. Note that the liver and heart isoforms of PFK-2/F-2,6-BPase respond oppositely to phosphorylation by PKA. The + and ⊖ symbols indicate activation and inhibition.

(as supplied by the liver). Epinephrine must be able to activate glycogenolysis in both liver and muscles.

Glucagon is involved in the long-term maintenance of steady-state levels of glucose in the blood. It performs this function by stimulating the liver to release glucose from glycogen stores into the bloodstream. To further elevate glucose levels, glucagon also stimulates liver gluconeogenesis by activating F-2,6-BPase activity (see Figure 22.10). It is important to note, however, that stabilization of blood glucose levels is managed almost entirely by the liver. Glucagon does not activate the phosphorylase cascade in muscle (since muscle membranes do not contain glucagon receptors). Muscle glycogen breakdown occurs only in response to epinephrine release, and muscle tissue does not participate in maintenance of steady-state glucose levels in the blood.

Glucagon and epinephrine both trigger glycogen breakdown and inhibit glycogen synthesis (in liver and muscles, respectively), but their other effects on metabolic pathways are adapted exquisitely to the needs of the tissues involved. The liver must

Critical Developments in Biochemistry

O-GlcNAc Signaling and the Hexosamine Biosynthetic Pathway

O-linked β -N-acetylglucosamine (O-GlcNAc) is a post-translational modification consisting of a single N-acetylglucosamine moiety attached in O- β -glycosidic linkage to Ser and Thr residues. Modification with a single O-GlcNAc is a signaling device similar to phosphorylation. Emerging research reveals that O-GlcNAc signaling and its crosstalk with phosphorylation modulate a wide array of cellular events. Such signaling and crosstalk are altered in diseases such as diabetes and cancer.

Uridine diphosphate N-acetylglucosamine (UDP-GlcNAc), the high-energy donor substrate for O-GlcNAcylation, is synthesized in the **hexosamine biosynthetic pathway (HBP)**—see figure, a nexus of glucose, nitrogen, fatty acid, and nucleic acid metabolic pathways which consumes approximately 2% to 3% of total cellular glucose. The amide N of glutamine is transferred to fructose-6-P to form glucosamine-6-P by glutamine:fructose-6-P aminotransferase (GFAT), the rate-limiting step in the HBP. O-GlcNAc-dependent glycosylation (O-GlcNAcylation) of proteins is catalyzed by O-GlcNAc transferase (OGT) and O-GlcNAc groups are removed from protein targets by O-GlcNAcase (OGA).

O-GlcNAcylation is intertwined with cellular metabolism; sugars can be attached or removed dynamically in response to changes in the cellular environment triggered by stress, hormones, or nutrients. In some cases, the same Ser or Thr residues may be either phosphorylated or modified by O-GlcNAc, provoking different cellular responses. Moreover, O-GlcNAcylated and phosphorylated residues can be in proximity to each other, and either can sterically impair the attachment of the other.

O-GlcNAcylation plays a direct role in insulin signaling and cancer. Cellular stimulation by insulin provokes OGT association with the

insulin receptor, followed by OGT phosphorylation, and an increase in OGT activity, resulting in O-GlcNAcylation of several components of the insulin signaling pathway. In cancer cells, expression of the transcription factor c-Myc is typically enhanced. c-Myc is O-GlcNAcylated at a Thr residue that is also a phosphorylation site, and these modifications have opposing effects on the activity of c-Myc. Similar interaction between O-GlcNAcylation and phosphorylation, with consequent effects on activity, are observed for several other transcription factors, oncogenes, and tumor suppressors that play essential roles in tumorigenesis and cell proliferation. For example, in the fasting state, glucagon stimulates gluconeogenesis by activating the transcription factor called CREB (cyclic-ATP-responsive element-binding protein). The pathway between glucagon and CREB begins with cAMP generation inside the cell in response to glucagon binding to its membrane receptor. cAMP activates protein kinase A (PKA), which phosphorylates CREB, enhancing expression of pyruvate carboxylase, PEP carboxykinase, and glucose-6-phosphatase, thus stimulating gluconeogenesis. cAMP also triggers O-GlcNAcylation of CRTC, which binds to CREB, further stimulating gluconeogenesis. Phosphorylated CREB also promotes expression of peroxisome proliferator-activated receptor- γ co-activator 1 α (PGC1 α), which provides prolonged stimulation of gluconeogenic gene transcription.

Figure 22.21 The effects of cortisol on carbohydrate and protein metabolism in the liver.

export glucose to the bloodstream to support other tissues. Thus, in the liver, PFK-2 is phosphorylated and inhibited by protein kinase A (PKA), lowering [fructose-2,6-bisphosphate], inhibiting glycolysis, and activating gluconeogenesis (see Figure 22.20). In muscles, the glucose provided by glycogen breakdown is used immediately and locally to provide ATP energy for contraction. Therefore, glycolysis should be activated in concert with glycogen breakdown in muscles. Activation of glycolysis is accomplished in different ways, depending on the muscle. Heart muscle PFK-2 is activated upon phosphorylation at Ser⁴⁶⁶ and Ser⁴⁸³ by PKA in response to epinephrine, thus activating glycolysis (see Figure 22.20). Unlike heart PFK-2, skeletal muscle PFK-2 is not a substrate for PKA. Instead, skeletal muscle PFK-1 is phosphorylated and activated by PKA (see Figure 22.20).

Cortisol and Glucocorticoid Effects on Glycogen Metabolism Glucocorticoids are a class of steroid hormones that exert distinct effects on liver, skeletal muscle, and adipose tissue. The effects of cortisol, a typical glucocorticoid, are best described as catabolic because cortisol promotes protein breakdown and decreases protein synthesis in skeletal muscle. In the liver, however, it stimulates gluconeogenesis and increases glycogen synthesis. Cortisol-induced gluconeogenesis results primarily from increased conversion of amino acids into glucose (Figure 22.21). Specific effects of cortisol in the liver include increased expression of several genes encoding enzymes of the gluconeogenic pathway, activation of enzymes involved in amino acid metabolism, and stimulation of the urea cycle, which disposes of nitrogen liberated during amino acid catabolism.

22.6 | How Does Glucose Provide Electrons for Biosynthesis?

Cells require a constant supply of NADPH for reductive reactions vital to biosynthetic purposes. Much of this requirement is met by a glucose-based metabolic sequence variously called the **pentose phosphate pathway**, the **hexose monophosphate shunt**, or the **phosphogluconate pathway**. In addition to providing NADPH for biosynthetic processes, this pathway produces *ribose-5-phosphate*, which is essential for nucleic acid synthesis. Several metabolites of the pentose phosphate pathway can also be shuttled into glycolysis.

22.6a The Pentose Phosphate Pathway Operates Mainly in Liver and Adipose Cells

The pentose phosphate pathway begins with glucose-6-phosphate, a six-carbon sugar, and produces three-, four-, five-, six-, and seven-carbon sugars (Figure 22.22). As will be seen, the pathway begins with two successive oxidations that lead to the reduction

Figure 22.22 The pentose phosphate pathway. The numerals in the blue circles indicate the steps discussed in the text. The glucose-6-phosphate dehydrogenase reaction is inhibited by the tumor suppressor p53. Steps 1–3 involve two oxidations. Steps 4–9 interconvert 3-, 4-, 5-, 6-, and 7-carbon sugars.

of NADP^+ to NADPH and the release of CO_2 . Five subsequent nonoxidative steps produce a variety of carbohydrates, some of which may enter the glycolytic pathway. The enzymes of the pentose phosphate pathway are particularly abundant in the cytoplasm of liver and adipose cells. These enzymes are largely absent in muscle, where glucose-6-phosphate is utilized primarily for energy production via glycolysis and the TCA cycle. These pentose phosphate pathway enzymes are located in the cytosol, which is the site of fatty acid synthesis, a pathway heavily dependent on NADPH for reductive reactions.

22.6b The Pentose Phosphate Pathway Begins with Two Oxidative Steps

The aldehyde group of glucose-6-P is oxidized to a carboxyl group and then lost as CO_2 in the first two steps of the pentose phosphate pathway.

Step 1. Glucose-6-Phosphate Dehydrogenase The pentose phosphate pathway begins with the oxidation of glucose-6-phosphate. The products of the reaction are a cyclic ester (the lactone of phosphogluconic acid) and NADPH (Figure 22.23). **Glucose-6-phosphate dehydrogenase (G6PDH)**, which catalyzes this reaction, is highly specific for NADP^+ . As the first step of a major pathway, the reaction is irreversible and highly regulated. Glucose-6-phosphate dehydrogenase is strongly inhibited by the product coenzyme, NADPH, and also by fatty acid esters of coenzyme A (which are intermediates of fatty acid biosynthesis). Inhibition due to NADPH depends upon the cytosolic $\text{NADP}^+/\text{NADPH}$ ratio, which in the liver is about 0.015 (compared to about 725 for the NAD^+/NADH ratio in the cytosol). G6PDH is the rate-limiting step of the pentose phosphate pathway. G6PDH is directly inhibited by the tumor suppressor p53.

Step 2. Gluconolactonase The gluconolactone produced in step 1 is hydrolytically unstable and readily undergoes a spontaneous ring-opening hydrolysis, although an enzyme, gluconolactonase, accelerates this reaction (Figure 22.24). The linear product, the sugar acid 6-phospho-D-gluconate, is further oxidized in step 3.

Figure 22.23 The glucose-6-phosphate dehydrogenase reaction is the first step in the pentose phosphate pathway and is the committed step in the pentose phosphate pathway.

Figure 22.24 The gluconolactonase reaction is the second pentose phosphate pathway reaction (step 2 in Figure 22.22).

Step 3. 6-Phosphogluconate Dehydrogenase The oxidative decarboxylation of 6-phosphogluconate by *6-phosphogluconate dehydrogenase* yields D-ribulose-5-phosphate and another equivalent of NADPH. There are two distinct steps in this reaction (Figure 22.25): The initial NADP⁺-dependent dehydrogenation yields a β -keto acid, 3-keto-6-phosphogluconate, which is very susceptible to decarboxylation (the second step). The resulting product, D-ribulose-5-P, is the substrate for the nonoxidative reactions composing the rest of this pathway.

22.6c There Are Four Nonoxidative Reactions in the Pentose Phosphate Pathway

This portion of the pathway begins with an isomerization and an epimerization, and it leads to the formation of either D-ribose-5-phosphate or D-xylulose-5-phosphate. These intermediates can then be converted into glycolytic intermediates or directed to biosynthetic processes.

Step 4. Phosphopentose Isomerase This enzyme interconverts ribulose-5-P and ribose-5-P via an enediol intermediate (Figure 22.26). The reaction (and mechanism) is quite similar to the phosphoglucosomerase reaction of glycolysis, which interconverts glucose-6-P and fructose-6-P. The ribose-5-P produced in this reaction is utilized in the biosynthesis of coenzymes (including NADH, NADPH, FAD, and B₁₂), nucleotides, and nucleic acids (DNA and RNA). The net reaction for the first four steps of the pentose phosphate pathway is

Step 5. Phosphopentose Epimerase This reaction converts ribulose-5-P to another ketose, namely, xylulose-5-P. This reaction also proceeds by an enediol intermediate but involves an inversion at C-3 (Figure 22.27). In the reaction, an acidic proton located α - to a carbonyl carbon is removed to generate the enediolate, but the proton is added back to the same carbon from the opposite side. Note the distinction in nomenclature here. Interchange of groups on a single carbon is an epimerization, and interchange of groups between carbons is an isomerization.

Step 3

Figure 22.25 The 6-phosphogluconate dehydrogenase reaction is the third step in the pentose phosphate pathway (Step 3 in Figure 22.22).

Step 4

Figure 22.26 The phosphopentose isomerase reaction is the fourth reaction of the pentose phosphate pathway. It involves an enediol intermediate.

Step 5

Figure 22.27 The phosphopentose epimerase reaction is the fifth step of the pentose phosphate pathway. It interconverts ribulose-5-P and xylulose-5-phosphate. The mechanism involves an enediol intermediate and occurs with inversion at C-3.

Human Biochemistry

Aldose Reductase and Diabetic Cataract Formation

The complications of diabetes include a high propensity for cataract formation in later life, both in type 1 and type 2 diabetics. Hyperglycemia is the suspected cause, but by what mechanism? Several lines of evidence point to the **polyol pathway**, in which glucose and other simple sugars are reduced in NADPH-dependent reactions. Glucose, for example, is reduced by *aldose reductase* to sorbitol (see accompanying figure), which accumulates in lens fiber cells, increasing the intracellular osmotic pressure and eventually rupturing the

cells. The involvement of aldose reductase in this process is supported by the fact that animals that have high levels of this enzyme in their lenses (such as rats and dogs) are prone to develop diabetic cataracts, whereas mice that have low levels of lens aldose reductase activity are not. Moreover, aldose reductase inhibitors such as **tolrestat** and **epalrestat** suppress cataract formation. These drugs or derivatives from them may represent an effective preventive therapy against cataract formation in people with diabetes.

(a)

(b)

Cataract formation is a common complication of type 1 and type 2 diabetes. **(a)** The reduction of glucose to sorbitol. **(b)** Tolrestat and epalrestat are aldose reductase inhibitors that suppress cataract formation.

To this point, the pathway has generated a pool of pentose phosphates. The $\Delta G^{\circ'}$ for each of the last two reactions is small, and the three pentose-5-phosphates coexist at equilibrium. The pathway has also produced two molecules of NADPH for each glucose-6-P converted to pentose-5-phosphate. The next three steps rearrange the five-carbon skeletons of the pentoses to produce three-, four-, six-, and seven-carbon units, which can be used for various metabolic purposes. Why should the cell do this? Very often, the cellular need for NADPH is considerably greater than the need for ribose-5-phosphate. The next three steps thus return some of the five-carbon units to glyceraldehyde-3-phosphate and fructose-6-phosphate, which can enter the glycolytic pathway. The advantage of this is that the cell has met its needs for NADPH and ribose-5-phosphate in a single pathway, yet at the same time it can return the excess carbon metabolites to glycolysis.

Step 6

Figure 22.28 The transketolase reaction of step 6 in the pentose phosphate pathway.

Step 8

Figure 22.29 The transketolase reaction of step 8 in the pentose phosphate pathway.

Steps 6 and 8. Transketolase The transketolase enzyme acts at both steps 6 and 8 of the pentose phosphate pathway. In both cases, the enzyme catalyzes the transfer of two-carbon units. In these reactions (and also in step 7, the transaldolase reaction, which transfers three-carbon units), the donor molecule is a ketose and the recipient is an aldose. In step 6, xylulose-5-phosphate transfers a two-carbon unit to ribose-5-phosphate to form glyceraldehyde-3-phosphate and sedoheptulose-7-phosphate (Figure 22.28). Step 8 involves a two-carbon transfer from xylulose-5-phosphate to erythrose-4-phosphate to produce another glyceraldehyde-3-phosphate and a fructose-6-phosphate (Figure 22.29). Three of these products enter directly into the glycolytic pathway. (The sedoheptulose-7-phosphate is taken care of in step 7, as we shall see.) Transketolase is a thiamine pyrophosphate–dependent enzyme, and the mechanism (Figure 22.30) involves abstraction of the acidic thiazole proton of TPP, attack by the resulting carbanion at the carbonyl carbon of the ketose phosphate substrate, expulsion of the glyceraldehyde-3-phosphate product, and transfer of the two-carbon unit. Transketolase can process a variety of 2-keto sugar phosphates in a similar manner. It is specific for ketose substrates with the configuration shown but can accept a variety of aldose phosphate substrates.

Step 7. Transaldolase The transaldolase functions primarily to make a useful glycolytic substrate from the sedoheptulose-7-phosphate produced by the first transketolase reaction. This reaction (Figure 22.31) is quite similar to the aldolase reaction of glycolysis, involving formation of a Schiff base intermediate between the sedoheptulose-7-phosphate and an active-site lysine residue (Figure 22.32). Elimination of the erythrose-4-phosphate product leaves an enamine of dihydroxyacetone, which remains stable at the active site (without imine hydrolysis) until the other substrate comes into position. Attack of the enamine carbanion at the carbonyl carbon of glyceraldehyde-3-phosphate is followed by hydrolysis of the Schiff base (imine) to yield the product fructose-6-phosphate.

Figure 22.30 The mechanism of the TPP-dependent transketolase reaction. Ironically, the group transferred in the transketolase reaction might best be described as an aldol, whereas the transferred group in the transaldolase reaction is actually a ketol. Despite the irony, these names persist for historical reasons.

Step 7

Figure 22.31 The transaldolase reaction.

Figure 22.32 The transaldolase mechanism involves attack on the substrate by an active-site lysine. Departure of erythrose-4-P leaves the reactive enamine, which attacks the aldehyde carbon of glyceraldehyde-3-P. Schiff base hydrolysis yields the second product, fructose-6-P.

22.6d Utilization of Glucose-6-P Depends on the Cell's Need for ATP, NADPH, and Ribose-5-P

It is clear that glucose-6-phosphate can be used as a substrate either for glycolysis or for the pentose phosphate pathway. The cell makes this choice on the basis of its relative needs for biosynthesis and for energy from metabolism. ATP can be produced in abundance if glucose-6-phosphate is channeled into glycolysis. On the other hand, if NADPH or ribose-5-phosphate is needed, glucose-6-phosphate can be directed to the pentose phosphate pathway. The molecular basis for this regulatory decision depends on the enzymes that metabolize glucose-6-phosphate in glycolysis and the pentose phosphate pathway. In glycolysis, phosphoglucose isomerase converts glucose-6-phosphate to fructose-6-phosphate, which is utilized by phosphofructokinase (a highly regulated enzyme) to produce fructose-1,6-bisphosphate. In the pentose phosphate pathway, glucose-6-phosphate dehydrogenase (also highly regulated) produces 6-phosphogluconolactone from glucose-6-phosphate. Thus, the fate of glucose-6-phosphate is determined to a large extent by the relative activities of phosphofructokinase and glucose-6-P dehydrogenase. Recall from Section 18.3c that PFK is inhibited when the ATP/AMP ratio increases and that it is inhibited by citrate but activated by fructose-2,6-bisphosphate. Thus, when the energy charge is high, glycolytic flux decreases. Glucose-6-P dehydrogenase, on the other hand, is inhibited by high levels of NADPH and also by the acyl-CoA intermediates of fatty acid biosynthesis. Both of these are indicators that biosynthetic demands have been satisfied. If that is the case, glucose-6-phosphate dehydrogenase and the pentose

phosphate pathway are inhibited. If NADPH levels drop, the pentose phosphate pathway turns on and NADPH and ribose-5-phosphate are made for biosynthetic purposes.

Even when the latter choice has been made, however, the cell must still be responsive to the relative needs for ribose-5-phosphate and NADPH (as well as ATP). Depending on these relative needs, the reactions of glycolysis and the pentose phosphate pathway can be combined in novel ways to emphasize the synthesis of needed metabolites. There are four principal possibilities.

1. Both Ribose-5-P and NADPH Are Needed by the Cell In this case, the first four reactions of the pentose phosphate pathway predominate (Figure 22.33). NADPH is produced by the oxidative reactions of the pathway, and ribose-5-P is the principal product of carbon metabolism. As stated earlier, the net reaction for these processes is

2. More Ribose-5-P Than NADPH Is Needed by the Cell Synthesis of ribose-5-P can be accomplished without production of NADPH if the oxidative steps of the pentose phosphate pathway are bypassed. The key to this route is the withdrawal of fructose-6-P and glyceraldehyde-3-P, but not glucose-6-P, from glycolysis. The action of transketolase and transaldolase on fructose-6-P and glyceraldehyde-3-P produces three molecules of ribose-5-P from two molecules of fructose-6-P and one of glyceraldehyde-3-P. In this route, as in case 1, no carbon metabolites are returned to glycolysis. The net reaction for this route is

3. More NADPH Than Ribose-5-P Is Needed by the Cell Large amounts of NADPH can be supplied for biosynthesis without concomitant production of ribose-5-P if ribose-5-P produced in the pentose phosphate pathway is recycled to produce glycolytic intermediates. This alternative involves a complex interplay between the transketolase and transaldolase reactions to convert ribulose-5-P to fructose-6-P and glyceraldehyde-3-P, which can be recycled to glucose-6-P via gluconeogenesis. The net reaction for this process is

Note that in this scheme, the six hexose sugars have been converted to six pentose sugars with release of six molecules of CO₂, and the six pentoses are reconverted to five glucose molecules.

4. Both NADPH and ATP Are Needed by the Cell, but Ribose-5-P Is Not Under some conditions, both NADPH and ATP must be provided in the cell. This can be accomplished in a series of reactions similar to case 3 if the fructose-6-P and glyceraldehyde-3-P produced in this way proceed through glycolysis to produce ATP and pyruvate, which itself can yield even more ATP by continuing on to the TCA cycle. The net reaction for this alternative is

Figure 22.33 When biosynthetic demands dictate, the first four reactions of the pentose phosphate pathway predominate and the principal products are ribose-5-P and NADPH.

Critical Developments in Biochemistry

Integrating the Warburg Effect—ATP Consumption Promotes Cancer Metabolism

How and why do cells fine-tune the production of NADPH, ribose-5-phosphate, and ATP, as described in Section 22.6? The Warburg effect, described in Chapter 18, is a good example of these choices. It is exhibited by cancer cells, which metabolize glucose differently than normal, differentiated cells. Normal cells generally have low rates of glycolysis, followed by oxidation of pyruvate in the mitochondria, leading to efficient generation of ATP. Rapidly proliferating cancer cells, on the other hand, use glycolytic intermediates for the synthesis of macromolecules and must balance their ATP requirements and biosynthetic needs. Moreover, cancer cells must fine-tune their metabolism to choose between synthesizing NADPH, ribose-5-phosphate, or both. Tumor cells also face another problem: If too much ATP is produced by aerobic glycolysis, feedback inhibition of phosphofructokinase may limit glucose utilization altogether.

How do tumor cells manage these needs? One piece of the puzzle has been provided by Xiaodong Wang and coworkers, who have shown that ENTPD5, a UDPase in the endoplasmic reticulum, is associated with ATP consumption in tumor cells. UMP made in this reaction is transported into the cytosol, where it is converted back to UDP, then UTP, and then to UDP-glucose. These reactions are coupled to adenylate kinase (see figure) with net production of AMP. Consumption of ATP and production of AMP stimulates phosphofructokinase, so that glycolysis proceeds to make glyceraldehyde-3-phosphate, which can, together with fructose-6-phosphate, yield

ribose-5-phosphate in the pentose phosphate pathway. Cancer cells use this strategy, together with other regulatory controls (green and red in the figure) to fine-tune the production of NADPH, ribose-5-phosphate, and ATP.

Can cancer cells afford to sacrifice so much ATP in this way? Compare the possible yields from glucose with the needs of a proliferating cell. One glucose can generate up to 34 ATPs, or 2 NADPH plus about 28 ATP (if shunted through the pentose phosphate pathway), or six carbons for biosynthesis. By comparison, in fatty acid synthesis, one palmitate requires 16 carbons, 7 molecules of ATP, and 28 electrons from 14 NADPH. Thus, one glucose provides nearly five times the amount of ATP required to make a palmitate, but only one-seventh of the NADPH required. Clearly, proliferating cells must devote much of their available glucose to NADPH production and biosynthesis, yet still provide sufficient ATP for cellular energy needs.

A variety of cellular signals enable proliferating cells to modulate the production of NADPH, ribose-5-phosphate, and ATP. ENTPD5 expression is enhanced in tumors and promotes ATP consumption, stimulating aerobic glycolysis. The protein kinases P13K and AKT stimulate glucose uptake, as do hexokinase and phosphofructokinase. Phosphorylation by AMP kinase (AMPK) inhibits PFK, whereas p53 blocks synthesis of NADPH by inhibition of glucose-6-phosphate dehydrogenase.

Note that, except for the three molecules of CO_2 , all the other carbon from glucose-6-P is recovered in pyruvate.

The pentose phosphate pathway plays a pivotal role in helping cancer cells meet their needs for ATP, NADPH, ribose-5-phosphate, and fatty acids. Activation of oncogenic proteins and inactivation of tumor suppressors provide a plethora of mechanisms that modulate and regulate the reactions of this versatile pathway.

22.6e Xylulose-5-Phosphate Is a Metabolic Regulator

In addition to its role in the pentose phosphate pathway, xylulose-5-phosphate serves as a signaling molecule. When blood glucose concentration rises (for example, following a carbohydrate-rich meal), glycolysis and the pentose phosphate pathway are activated in the liver, and xylulose-5-phosphate produced in the latter pathway stimulates **protein phosphatase 2A (PP2A)**, which dephosphorylates the bifunctional enzyme PFK-2/F-2,6-BPase (Figure 22.34; see also Figure 22.10). Increases in [fructose-2,6-bisphosphate] stimulate glycolysis and inhibit gluconeogenesis. At the same time, PP2A dephosphorylates *carbohydrate-responsive element-binding protein (ChREBP)*, a transcription factor which then activates expression of liver genes for lipid synthesis. These effects are a powerful combination. Increased glycolysis produces substantial amounts of acetyl-CoA, the principal substrate for lipid synthesis. The pentose phosphate pathway produces NADPH, the source of electrons for lipid biosynthesis. Elevated expression of the appropriate genes sets the stage for lipid biosynthesis in the liver, an important consequence of ingestion of carbohydrates.

Figure 22.34 Xylulose-5-phosphate activation of PP2A affects multiple metabolic pathways. Activation of PP2A triggers dephosphorylation of the bifunctional PFK-2/F-2,6-BPase, which raises fructose-2,6-BP levels, in turn activating glycolysis and inhibiting gluconeogenesis. Simultaneously, ChREBP is dephosphorylated, leading to elevated expression of genes encoding enzymes for lipogenesis. These effects combine to trigger lipid biosynthesis in response to a carbohydrate-rich meal. Plus signs indicate activation.

Foundational Biochemistry Things You Should Know after Reading Chapter 22.

- Gluconeogenesis is the generation (genesis) of new (neo) glucose. Substrates for gluconeogenesis include pyruvate, lactate, and amino acids.
- Gluconeogenesis is not the reverse of glycolysis. It involves four new reactions—pyruvate carboxylase, PEP carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase. The resulting cellular free energy change for gluconeogenesis is strongly negative.
- Regulation of gluconeogenesis involves allosteric activation of pyruvate carboxylase by acetyl-CoA, allosteric inhibition of fructose-1,6-bisphosphatase by F-2,6-bisP and AMP, and substrate level control of glucose-6-phosphatase by glucose-6-phosphate.
- Dietary starch breakdown is unregulated and provides metabolic energy.
- Tissue glycogen represents an important reservoir of potential energy and metabolism of tissue glycogen is carefully controlled and regulated.
- Glucose units are activated for transfer into complex polysaccharides by formation of sugar nucleotides.
- UDP-Glucose synthesis is driven by pyrophosphate hydrolysis.
- Glycogen metabolism is highly regulated. Glycogen synthase is regulated by covalent modifications and hormones regulate glycogen synthesis and degradation.
- Glucagon and epinephrine stimulate glycogen breakdown. Epinephrine acts quickly, initiating a cascade of reactions that lead to rapid breakdown of glycogen, inhibition of glycogen synthesis, stimulation of glycolysis, and production of energy.
- Glucagon is involved in long-term maintenance of steady-state levels of glucose in the blood.
- The pentose phosphate pathway, operating mainly in liver and adipose tissue, provides electrons for biosynthesis.
- The pentose phosphate pathway begins with two oxidative reactions that convert glucose-6-phosphate to ribulose-5 phosphate, followed by four non-oxidative reactions.
- Utilization of glucose-6-phosphate depends on the cell's need for ATP, NADPH, and ribose-5-P.
- Xylulose-5-phosphate is a metabolic signal that stimulates protein phosphatase 2A.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Assessing the Overall Equation for Gluconeogenesis** Consider the balanced equation for gluconeogenesis in Section 22.1. Account for each of the components of this equation (that is, explain where each component comes from) and the indicated stoichiometry.
- NADH in Gluconeogenesis** While other anabolic pathways use NADPH as the reducing agent, gluconeogenesis uses NADH. Provide three possible reasons for why this is advantageous for the cell.
- Assessing the Energetics of Gluconeogenesis** (Integrates with Chapters 3 and 18.) Calculate ΔG° and ΔG for gluconeogenesis in the erythrocyte, using information from Tables 3.2, 18.1, 18.2, and Section 22.1 (assume $\text{NAD}^+/\text{NADH} = 20$, $[\text{GTP}] = [\text{ATP}]$, and $[\text{GDP}] = [\text{ADP}]$). Make sure that your values match those in Section 22.1.
- Decarboxylation Reactions** Explain why decarboxylation reactions like the conversion of oxaloacetate into PEP are highly favorable.
- Understanding the Regulation of the Fructose-1,6-Bisphosphatase Reaction** Use the data of Figure 22.9 to calculate the percent inhibition of fructose-1,6-bisphosphatase by 25 mM fructose-2,6-bisphosphate when fructose-1,6-bisphosphate is (a) 25 mM and (b) 100 mM.
- Regulation of Fructose-2,6-Bisphosphate** Glucagon is a hormone released when blood sugar levels are low. If this hormone had an effect on the activity of phosphofructokinase-2 (PFK-2) in liver cells, would you predict it to activate or inhibit PFK-2? Explain your answer.
- Understanding the Energetics of the Glycogen Synthase Reaction** (Integrates with Chapter 3.) Suggest an explanation for the exergonic nature of the glycogen synthase reaction ($\Delta G^\circ = -13.3 \text{ kJ/mol}$). Consult Chapter 3 to review the energetics of high-energy phosphate compounds if necessary.
- Glycogen in Muscles** Skeletal muscles contain high levels of glycogen. However, this muscle glycogen cannot be used to raise blood sugar during times of fasting. Explain why this is the case.
- Determining the Rate of Energy Consumption by Muscles During Exercise** Using the values in Table 23.1 for body glycogen content and the data in part b of the illustration for A Deeper Look (“Carbohydrate Utilization in Exercise”), calculate the rate of energy consumption by muscles in heavy exercise (in J/sec). Use the data for fast-twitch muscle.
- Assessing the Action of Sodium Borohydride on the Pentose Phosphate Pathway** Which reactions of the pentose phosphate pathway would be inhibited by NaBH_4 ? Why?
- Reversible Reactions in Gluconeogenesis** For the reversible reactions of glycolysis/gluconeogenesis, what determines the direction of the reaction?
- Determining the Extent of Branching in Glycogen** (Integrates with Chapter 7.) Imagine a glycogen molecule with 8000 glucose residues. If branches occur every eight residues, how many reducing ends does the molecule have? If branches occur every 12 residues, how many reducing ends does it have? How many nonreducing ends does it have in each of these cases?
- Describing the Regulation of Gluconeogenesis and Glycogen Metabolism** Explain the effects of each of the following on the rates of gluconeogenesis and glycogen metabolism:
 - Increasing the concentration of tissue fructose-1,6-bisphosphate.
 - Increasing the concentration of blood glucose.
 - Increasing the concentration of blood insulin.
 - Increasing the amount of blood glucagon.
 - Decreasing levels of tissue ATP.
 - Increasing the concentration of tissue AMP.
 - Decreasing the concentration of fructose-6-phosphate.
- Other Carbohydrates in Glycogen Metabolism** (Integrates with Chapter 18.) Can D-mannose, D-fructose, or D-galactose be stored as glycogen or serve as sources of NADPH through the pentose phosphate pathway?
- Fatty Acids and Gluconeogenesis** Although fatty acids cannot serve as precursors for gluconeogenesis, could triacylglycerides play a role in gluconeogenesis? Explain.
- Assessing the Energetics of the Glycogen Phosphorylase Reaction** (Integrates with Chapters 3 and 15.) The free energy change of the glycogen phosphorylase reaction is $\Delta G^\circ = +3.1 \text{ kJ/mol}$. If $[\text{P}_i] = 1 \text{ mM}$, what is the concentration of glucose-1-P when this reaction is at equilibrium?

17. Understanding Enzyme Mechanisms Related to Pyruvate Carboxylase

Based on the mechanism for pyruvate carboxylase (Figure 22.3), write reasonable mechanisms for the reactions that follow:

**18. Understanding the Mechanisms of Reactions Related to Transketolase** The mechanistic chemistry of the acetolactate synthase and phosphoketolase reactions (shown here) is similar to that of the transketolase reaction (Figure 22.30). Write suitable mechanisms for these reactions.

19. Malate/Aspartate Shuttle and Gluconeogenesis (Integrates with Chapter 20.) What is the contribution of the malate/aspartate shuttle to the gluconeogenesis pathway? (See Figure 20.31 and Figure 22.4 in Section 22.1e.)

20. Understanding the Mechanisms of Action of a Popular Diabetes Medication Metaglip is a prescribed preparation (from Bristol-Myers Squibb) for treatment of type 2 diabetes. It consists of metformin (see Human Biochemistry, box “Metformin—A Diabetes Drug with Multiple Actions” in Section 22.1.) together with glipizide. The actions of metformin and glipizide are said to be complementary. Suggest a mechanism for the action of glipizide.

21. Assessing the Mechanism of Action of Aldose Reductase Inhibitors Study the structures of tolrestat and epalrestat in the Human Biochemistry box “Aldose Reductase and Diabetic Cataract Formation” in Section 22.6, and suggest a mechanism of action for these inhibitors of aldose reductase.

22. Understanding a Version of the Pentose Phosphate Pathway That Produces Mainly Ribose-5-P Based on the discussion in Section 22.6, draw a diagram to show how several steps in the pentose phosphate pathway can be bypassed to produce large amounts of ribose-5-phosphate. Begin your diagram with fructose-6-phosphate.

- 23. Assessing the Labeling Patterns in Versions of the Pentose Phosphate Pathway** Consider the diagram you constructed in Problem 22. Which carbon atoms in ribose-5-phosphate are derived from carbon atoms in positions 1, 3, and 6 of fructose-6-phosphate?
- 24. Understanding a Version of the Pentose Phosphate Pathway That Produces Mainly NADPH** As described in Section 22.6, the pentose phosphate pathway may be used to produce large amounts of NADPH without significant net production of ribose-5-phosphate. Draw a diagram, beginning with glucose-6-phosphate, to show how this may be accomplished.
- 25. Understanding a Version of the Pentose Phosphate Pathway That Produces Mainly NADPH and ATP** Section 22.6 explains that the pentose phosphate pathway and the glycolytic pathway can be combined to provide both NADPH and ATP (as well as some NADH) without net ribose-5-phosphate synthesis. Draw a diagram to show how this may be accomplished.
- 26. Assessing the Labeling Patterns in Versions of the Pentose Phosphate Pathway** Consider the pathway diagram you constructed in Problem 25. What is the fate of carbon from positions 2 and 4 of glucose-6-phosphate after one pass through the pathway?
- 27. Understanding the Initial Reaction in Formation of Glycogen** Glycogenin catalyzes the first reaction in the synthesis of a glycogen particle, with Tyr¹⁹⁴ of glycogenin (Figure 22.11) combining with a glucose unit (provided by UDP-glucose) to produce a tyrosyl glucose. Write a mechanism to show how this reaction could occur.
- 28. Assessing the Biochemistry of Exercise** Study the graphs in the Deeper Look box “Carbohydrate Utilization in Exercise,” and explain the timing of the provision of energy from different metabolic sources during periods of heavy exercise.
- 29. Understanding the Chemistry and Energetics of Creatine Phosphate** (Integrates with Chapters 3 and 14.) What is the structure of creatine phosphate? Write reactions to indicate how it stores and provides energy for exercise.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

- 30.** Examine the PSAFE model for fructose-1,6-bisphosphatase, then describe the role of Arg²² in the conformational change between the R and T states of this enzyme.
- 31.** Using the PSAFE model for aldose reductase, describe the structure of the TIM barrel motif as well as the structure and location of the active site.

Think-Pair-Share Question

The product of the p53 tumor suppressor gene, the p53 protein, has multiple functions, including suppressing uncontrolled cell growth. Dysfunctional p53 has been identified as a strong contributing factor in the transformation of normal cells into cancerous cells for many different types of tumors. P53 has been shown to inhibit glycolysis and the pentose phosphate pathway (see Figures 22.8 and 22.22). What benefits may there be to a cancer cell from a dysfunctional p53 and a lesser inhibition of the glycolysis and pentose phosphate pathway? Discuss at least four products or intermediates from these pathways that benefit the growth of a normal cell and that would stimulate uncontrolled growth if these pathways are not properly regulated.

Proverbs (1497–1580)*

- ▶ The hummingbird's tremendous capacity to store and use fatty acids enables it to make migratory journeys of remarkable distances.

Essential Questions

Fatty acids are the principal form of stored energy for many organisms. There are two important advantages to this (i) The carbon in fatty acids (mostly $\text{—CH}_2\text{—}$ groups) is almost completely reduced compared to the carbon in sugars and amino acids. Therefore, oxidation of fatty acids will yield more energy (in the form of ATP) than any other form of carbon. (ii) Fatty acids are not as hydrated as monosaccharides and polysaccharides, and thus pack more closely in storage tissues. **How are fatty acids catabolized, and how is their inherent energy captured by organisms?**

The catabolism of fatty acids provides a rich source of energy for many organisms, primarily in the form of ATP. This chapter describes the mobilization of fats from dietary sources and from adipose tissue, and the pathways of fatty acid breakdown, including the oxidation pathway and the processing of unsaturated, odd-carbon and branched chain fatty acids.

23.1 | How Are Fats Mobilized from Dietary Intake and Adipose Tissue?

Fatty acids are acquired readily in the diet and can also be made from carbohydrates and the carbon skeletons of amino acids. Animals also store fatty acids (mainly as triglycerides) in adipose tissue, a central metabolic organ involved in the regulation of energy homeostasis in the body.

23.1a Modern Diets Are Often High in Fat

Fatty acids provide 30% to 60% of the calories in the diets of most Americans. For our caveman and cavewoman ancestors, the figure was probably closer to 20%. Dairy products were apparently not part of their diet, and the meat they consumed (from fast-moving animals) was low in fat. In contrast, modern domesticated cows and pigs

are actually bred for high fat content (and better taste). However, woolly mammoth burgers and saber-toothed tiger steaks are hard to find these days—even in the gourmet sections of grocery stores—and so, by default, we consume (and metabolize) large quantities of fatty acids from both animal and non-animal sources.

23.1b Triacylglycerols Are a Major Form of Stored Energy in Animals

Although some of the fat in our diets is in the form of phospholipids, triacylglycerols are a major source of fatty acids. Triacylglycerols are also our principal stored energy reserve. As shown in Table 23.1, the energy available in stores of fat in the average person far exceeds the energy available from protein, glycogen, and glucose. Overall, fat accounts for approximately 83% of available energy, partly because more fat is stored than protein and carbohydrate and partly because of the substantially higher energy yield per gram for fat compared with protein and carbohydrate. Complete combustion of fat yields about 37 kJ/g, compared with about 16 to 17 kJ/g for sugars, glycogen, and amino acids. In animals, fat is stored mainly as triacylglycerols in specialized cells called **adipocytes** or **adipose cells**. As shown in Figure 23.1, triacylglycerols, aggregated to form large globules, occupy most of the volume of adipose cells. Much smaller amounts of triacylglycerols are stored as small, aggregated globules in muscle tissue.

Figure 23.1 Scanning electron micrograph of an adipose cell (fat cell). Globules of triacylglycerols occupy most of the volume of such cells.

23.1c Hormones Trigger the Release of Fatty Acids from Adipose Tissue

The pathways for liberation of fatty acids from triacylglycerols, either from adipose cells or from the diet, are shown in Figures 23.2 and 23.3. Fatty acids are mobilized from adipocytes in response to hormone messengers such as adrenaline, glucagon, and adrenocorticotrophic hormone (ACTH). These signal molecules bind to receptors on the plasma membrane of adipose cells and lead to the activation of adenylyl cyclase, which forms cyclic AMP from ATP. In adipose cells, cAMP activates protein kinase A, which phosphorylates and activates a **triacylglycerol lipase** (also termed *hormone-sensitive lipase*) that hydrolyzes a fatty acid from C-1 or C-3 of triacylglycerols. Subsequent actions of *diacylglycerol lipase* and *monoacylglycerol lipase* yield fatty acids and glycerol. The cell then releases the fatty acids into the blood, where they are bound to **serum albumin** (the most abundant protein in blood serum). Serum albumin transports free fatty acids to sites of utilization.

23.1d Degradation of Dietary Triacylglycerols Occurs Primarily in the Duodenum

Dietary triacylglycerols are degraded to a small extent (via fatty acid release) by triacylglycerol lipases in the low-pH environment of the stomach, but mostly they pass untouched into the duodenum. Alkaline pancreatic juice secreted into the

Figure 23.2 Liberation of fatty acids from triacylglycerols in adipose tissue is hormone dependent.

duodenum (Figure 23.3a) raises the pH of the digestive mixture, allowing hydrolysis of the triacylglycerols by pancreatic lipase and by nonspecific esterases, which hydrolyze the fatty acid ester linkages. Pancreatic lipase cleaves fatty acids from the C-1 and C-3 positions of triacylglycerols, and other lipases and esterases attack the C-2 position (Figure 23.3b). These processes depend upon the presence of **bile salts**, a family of carboxylic acid salts with steroid backbones (see Chapter 8). These agents act as detergents to emulsify the triacylglycerols and facilitate the hydrolytic activity of the lipases and esterases. Short-chain fatty acids (10 or fewer carbons) released in this way are absorbed directly into the villi of the intestinal mucosa, whereas long-chain fatty acids, which are less soluble, form mixed micelles with bile salts and are carried in this fashion to the surfaces of the epithelial cells that cover the villi (Figure 23.4). The fatty acids pass into the epithelial cells, where they are condensed with glycerol to form new triacylglycerols. These triacylglycerols aggregate with lipoproteins to form particles called **chylomicrons**, which are then transported into the lymphatic system and on to the bloodstream, where they circulate to the liver, lungs, heart, muscles, and other organs. At these sites, the triacylglycerols are hydrolyzed to release fatty acids, which can then be oxidized in a highly exergonic metabolic pathway known as *β -oxidation*.

Figure 23.3 Dietary triacylglycerols are degraded primarily in the duodenum. **(a)** The pancreatic duct secretes digestive fluids into the duodenum, the first portion of the small intestine. **(b)** Hydrolysis of triacylglycerols by pancreatic and intestinal lipases. Pancreatic lipases cleave fatty acids at the C-1 and C-3 positions. Resulting monoacylglycerols with fatty acids at C-2 are hydrolyzed by intestinal lipases. Fatty acids and monoacylglycerols are absorbed through the intestinal wall and assembled into lipoprotein aggregates termed chylomicrons.

Human Biochemistry

Serum Albumin—Tramp Steamer of the Bloodstream

Human serum albumin, at a concentration of 40 mg/mL, is the most abundant protein in the blood serum. It is a single polypeptide of 585 amino acids (66.4 kDa); the absence of any glycosylations makes it novel among extracellular proteins. Serum albumin has three principal functions: (i) It provides 80% of the osmotic pressure of blood plasma; (ii) As the major macromolecular anion in the blood, it has important buffering capacity; (iii) It is the major transport vehicle of hydrophobic substances. In this latter role, serum albumin merits the sobriquet “tramp steamer of the bloodstream” because of its ability to nonspecifically bind and transport numerous hydrophobic substances, including drugs taken for pharmacological benefit. (Tramp steamers are ships that operate on an as-needed basis, hauling any sort of cargo from place to place.) As much as 90% of some drugs are bound by serum albumin.

The solubility of free fatty acids in blood plasma is limited, amounting to only 0.1 nM. However, the concentration of fatty acids, as bound to serum albumin, approaches 1 mM. Serum albumin possesses 11 distinct fatty acid-binding sites.

The heart-shaped tertiary structure of human serum albumin, with 11 molecules of decanoic acid bound (PDB id = 1E7F).

Figure 23.4 In the small intestine, fatty acids combine with bile salts in mixed micelles, which deliver fatty acids to epithelial cells that cover the intestinal villi. Fatty acids diffuse across the brush border membrane and into the epithelial cells. There, the fatty acids combine with glycerol to form new triacylglycerols, which aggregate with lipoproteins to form chylomicrons. Taken up by the lymphatic system, chylomicrons circulate to tissues throughout the body.

A Deeper Look

The Biochemistry of Obesity

Obesity is a worldwide health problem. It is associated with insulin resistance, type 2 diabetes, atherosclerosis, and ischemic heart disease—conditions that reduce life expectancy and present significant societal and economic consequences. Evidence is accumulating that obesity causes chronic low-grade inflammation, which contributes to the systemic metabolic dysfunction that is associated with obesity-linked disorders.

Fat consumed in the diet traverses the circulatory system either as serum albumin-bound free fatty acids (FFA) or in triglyceride-rich lipoproteins, which release FFA to cells through the action of membrane-associated lipoprotein lipases (LPL). Circulating fatty acids are taken up by the endothelial cells lining blood vessel walls and bind to cytosolic fatty acid-binding proteins (Figure 1).

Figure 1 Human fatty acid-binding protein with bound oleic acid (PDB id = 2LKK).

Binding to these proteins determines their destination and fate, such as serving as ligands for transcription factors in the nucleus. For example, *peroxisome proliferator-activated receptors* (PPARs) regulate the expression of genes that control fatty acid oxidation and triglyceride metabolism (Figure 2). Another transcription factor, *NHR-80*, regulates expression of desaturases, enzymes that convert saturated fatty acids into unsaturated fatty acids. Overexpression of *NHR-80* in the roundworm *C. elegans* extends the organism's life span significantly.

High levels of circulating FFA lead to altered deposition and accumulation of triglycerides in liver, muscle, and adipose tissue. In each of these tissues, altered fat accumulation provokes a cascade of signals that leads to stress and inflammatory responses and metabolic dysfunction. In this context, adipose tissue is not only involved in energy storage but also functions as an endocrine organ that plays a key role in integration of system metabolism by secreting a variety of signaling proteins.

Proteins secreted by adipose tissue are collectively called **adipokines**. These secreted proteins have either pro-inflammatory or anti-inflammatory activities. Altered production and/or secretion of these adipokines contributes to obesity-linked complications. The expression of adipokines varies depending on the site of the adipose tissue depot (see Figure 3). The two most abundant depots are visceral and

Figure 2 Trafficking of fatty acids. Fatty acids delivered to the nucleus are ligands for transcription factors including PPAR and RXR. The PPAR-RXR transcriptional complex is a key regulator of proteins central to handling of energy resources in the cell, including transport (lipoprotein metabolism), release (lipases), cellular uptake (fatty acid transporters), energy release (beta oxidation), and storage (adipogenesis).

Figure 3 Locations of adipose tissues in the human body.

subcutaneous adipose tissues, but each of the adipose depots in the body produces a unique collection of adipokines. The various adipokines are produced either by adipose cells themselves or by other associated cells including macrophages and immune system cells.

Pro-inflammatory adipokines include *tumor necrosis factor* (*TNF*), which induces systemic inflammation and apoptosis; *resistin* and *IL-6*, which induce insulin resistance; *lipocalin*, which binds and transports small lipophilic molecules like retinoids, arachidonic acid, and steroids; and *ANGPTL2*, which induces both inflammation and insulin resistance. Obese individuals also secrete high levels of *leptin*, which normally inhibits eating and promotes energy expenditure; however, obese individuals have often become leptin-resistant. Leptin also increases the production of *TNF* and *IL-6* and is thus considered a pro-inflammatory adipokine.

Anti-inflammatory adipokines include *adiponectin*, which protects against obesity-linked metabolic dysfunction in several ways. Adiponectin enhances insulin sensitivity and reduces plasma levels of glucose, free fatty acids, and triglycerides. The beneficial effects of adiponectin derive in part from its activation of AMP-activated protein kinase (AMPK), which stimulates glucose uptake and fatty acid oxidation in muscle and inhibits gluconeogenesis in the liver.

23.2 | How Are Fatty Acids Broken Down?

The earliest clue to the secret of fatty acid oxidation and breakdown came in the early 1900s, when Franz Knoop carried out experiments in which he fed modified fatty acids to dogs. Knoop's experiments showed that fatty acids must be degraded by *oxidation at the β -carbon* (Figure 23.5), followed by cleavage of the $C_\alpha-C_\beta$ bond. Repetition of this process yielded two-carbon units, which Knoop assumed must be acetate. Much later, Albert Lehninger showed that this degradative process took place in the mitochondria, and Knoop and Lehninger showed that the two-carbon unit released is *acetyl-CoA*, not free acetate. Because the entire process begins with oxidation of the carbon that is " β " to the carboxyl carbon, the process has come to be known as **β -oxidation**.

In mammalian cells, β -oxidation takes place primarily in mitochondria, but a similar pathway occurs in peroxisomes. In yeast and other lower eukaryotes, β -oxidation is

Figure 23.5 Fatty acids are degraded by repeated cycles of oxidation at the β -carbon and cleavage of the $C_\alpha-C_\beta$ bond to yield acetate units, in the form of acetyl-CoA. Each cycle of β -oxidation yields four electrons, captured as $FADH_2$ and $NADH$, which drive electron transport and oxidative phosphorylation pathways to produce ATP.

confined exclusively to peroxisomes. Mitochondrial β -oxidation provides energy to the organism (Figure 23.6), whereas peroxisomal β -oxidation is responsible for shortening long-chain fatty acids that are poor substrates for mitochondrial β -oxidation. Such shortened fatty acids then become substrates for mitochondrial β -oxidation.

23.2a Coenzyme A Activates Fatty Acids for Degradation

The process of β -oxidation begins with the formation of a thiol ester bond between the fatty acid and the thiol group of coenzyme A. This reaction, shown in Figure 23.6, is catalyzed by **acyl-CoA synthetase**, which is also called **acyl-CoA ligase** or **fatty acid thiokinase**. This condensation with CoA activates the fatty acid for reaction in the β -oxidation pathway. For long-chain fatty acids in higher eukaryotes, this reaction normally occurs at the outer mitochondrial membrane before entry of the fatty acid into the mitochondrion. However, it may also occur at the surface of the endoplasmic reticulum. Short- and medium-length fatty acids undergo this activating reaction in the mitochondria. In all cases, the reaction is accompanied by the hydrolysis of ATP to form AMP and pyrophosphate. As shown in Figure 23.6, the overall reaction has a net ΔG° of about -0.8 kJ/mol, so the reaction is favorable but easily reversible. However, there is more to the story. The pyrophosphate produced in this reaction is rapidly hydrolyzed by inorganic pyrophosphatase to two molecules of phosphate, with a net ΔG° of about -33.6 kJ/mol. Thus, pyrophosphate is maintained at a low concentration in the cell (usually less than $10 \mu\text{M}$), and the synthetase reaction is strongly promoted. The mechanism of the acyl-CoA synthetase reaction is shown in Figure 23.7 and involves attack of the fatty acid carboxylate on ATP to form an *acyl-adenylate intermediate*, which is subsequently attacked by CoA, forming a fatty acyl-CoA thioester.

Figure 23.6 The acyl-CoA synthetase reaction activates fatty acids for β -oxidation. The reaction is driven by hydrolysis of ATP to AMP and pyrophosphate as well as by the subsequent hydrolysis of pyrophosphate.

Figure 23.7 The mechanism of the acyl-CoA synthetase reaction involves fatty acid carboxylate attack on ATP to form an acyl-adenylate intermediate. The fatty acyl-CoA thioester product is formed by CoA attack on this intermediate.

23.2b Carnitine Carries Fatty Acyl Groups Across the Inner Mitochondrial Membrane

All of the other enzymes of the β -oxidation pathway are located in the mitochondrial matrix. Short-chain fatty acids, as already mentioned, are transported into the matrix as free acids and form the acyl-CoA derivatives there. However, long-chain fatty acyl-CoA derivatives cannot be transported into the matrix directly. These long-chain derivatives must first be converted to *acylcarnitine* derivatives, as shown in Figure 23.8. **Carnitine acyltransferase I**, associated with the outer mitochondrial membrane, catalyzes the formation of the *O*-acylcarnitine, which is then transported across the inner membrane by a **translocase**. At this point, the acylcarnitine is passed to **carnitine acyltransferase II** on the matrix side of the inner membrane, which transfers the fatty acyl group back to CoA to re-form the fatty acyl-CoA, leaving free carnitine, which can return across the membrane via the translocase.

Several additional points should be made. First, although oxygen esters usually have lower group-transfer potentials than thiol esters, the O—acyl bonds in acylcarnitines have high group-transfer potentials, and the transesterification reactions mediated by the acyltransferases have equilibrium constants close to 1. Second, note that eukaryotic cells maintain separate pools of CoA in the mitochondria and in the cytosol. The cytosolic pool is utilized principally in fatty acid biosynthesis, and the mitochondrial pool is important in the oxidation of fatty acids and pyruvate as well as some amino acids.

Figure 23.8 The formation of acylcarnitines and their transport across the inner mitochondrial membrane. The process involves the coordinated actions of carnitine acyltransferases on both the inner and outer mitochondrial membranes and of a translocase that shuttles *O*-acylcarnitines across the inner membrane.

Careers in Chemistry

Dr. Katherine Scheibel

Dr. Katherine Scheibel earned her B.S. at Cornell University where she double majored in Plant Sciences and Biology. She went on to earn a Ph.D. in Plant Biology at the University of California, Berkeley. Working in the lab of Professor Shauna Somerville, she studied the biology and genomics of powdery mildew, a plant pathogenic fungus.

After finishing her Ph.D., Dr. Scheibel knew that she wanted to teach but wanted a change

from a university setting. She currently works as an in-house subject matter expert for Cengage Academic Publishing where she lends her expertise to the development of textbooks, lab activities, and video presentations.

Whether it's teaching enzyme kinetics or the structure and function of biological molecules, Dr. Scheibel leans on the core concepts of biochemistry to explain aspects of biology.

23.2c β -Oxidation Involves a Repeated Sequence of Four Reactions

For saturated fatty acids, the process of β -oxidation involves a recurring cycle of four steps, as shown in Figure 23.9. The overall strategy in the first three steps is to create a carbonyl group on the β -carbon by oxidizing the $C_\alpha-C_\beta$ bond to form an olefin, with subsequent hydration and oxidation. In essence, this cycle is directly analogous to the sequence of reactions converting succinate to oxaloacetate in the TCA cycle. The fourth reaction of the cycle cleaves the β -keto ester in a reverse Claisen condensation, producing an acetate unit and leaving a fatty acid chain that is two carbons shorter than it began. (Recall from Chapter 19 that Claisen condensations involve attack by a nucleophilic agent on a carbonyl carbon to yield a β -keto acid.)

Figure 23.9 The β -oxidation of saturated fatty acids involves a cycle of four enzyme-catalyzed reactions. Step 1: Oxidation of a single bond to a double bond. Step 2: Hydration across the double bond. Step 3: Oxidation of the hydroxyl to a carbonyl. Step 4: α - β cleavage to produce an acetyl-CoA product. Each cycle produces single molecules of FADH_2 , NADH , and acetyl-CoA; consumes a water; and yields a fatty acid shortened by two carbons. (The delta [Δ] symbol connotes a double bond, and its superscript indicates the lower-numbered carbon involved.)

Figure 23.12 The acyl-CoA dehydrogenase reaction. The two electrons removed in this oxidation reaction are delivered to the electron-transport chain in the form of reduced coenzyme Q (UQH₂).

All acyl-CoA dehydrogenases carry noncovalently (but tightly) bound FAD, which is reduced during the oxidation of the fatty acid. As shown in Figure 23.12, FADH₂ transfers its electrons to an **electron transfer flavoprotein (ETF)**. Reduced ETF is reoxidized by a specific oxidoreductase (an iron–sulfur protein), which in turn sends the electrons on to the electron-transport chain at the level of coenzyme Q. Recall from Chapter 20 that mitochondrial oxidation of FAD in this way eventually results in the net formation of about 1.6 ATPs. The mechanism of the acyl-CoA dehydrogenase (Figure 23.13) involves deprotonation of the fatty acid chain at the α-carbon, followed by hydride transfer from the β-carbon to FAD.

Enoyl-CoA Hydratase Adds Water Across the Double Bond The next step in β-oxidation is the addition of the elements of H₂O across the new double bond in a stereospecific manner, yielding the corresponding hydroxyacyl-CoA.

The reaction is catalyzed by **enoyl-CoA hydratase** (Figure 23.14). A number of different enoyl-CoA hydratase activities have been detected in various tissues. Also called **crotonases**, these enzymes specifically convert *trans*-enoyl-CoA derivatives to L-β-hydroxyacyl-CoA. Enoyl-CoA hydratases will also metabolize *cis*-enoyl-CoA (at slower rates) to give specifically D-β-hydroxyacyl-CoA. In addition, there is a novel enoyl-CoA hydratase that converts *trans*-enoyl-CoA to D-β-hydroxyacyl-CoA.

Figure 23.14 Structures of mitochondrial (a) enoyl-CoA hydratase trimer (PDB id = 2DUB), (b) hydroxyacyl-CoA dehydrogenase dimer (PDB id = 1F0Y), and (c) ketoacyl thiolase dimer (PDB id = 1AFW).

Figure 23.13 The mechanism of acyl-CoA dehydrogenase. Removal of a proton from the α-C is followed by hydride transfer from the β-carbon to FAD.

L-Hydroxyacyl-CoA Dehydrogenase Oxidizes the β -Hydroxyl Group The third reaction of this cycle is the oxidation of the hydroxyl group at the β -position to produce a β -ketoacyl-CoA derivative. This second oxidation reaction is catalyzed by **L-hydroxyacyl-CoA dehydrogenase**, an enzyme that requires NAD^+ as a coenzyme (see Figure 23.9).

NADH produced in this reaction represents metabolic energy. Each NADH produced in mitochondria by this reaction drives the synthesis of 2.7 molecules of ATP in the electron-transport pathway. L-Hydroxyacyl-CoA dehydrogenase shows absolute specificity for the L-hydroxyacyl isomer of the substrate. (D-Hydroxyacyl isomers, which arise mainly from the metabolism of unsaturated fatty acids, are handled differently.)

β -Ketoacyl-CoA Intermediates Are Cleaved in the Thiolase Reaction The final step in the β -oxidation cycle is the cleavage of the β -ketoacyl-CoA. This reaction, catalyzed by ketoacyl **thiolase** (also known as **β -ketothiolase**, Figure 23.9), involves the attack of a cysteine thiolate from the enzyme on the β -carbonyl carbon, followed by cleavage to give the enolate of acetyl-CoA and an enzyme-thioester intermediate (Figure 23.15). Subsequent attack by the thiol group of a second CoA and departure of the cysteine thiolate yields a new (shorter) acyl-CoA. If the reaction in Figure 23.15 is read in reverse, it is easy to see that it is a Claisen condensation—an attack of the enolate anion of acetyl-CoA on a thioester. Despite the formation of a second thioester, this reaction has a very favorable K_{eq} , and it drives the three previous reactions of β -oxidation.

23.2d Repetition of the β -Oxidation Cycle Yields a Succession of Acetate Units

In essence, this series of four reactions has yielded a fatty acid (as a CoA ester) that has been shortened by two carbons and one molecule of acetyl-CoA. The shortened fatty acyl-CoA can now go through another β -oxidation cycle, as shown in Figure 23.9.

Figure 23.15 The mechanism of the thiolase reaction. Attack by an enzyme cysteine thiolate group at the β -carbonyl carbon produces a tetrahedral intermediate, which decomposes with departure of acetyl-CoA, leaving an enzyme thioester intermediate. Attack by the thiol group of a second CoA yields a new (shortened) acyl-CoA.

Human Biochemistry

Exercise Can Reverse the Consequences of Metabolic Syndrome

Metabolic syndrome is a combination of disorders that increase the risk of diabetes and cardiovascular disease. The hallmarks of metabolic syndrome include high blood pressure, elevated serum triglycerides, reduced serum high-density lipoprotein (HDL), insulin resistance, and obesity. The prevalence of these conditions is increasing in the United States. By most estimates, more than 40% of Americans are obese, and rising obesity has contributed to an epidemic of type 2 diabetes. Insights into how the body deals with high fat and high sugar diets are emerging from a variety of studies, and evidence points clearly to the benefits of exercise and dietary restriction. Endurance training (such as distance running) and resistance training (with weights) are both beneficial. Endurance training increases the mass of slow-twitch muscle fibers, resistance training builds fast-twitch muscle fibers, and both types of exercise reduce body fat, but in quite different ways.

Slow-twitch muscles depend on fatty acid oxidation and TCA cycle activity to support long periods of exercise and are termed *oxidative*. Effects of endurance training include increased expression of (i) *peroxisome proliferator-activated receptor δ* , a transcription factor that builds slow-twitch muscle fiber, and (ii) insulin receptors and glucose transporters. Fast-twitch muscles are adapted for short bursts of energy, which can be supplied by glycolysis and thus are termed *glycolytic*. Effects of resistance training include activation of metabolic processes by the serine/threonine kinase **Akt1**. Induction of the Akt1 pathway results in growth of fast-twitch skeletal muscle fibers and subsequent effects on several other organs. These include increased fat uptake and oxidation by the liver and heart, reduction of adipose (fat cell) mass, and reduced blood glucose and insulin levels.

Repetition of this cycle with a fatty acid with an even number of carbons eventually yields two molecules of acetyl-CoA in the final step. Complete β -oxidation of palmitic acid yields eight molecules of acetyl-CoA, seven molecules of $[FADH_2]$, and seven molecules of NADH (Figure 23.16 and Table 23.2). The acetyl-CoA can be further metabolized in the TCA cycle (as we have already seen). Alternatively, acetyl-CoA can also be used as a substrate in amino acid biosynthesis. As noted in Chapter 22, however, acetyl-CoA cannot be used as a substrate for gluconeogenesis.

Figure 23.16 Reduced coenzymes produced by β -oxidation and TCA cycle activity provide electrons that drive the synthesis of ATP in oxidative phosphorylation. Complete oxidation of palmitoyl-CoA yields a total of 115.7 ATP. Subtracting the 2 ATP equivalents consumed in forming the original CoA thioester, oxidation of palmitate produces 113.7 ATP. (Calculations are based on P/O ratios of 2.7 and 1.6 for the mitochondrial oxidation of NADH and FADH_2 (succinate), respectively. See Chapter 20.)

Table 23.2 Equations for the Complete Oxidation of Palmitoyl-CoA to CO_2 and H_2O

Equation	ATP Yield	Free Energy Yield (kJ/mol)
$\text{CH}_3(\text{CH}_2)_{14}\text{CO-CoA} + 7 [\text{FAD}] + 7 \text{H}_2\text{O} + 7 \text{NAD}^+ + 7 \text{CoA} \longrightarrow 8 \text{CH}_3\text{CO-CoA} + 7 [\text{FADH}_2] + 7 \text{NADH} + 7 \text{H}^+$		
$7 [\text{FADH}_2] + 11.2 \text{P}_i + 11.2 \text{ADP} + 3.5 \text{O}_2 \longrightarrow 7 [\text{FAD}] + 18.2 \text{H}_2\text{O} + 11.2 \text{ATP}$	11.2	342
$7 \text{NADH} + 7 \text{H}^+ + 18.9 \text{P}_i + 18.9 \text{ADP} + 3.5 \text{O}_2 \longrightarrow 7 \text{NAD}^+ + 25.9 \text{H}_2\text{O} + 18.9 \text{ATP}$	18.9	576

Total	113.7	3468

23.2e Complete β -Oxidation of One Palmitic Acid Yields 113.7 Molecules of ATP

If the acetyl-CoA is directed entirely to the TCA cycle in mitochondria, it can eventually generate approximately 10 high-energy phosphate bonds—that is, 10 molecules of ATP synthesized from ADP (Table 23.2). Including the ATP formed from $[\text{FADH}_2]$ and NADH, complete β -oxidation of a molecule of palmitoyl-CoA in mitochondria yields 115.7 molecules of ATP. Subtracting the two high-energy bonds needed to form palmitoyl-CoA, the substrate for β -oxidation, one concludes that β -oxidation of a molecule of palmitic acid yields 113.7 molecules of ATP. The ΔG° for complete combustion of palmitate to CO_2 is -9790 kJ/mol . The hydrolytic energy embodied in 113.7 ATPs is $113.7 \times 30.5 \text{ kJ/mol} = 3468 \text{ kJ/mol}$, so the overall efficiency of β -oxidation under standard-state conditions is approximately 35%. The large energy yield from fatty acid oxidation is a reflection of the highly reduced state of the carbon in fatty acids. Sugars, in which the carbon is already partially oxidized, produce less energy, carbon for carbon, than do fatty acids. The breakdown of fatty acids is regulated by a variety of metabolites and hormones.

23.2f Migratory Birds Travel Long Distances on Energy from Fatty Acid Oxidation

Because they represent the most highly concentrated form of stored biological energy, fatty acids are the metabolic fuel of choice for sustaining the incredibly long flights of many migratory birds. Although some birds migrate over landmasses and

eat frequently, other species fly long distances without stopping to eat. The American golden plover (Figure 23.17) flies directly from Alaska to Hawaii, a 3300 km flight requiring 35 hours (at an average speed of nearly 60 miles/hr) and more than 250,000 wing beats! The ruby-throated hummingbird, which winters in Central America and nests in eastern North America, often flies nonstop across the Gulf of Mexico. These and similar birds accomplish these prodigious feats by storing large amounts of fatty acids (as triacylglycerols) in the days before their migratory flights. The percentage of dry-weight body fat in these birds may be as high as 70% when migration begins (compared with values of 30% and less for nonmigratory birds).

23.2g Fatty Acid Oxidation Is an Important Source of Metabolic Water for Some Animals

Large amounts of metabolic water are generated by β -oxidation (130.7 H₂O per palmitoyl-CoA, see Table 23.2). For certain animals—including desert animals (such as gerbils) and killer whales (which do not drink seawater)—the oxidation of fatty acids can be a significant source of dietary water. A striking example is the camel (Figure 23.17), whose hump is essentially a large deposit of fat. Metabolism of fatty acids from this store provides needed water (as well as metabolic energy) during periods when drinking water is not available. It might well be said that “the ship of the desert” sails on its own metabolic water!

Figure 23.17 Animals whose existence is strongly dependent on fatty acid oxidation: The ruby-throated hummingbird and the golden plover (a) consume large amounts of fatty acids in long migrations. The orca (killer whale), camels, and gerbils (b) produce metabolic water from fatty acid oxidation to survive in conditions where fresh water is not available to them.

23.3 | How Are Odd-Carbon Fatty Acids Oxidized?

Fatty acids with odd numbers of carbon atoms are rare in mammals but fairly common in plants and marine organisms. Humans and animals whose diets include these food sources metabolize odd-carbon fatty acids via the β -oxidation pathway.

23.3a β -Oxidation of Odd-Carbon Fatty Acids Yields Propionyl-CoA

The final product of β -oxidation for odd-carbon fatty acids is the three-carbon propionyl-CoA instead of acetyl-CoA. Three specialized enzymes then carry out the reactions that convert propionyl-CoA to succinyl-CoA, a TCA cycle intermediate. (Because propionyl-CoA is a degradation product of methionine, valine, and isoleucine, this sequence of reactions is also important in amino acid catabolism.) The pathway involves an initial carboxylation at the α -carbon of propionyl-CoA to produce D-methylmalonyl-CoA (Figure 23.18). The reaction is catalyzed by a biotin-dependent enzyme, **propionyl-CoA carboxylase**. The mechanism involves ATP-driven carboxylation of biotin at N_1 , followed by nucleophilic attack by the α -carbanion of propionyl-CoA in a stereospecific manner.

D-Methylmalonyl-CoA, the product of this reaction, is converted to the L-isomer by **methylmalonyl-CoA epimerase** (Figure 23.18). (This enzyme has often and incorrectly been called methylmalonyl-CoA racemase. It is not a racemase because the CoA moiety contains five other asymmetric centers.) The epimerase reaction involves a carbanion at the α -position formed via a reversible dissociation of the acidic α -proton (Figure 23.19). The L-isomer is the substrate for methylmalonyl-CoA mutase. Methylmalonyl-CoA epimerase is an impressive catalyst. The pK_a for the proton that must dissociate to initiate this reaction is approximately 21! If binding of a proton to the α -anion is diffusion limited, with $k_{on} = 10^9 M^{-1} \text{sec}^{-1}$, then the initial proton dissociation must be rate limiting and the rate constant must be

$$k_{off} = K_a \cdot k_{on} = (10^{-21} M) \cdot (10^9 M^{-1} \text{sec}^{-1}) = 10^{-12} \text{sec}^{-1}$$

The turnover number of methylmalonyl-CoA epimerase is 100sec^{-1} , and thus the enzyme enhances the reaction rate by a factor of 10^{14} .

Figure 23.18 The conversion of propionyl-CoA (formed from β -oxidation of odd-carbon fatty acids) to succinyl-CoA is carried out by a trio of enzymes, as shown. Succinyl-CoA can enter the TCA cycle.

Figure 23.19 The methylmalonyl-CoA epimerase mechanism involves a resonance-stabilized carbanion at the α -position.

23.3b A B₁₂-Catalyzed Rearrangement Yields Succinyl-CoA from L-Methylmalonyl-CoA

The third reaction, catalyzed by **methylmalonyl-CoA mutase**, is quite unusual because it involves a migration of the carbonyl-CoA group from one carbon to its neighbor (Figure 23.18). The mutase reaction is vitamin B₁₂-dependent and begins with **homolytic cleavage** of the Co³⁺—C bond in 5'-deoxyadenosylcobalamin, reducing the cobalt to Co²⁺ (see A Deeper Look, “The Activation of Vitamin B₁₂”). Transfer of a hydrogen atom from the substrate to the deoxyadenosyl group produces a methylmalonyl-CoA radical, which then can undergo a classic B₁₂-catalyzed rearrangement to yield a succinyl-CoA radical. Hydrogen transfer from the deoxyadenosyl group yields succinyl-CoA and regenerates the B₁₂ coenzyme (see problem 20 at the end of the chapter).

23.3c Net Oxidation of Succinyl-CoA Requires Conversion to Acetyl-CoA

Succinyl-CoA derived from propionyl-CoA can enter the TCA cycle. Oxidation of succinate to oxaloacetate provides a substrate for glucose synthesis. Thus, although the acetate units produced in β -oxidation cannot be utilized in gluconeogenesis by animals, the occasional propionate produced from oxidation of odd-carbon fatty acids *can* be used for sugar synthesis. Alternatively, succinate introduced to the TCA cycle from odd-carbon fatty acid oxidation may be oxidized to CO₂. However, all of the four-carbon intermediates in the TCA cycle are regenerated in the cycle and thus

A Deeper Look

The Activation of Vitamin B₁₂

Conversion of inactive vitamin B₁₂ to active 5'-deoxyadenosylcobalamin involves three steps (see accompanying figure). Two flavoprotein reductases sequentially convert Co³⁺ in cyanocobalamin to the Co²⁺ state and then to the Co⁺ state. Co⁺ is an extremely powerful nucleophile. It attacks the C-5' carbon of ATP as shown, expelling the triphosphate anion to form 5'-deoxyadenosylcobalamin.

Because two electrons from Co⁺ are donated to the Co—carbon bond, the oxidation state of cobalt reverts to Co³⁺ in the active coenzyme. This is one of only two known adenosyl transfers (that is, nucleophilic attack on the ribose 5'-carbon of ATP) in biological systems.

Formation of the active coenzyme 5'-deoxyadenosylcobalamin from inactive vitamin B₁₂ is initiated by the action of flavoprotein reductases. The resulting Co⁺ species, dubbed a supernucleophile, attacks the 5'-carbon of ATP in an unusual adenosyl transfer. Homolytic cleavage of the Co³⁺—C bond produces a reactive free radical that facilitates rearrangements such as that in the methylmalonyl-CoA mutase reaction.

Figure 23.20 The malic enzyme reaction proceeds by oxidation of malate to oxaloacetate, followed by decarboxylation to yield pyruvate.

should be viewed as catalytic species. Net consumption of succinyl-CoA thus does not occur directly in the TCA cycle. Rather, the succinyl-CoA generated from β -oxidation of odd-carbon fatty acids must be converted to pyruvate and then to acetyl-CoA (which is completely oxidized in the TCA cycle). To follow this latter route, succinyl-CoA entering the TCA cycle must be first converted to malate in the usual way and then transported from the mitochondrial matrix to the cytosol, where it is oxidatively decarboxylated to pyruvate and CO_2 by **malic enzyme**, as shown in Figure 23.20. Pyruvate can then be transported back to the mitochondrial matrix, where it enters the TCA cycle via pyruvate dehydrogenase. Note that malic enzyme plays a role in fatty acid synthesis.

23.4 | How Are Unsaturated Fatty Acids Oxidized?

Unsaturated fatty acids are also catabolized by β -oxidation, but two additional mitochondrial enzymes—an isomerase and a novel reductase—are required to handle the *cis* double bonds of naturally occurring fatty acids.

23.4a An Isomerase and a Reductase Facilitate the β -Oxidation of Unsaturated Fatty Acids

As an example of oxidation of unsaturated fatty acids, consider the breakdown of oleic acid, an 18-carbon chain with a double bond at the 9,10-position. The reactions of β -oxidation proceed normally through three cycles, producing three molecules of acetyl-CoA and leaving the degradation product *cis*- Δ^3 -dodecenoyl-CoA, shown in Figure 23.21. This intermediate is not a substrate for acyl-CoA dehydrogenase. With a double bond at the 3,4-position, it is not possible to form another double bond at the 2,3- (or β -) position. As shown in Figure 23.21, this problem is solved by **enoyl-CoA isomerase**, an enzyme that rearranges this *cis*- Δ^3 double bond to a *trans*- Δ^2 double bond. This latter species can proceed through the normal route of β -oxidation.

23.4b Degradation of Polyunsaturated Fatty Acids Requires 2,4-Dienoyl-CoA Reductase

Polyunsaturated fatty acids pose a slightly more complicated situation for the cell. Consider, for example, the case of linoleic acid shown in Figure 23.22. As with oleic acid, β -oxidation proceeds through three cycles, and enoyl-CoA isomerase converts the *cis*- Δ^3 double bond to a *trans*- Δ^2 double bond to permit one more round of β -oxidation. What results this time, however, is a *cis*- Δ^4 enoyl-CoA, which is converted normally by acyl-CoA dehydrogenase to a *trans*- Δ^2 , *cis*- Δ^4 species. This, however, is a poor substrate for the enoyl-CoA hydratase. This problem is solved by **2,4-dienoyl-CoA reductase**, the product of which depends on the organism. The mammalian form of this enzyme produces a *trans*- Δ^3 enoyl product, as shown in Figure 23.22; this enoyl

Figure 23.21 β -Oxidation of unsaturated fatty acids. In the case of oleoyl-CoA, three β -oxidation cycles produce three molecules of acetyl-CoA and leave *cis*- Δ^3 -dodecenoyl-CoA. Rearrangement by enoyl-CoA isomerase gives the *trans*- Δ^2 species, which then proceeds normally through the β -oxidation pathway.

Figure 23.22 The oxidation pathway for polyunsaturated fatty acids in mammals, illustrated for linoleic acid. Three cycles of β -oxidation on linoleoyl-CoA yield the *cis*- Δ^3 , *cis*- Δ^6 intermediate, which is converted to a *trans*- Δ^2 , *cis*- Δ^6 intermediate. An additional round of β -oxidation gives *cis*- Δ^4 enoyl-CoA, which is oxidized to the *trans*- Δ^2 , *cis*- Δ^4 species by acyl-CoA dehydrogenase. The subsequent action of 2,4-dienoyl-CoA reductase yields the *trans*- Δ^3 product, which is converted by enoyl-CoA isomerase to the *trans*- Δ^2 form. Normal β -oxidation then produces five molecules of acetyl-CoA.

A Deeper Look

Can Natural Antioxidants in Certain Foods Improve Fat Metabolism?

Numerous beneficial effects have been attributed in recent years to the polyphenolic compounds in foods such as chocolate, red wine, and (black or green) tea. Principal among these compounds are the catechins, a class of antioxidants that have demonstrated protective effects against certain cancers, obesity, and heart disease as well as other beneficial health effects. Is it possible to demonstrate specific effects of catechins on cellular metabolism? Green tea extract, consisting almost entirely of six catechins (shown in the figure), added to the diets of rats increased muscle glycogen content, decreased muscle fatty acid synthesis, and increased fatty acid oxidation by rat skeletal muscle by 36%. In these same rats, exercise endurance capacity for swimming and running increased significantly, suggesting that fatty acids can be an effective source of energy in exercising muscle. Measurements of the catechin content of a range of teas, wines, and other beverages indicate that the broadest range and the highest levels of these compounds are found in tea, but that red wine has significant levels of catechins. (Green tea and black tea are made from the same shrub, *Camellia sinensis*.)

Tea plants

- (c) R = H (–)-epicatechin gallate (ECg),
R = OH (–)-epigallocatechin gallate (EGCg)

product can be converted by an enoyl-CoA isomerase to the *trans*- Δ^2 enoyl-CoA, which can then proceed normally through the β -oxidation pathway. *Escherichia coli* possesses a 2,4-dienoyl-CoA reductase that reduces the double bond at the 4,5-position to yield the *trans*- Δ^2 enoyl-CoA product in a single step.

23.5 | Are There Other Ways to Oxidize Fatty Acids?

Although β -oxidation in mitochondria¹ is the principal pathway of fatty acid catabolism, several other minor pathways play important roles in fat catabolism. For example, organelles other than mitochondria, including *peroxisomes* and *glyoxysomes*, carry out β -oxidation processes.

23.5a Peroxisomal β -Oxidation Requires FAD-Dependent Acyl-CoA Oxidase

Peroxisomes are so named because they carry out a variety of flavin-dependent oxidation reactions, regenerating oxidized flavins by reaction with oxygen to produce hydrogen peroxide, H_2O_2 . Peroxisomal β -oxidation is similar to mitochondrial

¹ β -Oxidation does not occur significantly in plant mitochondria. Most β -oxidation in plants occurs in peroxisomes.

Structure of acyl-CoA oxidase monomer from rat liver (PDB id = 1IS2). The enzyme is a homodimer, each monomer consisting of an N-terminal α -helical domain (blue), a β -sheet domain (orange), and a C-terminal α -helical domain (violet).

Figure 23.23 The acyl-CoA oxidase reaction in peroxisomes. Electrons captured as FADH₂ are used to produce the hydrogen peroxide required for degradative processes in peroxisomes and thus are not available for eventual generation of ATP. (Compare this reaction with the acyl-CoA dehydrogenase of mitochondria shown in Figure 23.12.)

β -oxidation, except that the initial double-bond formation is catalyzed by an FAD-dependent **acyl-CoA oxidase** (Figure 23.23). The action of this enzyme in the peroxisomes transfers the liberated electrons directly to oxygen instead of the electron-transport chain. As a result, each two-carbon unit oxidized in peroxisomes produces fewer ATPs. (Compare Figure 23.23 with Figure 23.12.) The enzymes responsible for fatty acid oxidation in peroxisomes are inactive with acyl chains of eight carbons or fewer. Such short-chain products must be transferred to the mitochondria for further breakdown. Similar β -oxidation enzymes are also found in **glyoxysomes**—peroxisomes in plants that also carry out the reactions of the glyoxylate pathway.

23.5b Branched-Chain Fatty Acids Are Degraded Via α -Oxidation

Although β -oxidation is universally important, there are some instances in which it cannot operate effectively. For example, branched-chain fatty acids with alkyl branches at odd-numbered carbons are not effective substrates for β -oxidation. For such species, **α -oxidation** is a useful alternative. Consider **phytol**, a breakdown product of chlorophyll that occurs in the fat of ruminant animals such as sheep and cows and also in dairy products. Ruminants oxidize phytol to phytanic acid, and digestion of phytanic acid from dairy products is thus an important dietary consideration for humans. The methyl group at C-3 will block β -oxidation, but, as shown in Figure 23.24, *phytanic acid*

Figure 23.24 Branched-chain fatty acids are oxidized by α -oxidation, as shown for phytanic acid. The product of the phytanic acid α -oxidase, pristanic acid, is a suitable substrate for normal β -oxidation. Isobutyryl-CoA and propionyl-CoA can both be converted to succinyl-CoA, which can enter the TCA cycle.

α -hydroxylase places an —OH group at the α -carbon, and *phytanic acid* α -oxidase decarboxylates it to yield *pristanic acid*. The CoA ester of this metabolite can undergo β -oxidation in the normal manner. The terminal product, isobutyryl-CoA, can be sent into the TCA cycle by conversion to succinyl-CoA.

23.5c ω -Oxidation of Fatty Acids Yields Small Amounts of Dicarboxylic Acids

In the endoplasmic reticulum of eukaryotic cells, the oxidation of the terminal carbon of a normal fatty acid—a process termed omega oxidation (ω -oxidation)—can lead to the synthesis of small amounts of dicarboxylic acids (Figure 23.25). **Cytochrome P-450**, a monooxygenase enzyme that requires NADPH as a coenzyme and uses O_2 as a substrate, places a hydroxyl group at the terminal carbon. Subsequent oxidation to a carboxyl group produces a dicarboxylic acid. Either end can form an ester linkage to CoA and be subjected to β -oxidation, producing a variety of smaller dicarboxylic acids. (Cytochrome P-450-dependent monooxygenases also play an important role as agents of **detoxification**, the degradation and metabolism of toxic hydrocarbon agents.)

Figure 23.25 Dicarboxylic acids can be formed by oxidation of the omega carbon of fatty acids in a cytochrome P-450-dependent reaction.

23.6 What Are Ketone Bodies, and What Role Do They Play in Metabolism?

Most of the acetyl-CoA produced by the oxidation of fatty acids in liver mitochondria undergoes further oxidation in the TCA cycle, as stated earlier. However, some of this acetyl-CoA is converted to three important metabolites: **acetone**, **acetoacetate**, and **β -hydroxybutyrate**. The process is known as **ketogenesis**, and these three metabolites are traditionally known as **ketone bodies**, despite the fact that β -hydroxybutyrate does not contain a ketone function.

23.6a Ketone Bodies Are a Significant Source of Fuel and Energy for Certain Tissues

Ketone bodies are synthesized primarily in the liver but are important sources of fuel and energy for many tissues, including brain, heart, and skeletal muscle. The brain, for example, normally uses glucose as its source of metabolic energy. However, during periods of starvation, ketone bodies may be the major energy source for the brain. Acetoacetate and β -hydroxybutyrate are normal substrates for kidney cortex and for heart muscle.

Ketone body synthesis occurs only in the mitochondrial matrix. The reactions responsible for the formation of ketone bodies are shown in Figure 23.26. The first reaction—the condensation of two molecules of acetyl-CoA to form acetoacetyl-CoA—is

Human Biochemistry

Large Amounts of Ketone Bodies Are Produced in Diabetes Mellitus

Diabetes mellitus is the most common endocrine disease and one of the leading causes of death in the United States, with approximately 6 million diagnosed cases and an estimated 4 million more borderline but undiagnosed cases. Diabetes is characterized by an abnormally high level of glucose in the blood. In **type 1 diabetes** (representing 10% or less of all cases), elevated blood glucose results from inadequate secretion of insulin by the islets of Langerhans in the pancreas. **Type 2 diabetes** (at least 90% of all cases) results from an insensitivity to insulin. Type 2 diabetics produce normal or even elevated levels of insulin, but their cells are not responsive to insulin, often due to a shortage of insulin receptors. In both cases, transport of glucose

into muscle, liver, and adipose tissue is significantly reduced, and despite abundant glucose in the blood, the cells are metabolically starved. They respond by turning to increased gluconeogenesis and catabolism of fat and protein. In type 1 diabetes, increased gluconeogenesis consumes most of the available oxaloacetate, but breakdown of fat (and, to a lesser extent, protein) produces large amounts of acetyl-CoA. This increased acetyl-CoA would normally be directed into the TCA cycle, but with oxaloacetate in short supply, it is used instead for production of unusually large amounts of ketone bodies. Acetone can often be detected on the breath of type 1 diabetics, an indication of high plasma levels of ketone bodies.

Figure 23.26 The formation of ketone bodies, synthesized primarily in liver mitochondria.

catalyzed by thiolase, which is also known as **acetoacetyl-CoA thiolase** or **acetyl-CoA acetyltransferase**. This is the same enzyme that carries out the thiolase reaction in β -oxidation, but here it runs in reverse. The second reaction adds another molecule of acetyl-CoA to give 3-hydroxy-3-methylglutaryl-CoA, commonly abbreviated HMG-CoA. These two mitochondrial matrix reactions are analogous to the first two steps in cholesterol biosynthesis, a cytosolic process. HMG-CoA is converted to acetoacetate and acetyl-CoA by the action of **HMG-CoA lyase** in a mixed aldol-Claisen ester cleavage reaction. This reaction is mechanistically similar to the reverse of the citrate synthase reaction in the TCA cycle. A membrane-bound enzyme, **beta-hydroxybutyrate dehydrogenase**, then can reduce acetoacetate to beta-hydroxybutyrate.

Acetoacetate and beta-hydroxybutyrate are transported through the blood from liver to target organs and tissues, where they are converted to acetyl-CoA (Figure 23.27). Ketone bodies

Figure 23.27 Reconversion of ketone bodies to acetyl-CoA in the mitochondria of many tissues (other than liver) provides significant metabolic energy.

are easily transportable forms of fatty acids that move through the circulatory system without the need for complexation with serum albumin and other fatty acid-binding proteins.

23.6b β -Hydroxybutyrate Is a Signaling Metabolite

In addition to its role as a circulating energy source for certain tissues in the fasting state, β -hydroxybutyrate (β OHB) functions as a signaling molecule (Figure 23.28). β OHB is a ligand for two G-protein–coupled membrane receptor proteins (**GPCRs**) that regulate a variety of cellular metabolic processes via second messengers such as cAMP and Ca^{2+} . β OHB also binds and activates the *hydroxycarboxylic acid receptor 2* (**HCAR2**); in contrast, activity of the *free fatty acid receptor 3* (**FFAR3**) is antagonized when β OHB binds to it.

In a separate signaling role, β -hydroxybutyrate provides indirect activation of **histone acetyltransferases (HATs)** that acetylate lysine residues on histones (acetylation activates gene expression) and a variety of other nuclear and cytosolic signaling proteins. As shown in Figure 23.28, uptake of β -hydroxybutyrate increases the cellular pool of acetyl-CoA, the substrate for lysine acetylation by HATs. β -hydroxybutyrate is also an inhibitor of several **histone deacetylase** enzymes (known as **HDACs**; Section 29.3) that remove acetyl groups from lysine residues on these same signaling proteins. By these various mechanisms, β -hydroxybutyrate regulates gene expression, lipid metabolism, metabolic rate, and resistance to oxidative stress.

Figure 23.28 Cellular signaling mediated by β -hydroxybutyrate (β OHB), including activation of the HCAR2 receptor, antagonism of the FFAR3 receptor, activation of histone acetyltransferases (HATs), and inhibition of deacetylases (HDACs). β -Hydroxybutyrate taken up by mitochondria is converted to acetyl-CoA and then to citrate (by citrate synthase—CS). Citrate exported to the cytosol can be converted back to acetyl-CoA by ATP citrate lyase (ACLY).

Foundational Biochemistry Things You Should Know after Reading Chapter 23.

- Triacylglycerols are a major form of stored energy in animals.
- Hormones trigger the release of fatty acids from adipose tissue. Degradation of dietary triacylglycerols occurs primarily in the duodenum.
- Degradation of fatty acids occurs by oxidation of the carbon that is β to the carboxyl carbon. The process is referred to as β -oxidation.
- Coenzyme A activates fatty acids for degradation via the formation of thioesters in the acyl-CoA synthetase reaction.
- The mechanism of the acyl-CoA synthetase involves nucleophilic attack by the carboxylate oxygen of a fatty acid at the α -P of ATP, forming a reactive mixed anhydride that breaks down to yield a fatty-acyl-CoA.
- Carnitine carries fatty acyl groups across the inner mitochondrial membrane.
- β -Oxidation involves a repeated sequence of four reactions: acyl-CoA dehydrogenase, enoyl-CoA hydratase, L-hydroxyacyl-CoA dehydrogenase, and thiolase.
- Repetition of the β -oxidation cycle yields a succession of acetate units.
- Three of the enzymes in the β -oxidation cycle, the enoyl-CoA hydratase (ECH), the hydroxyacyl-CoA dehydratase (HACD), and the ketoacyl thiolase (KACT), are associated in a trifunctional enzyme complex. Fatty acyl substrates migrate through substrate channels in this complex without diffusing into the bulk solvent.
- Complete β -oxidation of one palmitic acid yields 113.7 molecules of ATP.
- β -Oxidation of odd-carbon fatty acids yields propionyl-CoA. Net oxidation of succinyl-CoA obtained from propionyl-CoA requires conversion to acetyl-CoA.
- Propionyl-CoA is converted to succinyl-CoA by the combined action of propionyl-CoA carboxylase, methylmalonyl-CoA epimerase, and methylmalonyl-CoA mutase. Methylmalonyl-CoA mutase is a vitamin B₁₂-dependent enzyme.
- An isomerase and a reductase facilitate the β -oxidation of unsaturated fatty acids.
- Degradation of polyunsaturated fatty acids requires 2,4-dienoyl-CoA reductase.
- Peroxisomal β -oxidation requires FAD-dependent acyl-CoA oxidase.
- Branched-chain fatty acids are degraded via α -oxidation.
- ω -Oxidation of fatty acids yields small amounts of dicarboxylic acids.
- The ketone bodies—acetone, acetoacetate, and β -hydroxybutyrate—are a significant source of fuel and energy for certain tissues, including brain, heart, and skeletal muscle.
- Ketone body formation involves several enzymes, including thiolase, HMG-CoA synthase, HMG-CoA lyase, and β -hydroxybutyrate dehydrogenase.
- β -Hydroxybutyrate is a signaling metabolite. It is a ligand for two G-protein-coupled membrane receptor proteins that regulate a variety of cellular metabolic processes via second messengers such as cAMP and Ca²⁺.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Determining the Amount of Water Produced from Fatty Acid Oxidation**
Calculate the volume of metabolic water available to a camel through fatty acid oxidation if it carries 30 pounds of triacylglycerol in its hump.
- Determining the Amount of ATP Produced from Fatty Acid Oxidation**
Calculate the approximate number of ATP molecules that can be obtained from the oxidation of *cis*-11-heptadecenoic acid to CO₂ and water.
- Assessing the Mechanism of Oxidation of Phytanic Acid**
Phytanic acid, the product of chlorophyll that causes problems for individuals with Refsum's disease, is 3,7,11,15-tetramethyl hexadecanoic acid. Suggest a route for its oxidation that is consistent with what you have learned in this chapter. (*Hint*: The methyl group at C-3 effectively blocks hydroxylation and normal β -oxidation. You may wish to initiate breakdown in some other way.)
- Examining the Labeling of Glucose from ¹⁴C-labeled Acetate**
Even though acetate units, such as those obtained from fatty acid oxidation, cannot be used for net synthesis of carbohydrate in animals, labeled carbon from ¹⁴C-labeled acetate can be found in newly synthesized glucose (for example, in liver glycogen) in animal tracer studies. Explain how this can be. Which carbons of glucose would you expect to be the first to be labeled by ¹⁴C-labeled acetate?
- Assessing the Fatty Acid-Binding Capability of Serum Albumin** Human serum albumin (66.4 kDa) is a soluble protein present in blood at

0.75 mM or so. Among other functions, albumin acts as the major transport vehicle for fatty acids in the circulation, carrying fatty acids from storage sites in adipose tissue to their sites of oxidation in liver and muscle. The albumin molecule has up to 11 distinct binding sites. Consult the biochemical literature to learn about the fatty acid-binding sites of albumin. Where are they located on the protein? What are their relative affinities? (Two suitable references with which to begin your study are Bhattacharya, A. A., Grüne, T., and Curry, S., 2000. Crystallographic analysis reveals common modes of binding of medium- and long-chain fatty acids in human serum albumin. *Journal of Molecular Biology* 303:721–732; and Simard, J. R., et al., 2005. Locating high-affinity fatty acid-binding sites on albumin by X-ray crystallography and NMR spectroscopy. *Proceedings of the National Academy of Sciences, U.S.A.* 102:17958–17963.)

- Fatty Acid Catabolism and Gluconeogenesis** The catabolism of fatty acids cannot provide the carbons needed for gluconeogenesis (see Chapter 22), but can provide other molecules to benefit this pathway? Name at least two such molecules.
- Fatty Acid Catabolism in Mitochondria or Peroxisomes and Weight Regulation** What difference in weight regulation could be predicted if more fatty acids underwent catabolism in peroxisomes (see Section 23.5a) rather than in the mitochondria?
- Binding Properties of Albumin** Refer to Human Biochemistry box, "Serum albumin – Tramp Steamer of the Bloodstream" and explain how elevated levels of free fatty acids could affect the pharmacology of drugs.

- 9. Understanding the Implications of Storing Energy in the Form of Fat Versus Protein or Carbohydrate** Overweight individuals who diet to lose weight often view fat in negative ways, but the “weighty” consequences might be even worse if excess calories were stored in other forms. Consider a person who is 10 pounds “overweight,” and estimate how much more he or she would weigh if excess energy were stored as carbohydrate instead of fat.
- 10. Understanding the Consequences of Vitamin B₁₂ Deficiency** What would be the consequences of a deficiency in vitamin B₁₂ for fatty acid oxidation? What metabolic intermediates might accumulate?
- 11. Balancing the Equations for Fatty Acid Oxidation** Write properly balanced chemical equations for the oxidation to CO₂ and water of (a) myristic acid, (b) stearic acid, (c) α-linolenic acid, and (d) arachidonic acid.
- 12. Tracing Tritium Incorporation into Acetate from Fatty Acid Oxidation** How many tritium atoms are incorporated into acetate if a molecule of palmitic acid is oxidized in 100% tritiated water?
- 13. Fatty Acid Oxidation in Isotopically-labeled Water** If the β-oxidation of a fatty acid happened in the presence of H₂¹⁸O, which products would contain ¹⁸O?
- 14. Understanding the Consequences of Carnitine Deficiency** What would be the consequences of a carnitine deficiency for fatty acid oxidation?
- 15. Glucagon and Lipases** Glucagon is a hormone released when blood sugar levels are low. Give a reason for why glucagon activates lipases.
- 16. Villi on the Surface of Epithelial Cells of the Digestive System** The membranes of the epithelial cells of the digestive system possess indentations known as microvilli (see Figure 23.3). What is the advantage of these structures?
- 17. Assessing Energy Consumption by a Migrating Bird** The ruby-throated hummingbird flies 500 miles nonstop across the Gulf of Mexico. The flight takes 10 hours at 50 mph. The hummingbird weighs about 4 grams at the start of the flight and about 2.7 grams at the end. Assuming that all the lost weight is fat burned for the flight, calculate the total energy required by the hummingbird in this prodigious flight. Does anything about the results of this calculation strike you as unusual?
- 18. Understanding Human Energy Consumption During Exercise** Energy production in animals is related to oxygen consumption. The ruby-throated hummingbird consumes about 250 mL of oxygen per hour during its migration across the Gulf of Mexico. Use this number and the data in problem 11 to determine a conversion factor for energy expended per liter of oxygen consumed. If a human being consumes 12.7 kcal/min while running 8-minute miles, how long could a human run on the energy that the hummingbird consumes in its trans-Gulf flight? How many 8-minute miles would a person have to run to lose 1 pound of body fat?
- 19. Understanding the Mechanism of the HMG-CoA Synthase Reaction** Write a reasonable mechanism for the HMG-CoA synthase reaction shown in Figure 23.26.
- 20. Understanding the Mechanism of the Methylmalonyl-CoA Mutase Reaction** The methylmalonyl-CoA mutase reaction (see Figure 23.18) involves vitamin B₁₂ as a coenzyme. Write a reasonable mechanism for this reaction. (*Hint:* The reaction begins with abstraction of a hydrogen atom—that is, a proton plus an electron—from the substrate by vitamin B₁₂. Consider the chemistry shown in A Deeper Look: “The Activation of Vitamin B₁₂” as you write your mechanism.)
- 21. Assessing the Oxidation States of Cobalt in the Methylmalonyl-CoA Mutase Reaction** Discuss the changes of the oxidation state of cobalt in the course of the methylmalonyl-CoA mutase reaction. Why do they occur as you suggested in your answer to problem 20?
- 22. Extending the Mechanism of Methylmalonyl-CoA Mutase to Similar Reactions** Based on the mechanism for the methylmalonyl-CoA mutase (see problem 20), write reasonable mechanisms for the following reactions.

- 23. Understanding the Toxicity of Unripened Akee Fruit** A popular dish in the Caribbean islands consists of akee and salt fish. Unripened akee fruit (from the akee tree, native to West Africa but brought to the Caribbean by enslaved Africans) is quite poisonous. The unripened fruit contains hypoglycin (structure shown below), a metabolite that serves as a substrate for acyl-CoA dehydrogenase. However, the product of this reaction irreversibly inhibits the acyl-CoA dehydrogenase by reacting covalently with FAD on the enzyme. Consumption of unripened akee fruit can lead to vomiting and, in severe cases, convulsions, coma, and death. Write a reaction scheme to show the product of the acyl-CoA dehydrogenase reaction that reacts with FAD.

Hypoglycin A

- 24. Exploring Substrate Channeling in Multi-Functional Enzyme Aggregates** In mammalian mitochondria, three of the enzymes in the membrane-bound β-oxidation system are components of a multifunctional enzyme (MFE). Similarly, glyoxysomes (in plants), peroxisomes (in most species), and gram-negative bacteria carry out several reactions of β-oxidation via MFEs. In all these cases, the components of an MFE must cooperate to carry or channel the acyl-CoA substrate from one active site to the next in a cyclic fashion. The structure of the complete MFE from *Pseudomonas fragi* provides insights into how this channeling might occur. Consult the journal article that describes this structure (Ishikawa, M., et al., 2004. Structural basis for channelling mechanism of a fatty acid β-oxidation multienzyme complex. *EMBO Journal* 23:2745–2754), and explain in your own words how this substrate channeling occurs.
- 25. Comparing the Electron Transfer Characteristics of FAD/FADH₂ and NAD⁺/NADH** Study Figure 23.12 and comment on why nature uses FAD/FADH₂ as a cofactor in the acyl-CoA dehydrogenase reaction rather than NAD⁺/NADH.
- 26. Understanding a Ubiquitous Series of Metabolic Reactions** Study Figure 23.9. Where else in metabolism have you seen the chemical strategy and logic of the β-oxidation pathway? Why is it that these two pathways are carrying out the same chemistry?

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

27. Using the PSafe model for enoyl-CoA hydratase, give an example of a case in which conserved residues in slightly different positions can change the catalytic rate of reaction.

Think-Pair-Share Question

The β -oxidation of different fatty acids generates different amounts of products. Review the list of C_{18} fatty acids shown in Table 8.1.

- For each fatty acid, determine the number of NADH and $FADH_2$ generated. In addition, determine the grand total of ATP generated, assuming that each NADH and $FADH_2$ generate 2.7 or 1.6 ATP molecules, respectively. Do include all the NADH, $FADH_2$, and GTP generated from acetyl-CoA through the TCA cycle. If NADPH is required to resolve “unsaturated bond issues,” subtract 4 ATP molecules. Use Figures 23.21 and 23.22 as your guide.
- As outlined in Section 23.2 and Table 23.2, the β -oxidation of fatty acids can be an important source of water. Does the β -oxidation of the different C_{18} fatty acids listed in Table 8.1 yield different amounts of water?

◀ Walrus basking on the beach. Blubber – a layer of fat reinforced by fibrous connective tissue just below the skin – insulates the walrus and serves as an energy reserve.

Essential Question

Lipids—including fatty acids, triglycerides, glycerophospholipids, sphingolipids, and steroids—are key components of membranes and essential energy sources for organisms. They may also serve as signal molecules in biological systems. All lipids are synthesized from smaller constituent molecules. **What are the pathways of lipid synthesis in biological systems and how are lipids transported throughout the body?**

We have already seen several cases in which the synthesis of a class of biomolecules is conducted differently from degradation (glycolysis versus gluconeogenesis and glycogen or starch breakdown versus polysaccharide synthesis, for example). Likewise, the synthesis of fatty acids and other lipid components is different from their degradation.

24.1 | How Are Fatty Acids Synthesized?

Fatty acid synthesis involves a set of reactions that follow a strategy different in several ways from the corresponding degradative process:

1. Fatty acid synthesis occurs in the cytosol, whereas fatty acid degradation takes place in mitochondria.
2. Intermediates in fatty acid synthesis are linked covalently to the sulfhydryl groups of special proteins, the **acyl carrier proteins** (ACPs). In contrast, fatty acid breakdown intermediates are bound to the—SH group of coenzyme A.
3. In animals, the enzymes of fatty acid synthesis are components of one long polypeptide chain, the **fatty acid synthase**, whereas no similar association exists for the degradative enzymes. (Plants and bacteria employ separate enzymes to carry out the biosynthetic reactions.)
4. The coenzyme for the oxidation–reduction reactions of fatty acid synthesis is $\text{NADP}^+/\text{NADPH}$, whereas degradation involves the NAD^+/NADH couple.

Key Questions

- 24.1 How Are Fatty Acids Synthesized?
- 24.2 How Are Complex Lipids Synthesized?
- 24.3 How Are Eicosanoids Synthesized, and What Are Their Functions?
- 24.4 How Is Cholesterol Synthesized?
- 24.5 How Are Lipids Transported Throughout the Body?
- 24.6 How Are Bile Acids Biosynthesized?
- 24.7 How Are Steroid Hormones Synthesized and Utilized?

24.1a Formation of Malonyl-CoA Activates Acetate Units for Fatty Acid Synthesis

The design strategy for fatty acid synthesis is this:

1. Fatty acid chains are constructed by the addition of two-carbon units derived from *acetyl-CoA*.
2. The acetate units are activated by formation of *malonyl-CoA* (at the expense of ATP).
3. The addition of two-carbon units to the growing chain is driven by decarboxylation of malonyl-CoA.
4. The elongation reactions are repeated until the growing chain reaches 16 carbons in length (palmitic acid).
5. Other enzymes then add double bonds and additional carbon units to the chain.

24.1b Fatty Acid Biosynthesis Depends on the Reductive Power of NADPH

Fatty acids are synthesized from acetyl-CoA building blocks in a reductive pathway driven by NADPH. The net reaction for the formation of palmitate from acetyl-CoA is

Levels of free fatty acids are very low in the typical cell. The palmitate made in this process is rapidly converted to CoA esters in preparation for the formation of triacylglycerols and phospholipids.

24.1c Cells Must Provide Cytosolic Acetyl-CoA and Reducing Power for Fatty Acid Synthesis

Eukaryotic cells face a dilemma in providing suitable amounts of substrate for fatty acid synthesis. Sufficient quantities of acetyl-CoA, malonyl-CoA, and NADPH must be generated *in the cytosol* for fatty acid synthesis. Malonyl-CoA is made by carboxylation of acetyl-CoA, so the problem reduces to generating sufficient acetyl-CoA and NADPH.

There are three principal sources of acetyl-CoA (Figure 24.1):

1. Amino acid degradation produces cytosolic acetyl-CoA.
2. Fatty acid oxidation produces mitochondrial acetyl-CoA.
3. Glycolysis yields cytosolic pyruvate, which (after transport into the mitochondria) is converted to acetyl-CoA by pyruvate dehydrogenase.

Chemistry in History

Dr. Konrad Emil Bloch

Dr. Konrad Emil Bloch (1912–2000) began his studies at the Technical University of Munich, before being forced to flee Germany due to Jewish persecution before the start of World War II. Dr. Bloch earned his Ph.D. in Biochemistry from Columbia University where he taught for seven years before moving on to faculty positions at the University of Chicago and Harvard University. Though his research ranged over many areas of lipid metabolism, Bloch devoted more than twenty

years to the study of cholesterol biosynthesis. He and his collaborators showed that squalene is synthesized from acetate units and that cholesterol is derived from squalene. Konrad Bloch and Feodor Lynen received the Nobel Prize in Medicine or Physiology in 1964 for their studies of cholesterol and fatty acid metabolism.

Dr. Bloch stayed active as a scientist and a teacher until his death in Burlington, Massachusetts, in October 2000.

Figure 24.1 The citrate-malate-pyruvate shuttle provides cytosolic acetate units and some reducing equivalents (electrons) for fatty acid synthesis. The shuttle collects carbon substrates, primarily from glycolysis but also from fatty acid oxidation and amino acid catabolism. Pathways that provide carbon for fatty acid synthesis are shown in blue; pathways that supply electrons for fatty acid synthesis are shown in red.

The acetyl-CoA derived from amino acid degradation is normally insufficient for fatty acid biosynthesis, and the acetyl-CoA produced by pyruvate dehydrogenase and by fatty acid oxidation cannot cross the mitochondrial membrane to participate directly in fatty acid synthesis. Instead, acetyl-CoA is linked with oxaloacetate to form citrate, which is transported from the mitochondrial matrix to the cytosol (Figure 24.1). Here it can be converted back into acetyl-CoA and oxaloacetate by **ATP-citrate lyase**. In this manner, mitochondrial acetyl-CoA becomes the substrate for cytosolic fatty acid synthesis. (Oxaloacetate returns to the mitochondria in the form of either pyruvate or malate, which is then reconverted to acetyl-CoA and oxaloacetate, respectively.)

NADPH can be produced in the pentose phosphate pathway as well as by malic enzyme (Figure 24.1). Reducing equivalents (electrons) derived from glycolysis in the form of NADH can be transformed into NADPH by the combined action of malate dehydrogenase and malic enzyme:

How many of the 14 NADPH needed to form one palmitate can be made by this coupled MDH/malic enzyme route? The answer depends on the status of malate. Every citrate entering the cytosol produces one acetyl-CoA and one malate (Figure 24.1). Every malate oxidized by malic enzyme produces one NADPH, at the expense of a decarboxylation to pyruvate. Thus, when malate is oxidized, one NADPH is produced for every acetyl-CoA. Conversion of eight acetyl-CoA units to one palmitate would then be accompanied by production of eight NADPH. (As noted, a total of 14 NADPH are required. The remaining six are provided by the pentose phosphate pathway.) On the other hand, for every malate returned to the mitochondria, one NADPH fewer is produced.

24.1d Acetate Units Are Committed to Fatty Acid Synthesis by Formation of Malonyl-CoA

Rittenberg and Bloch showed in the late 1940s that acetate units are the building blocks of fatty acids. Their work, together with the discovery by Salih Wakil that bicarbonate is required for fatty acid biosynthesis, eventually made clear that this pathway involves synthesis of *malonyl-CoA*. The carboxylation of acetyl-CoA to form malonyl-CoA is essentially irreversible and is the **committed step** in the synthesis of fatty acids (Figure 24.2). The reaction is catalyzed by **acetyl-CoA carboxylase**, which contains a biotin prosthetic group. This carboxylase is the only enzyme of fatty acid synthesis in animals that is not part of the multienzyme complex fatty acid synthase.

24.1e Acetyl-CoA Carboxylase Is Biotin Dependent and Displays Ping-Pong Kinetics

The biotin prosthetic group of acetyl-CoA carboxylase is covalently linked to the ϵ -amino group of an active-site lysine in a manner similar to pyruvate carboxylase (see Figure 22.2). The reaction mechanism is also analogous to that of pyruvate carboxylase (see Figure 22.3): ATP-driven carboxylation of biotin is followed by transfer of the activated CO_2 to acetyl-CoA to form malonyl-CoA. The enzyme from *Escherichia coli* has three components: (1) a *biotin carboxyl carrier protein* (BCCP, a dimer of 22.5 kDa subunits); (2) *biotin carboxylase* (BC, a dimer of 51 kDa subunits), which adds CO_2 to the prosthetic group; and (3) *carboxyltransferase* (an $\alpha_2\beta_2$ tetramer with 30 and 35 kDa subunits), which transfers the activated CO_2 unit to acetyl-CoA. The long, flexible biotin-lysine chain (biocytin) enables the activated carboxyl group to be carried between the biotin carboxylase and the carboxyltransferase (Figure 24.3).

24.1f Acetyl-CoA Carboxylase in Animals Is a Multifunctional Protein

In animals, acetyl-CoA carboxylase (ACC) is a filamentous polymer (4 to 8×10^6 Da) composed of 265 kDa protomers. Each of these subunits contains the biotin carboxyl carrier moiety, biotin carboxylase, and carboxyltransferase activities as well as allosteric regulatory sites. Animal ACC is thus a multifunctional protein. The polymeric form is active, but the 265 kDa protomers are inactive. The activity of ACC is thus dependent upon the position of the equilibrium between these two forms:

Because this enzyme catalyzes the committed step in fatty acid biosynthesis, it is carefully regulated. *Palmitoyl-CoA*, the final product of fatty acid biosynthesis, shifts the equilibrium toward the inactive protomers, whereas *citrate*, an important allosteric activator of this enzyme, shifts the equilibrium toward the active polymeric form of the enzyme. Acetyl-CoA carboxylase shows the kinetic behavior of a Monod-Wyman-Changeux *V*-system¹ allosteric enzyme in which allosteric effectors shift the T/R equilibrium between active R conformers and inactive T conformers.

¹The MWC *V*-system is an allosteric model characterized by (1) S binds equally well to R and T, but only R is active (T is inactive), and (2) effectors (A binds only to R; I binds only to T) regulate activity by shifting the relative R versus T distribution.

Step 1 The carboxylation of biotin**Step 2** The transcarboxylation reaction**Figure 24.2** The acetyl-CoA carboxylase reaction produces malonyl-CoA for fatty acid synthesis.

(a) The reaction uses bicarbonate as a substrate and is driven by ATP. (b) A mechanism for the acetyl-CoA carboxylase reaction. **(Step 1)** Bicarbonate is activated for carboxylation reactions by formation of N-carboxybiotin. ATP drives the reaction forward, with transient formation of a carbonylphosphate intermediate. **(Step 2)** In a typical biotin-dependent reaction, nucleophilic attack by the acetyl-CoA carbanion on the carboxyl carbon of N-carboxybiotin—a transcarboxylation—yields the carboxylated product.

**Figure 24.3** In the acetyl-CoA carboxylase reaction, the biotin ring, on its flexible tether, acquires carboxyl groups from carbonylphosphate on the biotin carboxylase subunit and transfers them to acyl-CoA molecules on the carboxyltransferase subunits. Colors of the domains correspond to those in Figure 24.4.

Carboxyltransferase domain of yeast acetyl-CoA carboxylase (PDB id = 1OD2)

The carboxyltransferase component of acetyl-CoA carboxylase-1 from *Saccharomyces cerevisiae*. Unlike the *E. coli* carboxyltransferase (CT) $\alpha_2\beta_2$ heterotetramer, the yeast CT domain is a component of the ACC dimer. The N- and C-subdomains of one monomer are cyan and yellow, whereas those of the other monomer are purple and green. CoA is shown as a ball-and-stick model in one subunit.

Figure 24.5 The activity of acetyl-CoA carboxylase is modulated by phosphorylation and dephosphorylation. The dephospho form of the enzyme is activated by low [citrate] and inhibited only by high levels of fatty acyl-CoA. In contrast, the phosphorylated form of the enzyme is activated only by high levels of citrate but is very sensitive to inhibition by fatty acyl-CoA.

24.1g Phosphorylation of ACC Modulates Activation by Citrate and Inhibition by Palmitoyl-CoA

The regulatory effects of citrate and palmitoyl-CoA are dependent on the phosphorylation state of acetyl-CoA carboxylase. The animal enzyme is phosphorylated at eight to ten sites on each enzyme subunit (Figure 24.4). Some of these sites are regulatory, whereas others are silent and have no effect on enzyme activity. Unphosphorylated acetyl-CoA carboxylase binds citrate with high affinity and thus is active at very low citrate concentrations (Figure 24.5). Phosphorylation of the regulatory sites decreases the affinity of the enzyme for citrate, and in this case, high levels of citrate are required to activate the carboxylase. The inhibition by fatty acyl-CoAs operates in a similar but opposite manner. Thus, low levels of fatty acyl-CoA inhibit the phosphorylated carboxylase, but the dephosphoenzyme is inhibited only by high levels of fatty acyl-CoA. Specific phosphatases act to dephosphorylate ACC, thereby increasing the sensitivity to citrate.

24.1h Acyl Carrier Proteins Carry the Intermediates in Fatty Acid Synthesis

The basic building blocks of fatty acid synthesis are acetyl and malonyl groups, but they are not transferred directly from CoA to the growing fatty acid chain. Rather, they are first passed to ACP. This protein consists (in *E. coli*) of a single polypeptide chain of 77 residues to which is attached (on a serine residue) a **phosphopantetheine group**, the same group that forms the business end of coenzyme A. Thus, ACP is a somewhat larger version of coenzyme A, specialized for use in fatty acid biosynthesis (Figure 24.6).

Figure 24.4 Schematic of the acetyl-CoA carboxylase polypeptide, with domains and phosphorylation sites indicated, along with the protein kinases responsible. Phosphorylation at Ser¹²⁰⁰ is primarily responsible for decreasing the affinity for citrate.

Figure 24.6 Fatty acids are conjugated both to coenzyme A and to acyl carrier protein through the sulfhydryl of phosphopantetheine prosthetic groups.

24.1i In Some Organisms, Fatty Acid Synthesis Takes Place in Multienzyme Complexes

The enzymes that catalyze formation of acetyl-ACP and malonyl-ACP and the subsequent reactions of fatty acid synthesis are organized quite differently in different organisms. Fatty acid synthesis in mammals occurs on homodimeric **fatty acyl synthase I (FAS I)**, each 270 kDa polypeptide of which contains all reaction centers required to produce a fatty acid. In lower eukaryotes, such as yeast and fungi, the enzymatic activities of FAS are distributed over two multifunctional peptide chains, which form 2.6-megadalton $\alpha_6\beta_6$ complexes. In plants, most bacteria, and parasites, the enzymes of fatty acid synthesis are separated and independent, and this collection of enzymes is referred to as **fatty acyl synthase II (FAS II)**.

24.1j Decarboxylation Drives the Condensation of Acetyl-CoA and Malonyl-CoA

The individual steps in the elongation of the fatty acid chain are quite similar across all organisms. The mammalian pathway (Figure 24.7) is a cycle of elongation that involves six enzyme activities. The elongation cycle is initiated by transfer of the acyl moiety of acetyl-CoA to the acyl carrier protein by the **malonyl-CoA–acetyl-CoA-ACP transacylase (MAT)**, which also transfers the malonyl group of malonyl-CoA to ACP.

The **β -ketoacyl-ACP synthase (KS)** catalyzes the decarboxylative condensation of the acyl group with malonyl-ACP to produce a β -ketoacyl-ACP intermediate (acetoacetyl-ACP in the first cycle). The mechanism (Figure 24.8) begins with acetyl group transfer to MAT, followed with attack by the ACP thiol sulfur to form an acetyl-ACP. The acetyl group is transferred to a cysteine sulfur on KS, freeing the ACP thiol to acquire the malonyl group. In the condensation reaction that follows, decarboxylation of the malonyl group creates a transient, highly nucleophilic carbanion that can attack the acetate group.

The net reaction for each turn of this cycle (see Figure 24.7) is addition of a two-carbon unit to the acyl group. Why is the three-carbon malonyl group used here as a two-carbon donor? The answer is that this is yet another example of a decarboxylation driving a desired but otherwise thermodynamically unfavorable reaction. The decarboxylation that accompanies the reaction with malonyl-ACP drives the synthesis of acetoacetyl-ACP. Note that hydrolysis of ATP drove the carboxylation of acetyl-CoA to form malonyl-ACP, so, indirectly, ATP is responsible for the condensation reaction to form acetoacetyl-ACP. Malonyl-CoA can be viewed as a form of stored energy for driving fatty acid synthesis.

Figure 24.7 The pathway of palmitate synthesis from acetyl-CoA and malonyl-CoA. Acetyl and malonyl building blocks are introduced as ACP conjugates. Decarboxylation drives the β -ketoacyl-ACP synthase and results in the addition of two-carbon units to the growing chain. The first turn of the cycle begins at ❶ and goes to butyryl-ACP; subsequent turns of the cycle are indicated as ❷ through ❹.

It is also worth noting that the carbon of the carboxyl group that was added to drive this reaction is the one removed by the condensing enzyme. Thus, all the carbons of acetoacetyl-ACP (and of the fatty acids to be made) are derived from acetate units of acetyl-CoA.

Figure 24.8 A mechanism for mammalian ketoacyl synthase. An acetyl group is transferred from CoA to MAT, then to the acyl carrier protein, and then to ketoacyl synthase. Next, a malonyl group is transferred to MAT and then to the acyl carrier protein. Decarboxylation of the malonyl group creates a transient carbanion on the acyl group of ACP, which attacks the KS acetyl group to form a ketoacyl-ACP. A cycle (see Figure 24.7) of keto group reduction (by KR), water removal (by DH), and double-bond reduction (by ER; see next section) will finally produce an acyl group increased in length by two carbons.

24.1k Reduction of the β -Carbonyl Group Follows a Now-Familiar Route

The next three steps—reduction of the β -carbonyl group by **β -ketoacyl-ACP reductase (KR)** to form a β -alcohol, then dehydration by **β -hydroxyacyl-ACP dehydratase (DH)** and reduction by **2,3-*trans*-enoyl-ACP reductase (ER)** to saturate the chain (see Figure 24.7)—look very similar to the fatty acid degradation pathway in reverse. However, there are two crucial differences between fatty acid biosynthesis and fatty acid oxidation (besides the fact that different enzymes are involved): First, the alcohol formed in biosynthesis has the D-configuration rather than the L-form seen in catabolism; and second, the reducing coenzyme is NADPH, whereas NAD^+ and FAD are the oxidants in the catabolic pathway.

The net result of the first turn of the biosynthetic cycle is the synthesis of a four-carbon unit, a butyryl group, from two smaller building blocks. In the next cycle of the process, this butyryl-ACP condenses with another malonyl-ACP to make a six-carbon β -ketoacyl-ACP and CO_2 . Subsequent reduction to a β -alcohol, dehydration, and another reduction yield a six-carbon saturated acyl-ACP. This cycle continues with the net addition of a two-carbon unit in each turn until the chain is 16 carbons long (see Figure 24.7). The KS cannot accommodate larger substrates, so the reaction cycle ends with a 16-carbon chain. Hydrolysis of the C_{16} -acyl-ACP yields a palmitic acid and the free ACP.

In the end, seven malonyl-CoA molecules and one acetyl-CoA yield a palmitate (shown here as palmitoyl-CoA):

The formation of seven malonyl-CoA molecules requires

Thus, the overall reaction of acetyl-CoA to yield palmitic acid is

Note: These equations are stoichiometric and charge balanced. See problem 1 at the end of the chapter for practice in balancing these equations.

24.11 Eukaryotes Build Fatty Acids on Megasyntase Complexes

The multiple enzyme domains of eukaryotic fatty acyl synthases are arrayed on large protein structures termed **megasyntases**. The individual enzyme domains of these structures in all eukaryotes are homologous to the corresponding small, discrete enzymes of bacterial FAS pathways. Remarkably, however, lower eukaryotes such as fungi and higher eukaryotes such as mammals have evolved entirely different megasyntase architectures for fatty acid synthesis. Mammalian homodimeric FAS has a flattened X-shape, whereas the fungal dodecameric FAS is a large, closed barrel, with two reaction chambers separated by equatorial stabilizing struts (Figure 24.9). In the fungal structure, the six α -subunits form a central ring that is a trimer of dimers (Figure 24.10a,b). Each α -subunit contributes an extended α -helical segment to the center of the structure. Pairs of these helices form three coiled-coil struts anchored by a six-helix bundle in the center of the barrel. Each α -subunit contains KR and KS domains. Three KR and three KS active sites are oriented toward the upper reaction chamber, and three of each face the lower chamber. The β -subunit trimers form rounded caps over the upper and lower reaction chambers. Each chamber contains three pores that allow substrates (acetyl-CoA and malonyl-CoA) to diffuse in and palmitoyl-CoA to exit. On each end of the structure, the active sites of the four β -subunit enzyme domains (see Figure 24.9) are oriented toward the interior of the reaction chamber. Three ACP domains in each chamber shuttle growing acyl chains from site to site during the catalytic cycle. Each ACP is tethered by two flexible linker peptides, which facilitate its site-to-site movement (Figure 24.10c). The phosphopantetheine arm on each ACP can extend outward to reach into active sites or may retract to insert its acyl chain in a protective hydrophobic cavity during intersite transport.

The homodimeric mammalian FAS contains all six functional enzyme domains on each subunit (Figures 24.9 and 24.11). In the X-shaped dimer, three of the domains—including KS, ER, and DH—form dimeric structures, whereas the KR and MAT

Figure 24.9 Organization of enzyme functions on two eukaryotic fatty acid synthases. (*left*) Fungal FAS is a closed barrel 260 Å high and 230 Å wide. (*right*) Mammalian (pig) FAS is an asymmetric X-shape 210 Å high, 180 Å wide, and 90 Å deep. The arrangement of functional domains along the FAS polypeptides is shown at the bottom of the figure. KS domains form dimers in both structures. KR domains form dimers in the fungal enzyme, whereas ER and DH domains form dimers in the mammalian complex.

Figure 24.10 Structure of the yeast fatty acyl synthase. **(a)** FAS from *S. cerevisiae* possesses two trimeric reaction chambers separated by equatorial stabilizing struts. ACP domains are located at the equatorial base of each reaction chamber, close to the catalytic site of KS. **(b)** The equatorial base of this structure is an α_6 trimer of dimers, with alternating KS and KR domains. The central stabilizing struts are α -helical extensions of the functional domains arranged around the outside of the ring. A central six-helix bundle stabilizes the structure. **(c)** The ACP domains (red) are tethered on flexible linkers (yellow) so that they can move from one active site to the next in the catalytic cycle. Comparison of the ACP domains of *S. cerevisiae* and *E. coli* reveals that the ACP domains probably extend the acyl-phosphopantetheine group to active sites but then retract the acyl group into a hydrophobic cleft while moving from one site to the next (PDB = 2UV8; images courtesy of Marc Leibundgut and Nenad Ban, ETH [Zurich]).

domains are separated and lie near the ends of the extended arms. The arms form reaction chambers on either side of the structure. The flexible ACP domains do not appear in this structure (probably because they are not fixed in any one position in the crystals used for the structural studies). However, since it follows the KR domain in the polypeptide sequence, the ACP domain probably lies at the end of each KR arm, where it can rotate to interact with the adjacent active sites.

In both the fungal and the mammalian FAS structures, the close association of enzymic domains within one large complex permits efficient transfer of intermediates from

Figure 24.11 Structural studies reveal that mammalian FAS homodimer is X-shaped. The ACP domains are probably located adjacent to the KR domains at the ends of the arms (PDB id = 2VZ8; image courtesy of Marc Leibundgut and Nenad Ban, ETH [Zurich]).

one active site to the next. In addition, the presence of all these enzyme domains on one or two polypeptides allows the cell to coordinate synthesis of all enzymes needed for fatty acid synthesis.

24.1m C₁₆ Fatty Acids May Undergo Elongation and Unsaturation

As seen already, palmitate is the primary product of the fatty acid synthase. Cells synthesize many other fatty acids. Shorter chains are easily made if the chain is released before reaching 16 carbons in length. Longer chains are made through special elongation reactions, which occur both in the mitochondria and at the surface of the endoplasmic reticulum (ER).

Additional Elongation The fatty acid elongation reactions in the ER are actually quite similar to those we have just discussed: addition of two-carbon units at the carboxyl end of the chain by means of oxidative decarboxylations involving malonyl-CoA. As was the case for the fatty acid synthase, this decarboxylation provides the thermodynamic driving force for the condensation reaction. The mitochondrial reactions involve addition (and subsequent reduction) of acetyl units. These reactions (Figure 24.12) are essentially a reversal of fatty acid oxidation, except that NADPH is utilized in the saturation of the double bond, instead of FADH₂.

Introduction of a Single *cis* Double Bond Both prokaryotes and eukaryotes are capable of introducing a single *cis* double bond in a newly synthesized fatty acid. Bacteria such as *E. coli* carry out this process in an O₂-independent pathway, whereas eukaryotes have adopted an O₂-dependent pathway. There is a fundamental chemical difference between the two. The O₂-dependent reaction can occur anywhere in the fatty acid chain, with no (additional) need to activate the desired bond toward dehydrogenation. However, in the absence of O₂, some other means must be found to activate the bond in question. Thus, in the bacterial reaction, dehydrogenation occurs while the bond of interest is still near the β -carbonyl or β -hydroxy group and the thioester group at the end of the chain.

In *E. coli*, the biosynthesis of a monounsaturated fatty acid begins with four normal cycles of elongation to form a 10-carbon intermediate, β -hydroxydecanoyl-ACP (Figure 24.13). At this point, **β -hydroxydecanoyl thioester dehydrase** forms a double bond β,γ to the thioester and in the *cis* configuration. This is followed by three rounds

of the normal elongation reactions to form *palmitoleoyl-ACP*. Elongation may terminate at this point or may be followed by additional biosynthetic events. The principal unsaturated fatty acid in *E. coli*, *cis-vaccenic acid*, is formed by an additional elongation step, using palmitoleoyl-ACP as a substrate.

24.1n Unsaturation Reactions Occur in Eukaryotes in the Middle of an Aliphatic Chain

The addition of double bonds to fatty acids in eukaryotes does not occur until the fatty acyl chain has reached its full length (usually 16 to 18 carbons). Dehydrogenation of stearoyl-CoA occurs in the middle of the chain, despite the absence of any useful functional group on the chain to facilitate activation:

This impressive reaction is catalyzed by **stearoyl-CoA desaturase**, a 53 kDa enzyme containing a nonheme iron center. NADH and O₂ are required, as are two other proteins: **cytochrome b₅ reductase** (a 43 kDa flavoprotein) and **cytochrome b₅** (16.7 kDa). All three proteins are associated with the ER membrane. Cytochrome b₅ reductase transfers a pair of electrons from NADH through FAD to cytochrome b₅ (Figure 24.14). Oxidation of reduced cytochrome b₅ is coupled to reduction of nonheme Fe³⁺ to Fe²⁺ in the desaturase. The Fe³⁺ accepts a pair of electrons (one at a time in a cycle) from cytochrome b₅ and creates a *cis* double bond at the 9,10-position of the stearoyl-CoA substrate. O₂ is the terminal electron acceptor in this fatty acyl desaturation cycle. Note that two water molecules are made, which means that four electrons are transferred overall. Two of these come through the reaction sequence from NADH, and two come from the fatty acyl substrate that is being dehydrogenated.

Figure 24.12 Fatty acids longer than palmitate are made in a sequence of four steps. (1) Elongation of fatty acids in mitochondria is initiated by the thiolase reaction. The β-ketoacyl intermediate thus formed undergoes the same three reactions (in reverse order) that are the basis of β-oxidation of fatty acids. (2) Reduction of the β-keto group is followed by (3) dehydration to form a double bond. (4) Reduction of the double bond yields a fatty acyl-CoA that is elongated by two carbons. Note that the reducing coenzyme for the second step is NADH, whereas the reductant for the fourth step is NADPH.

Figure 24.13 Double bonds are introduced into the growing fatty acid chain in *E. coli* by specific dehydrases. Palmitoleoyl-ACP is synthesized by a sequence of reactions involving four rounds of chain elongation, followed by double-bond insertion by β-hydroxydecanoyl thioester dehydrase and three additional elongation steps. Another elongation cycle produces *cis*-vaccenic acid.

Figure 24.14 The conversion of stearoyl-CoA to oleoyl-CoA in eukaryotes is catalyzed by stearoyl-CoA desaturase in a reaction sequence that also involves cytochrome b_5 and cytochrome b_5 reductase. Two electrons are passed from NADH through the chain of reactions as shown, and two electrons are derived from the fatty acyl substrate.

24.1o The Unsaturation Reaction May Be Followed by Chain Elongation

Additional chain elongation can occur following this single desaturation reaction. The oleoyl-CoA produced can be elongated by two carbons to form a 20:1 *cis*- Δ^{11} fatty acyl-CoA. If the starting fatty acid is palmitate, reactions similar to the preceding scheme yield palmitoleoyl-CoA (16:1 *cis*- Δ^9), which subsequently can be elongated to yield *cis*-vaccenic acid (18:1 *cis*- Δ^{11}). Similarly, C_{16} and C_{18} fatty acids can be elongated to yield C_{22} and C_{24} unsaturated fatty acids, such as are often found in sphingolipids.

24.1p Mammals Cannot Synthesize Most Polyunsaturated Fatty Acids

Organisms differ with respect to formation, processing, and utilization of polyunsaturated fatty acids. *E. coli*, for example, does not have any polyunsaturated fatty acids. Eukaryotes *do* synthesize a variety of polyunsaturated fatty acids, certain organisms more than others. For example, plants manufacture double bonds between the Δ^9 and the methyl end of the chain, but mammals cannot. Plants readily desaturate oleic acid at the 12-position (to give linoleic acid) or at both the 12- and 15-positions (producing linolenic acid). Mammals require polyunsaturated fatty acids but must acquire them in their diet. As such, these fatty acids are referred to as **essential fatty acids**. On the other hand, mammals *can* introduce double bonds between the double bond at the 8- or 9-position and the carboxyl group. Enzyme complexes in the ER desaturate the 5-position, provided a double bond exists at the 8-position, and form a double bond at the 6-position if one already exists at the 9-position. Thus, oleate can be unsaturated at the 6,7-position to give an 18:2 *cis*- Δ^6, Δ^9 fatty acid.

24.1q Arachidonic Acid Is Synthesized from Linoleic Acid by Mammals

Mammals can add additional double bonds to unsaturated fatty acids in their diets. Their ability to make arachidonic acid from linoleic acid is one example (Figure 24.15). This fatty acid is the precursor for prostaglandins (the mediators of pain and inflammation) and other biologically active derivatives such as leukotrienes. Synthesis involves formation of a linoleoyl ester of CoA from dietary linoleic acid, followed by introduction of a double bond at the 6-position. The triply unsaturated product is then elongated (by malonyl-CoA with a decarboxylation step) to yield a 20-carbon fatty acid with double bonds at the 8-, 11-, and 14-positions. A second desaturation reaction at the 5-position, followed by a reverse *acyl-CoA synthetase* reaction (see Chapter 23), liberates the product, a 20-carbon fatty acid with double bonds at the 5-, 8-, 11-, and 14-positions.

Figure 24.15 Arachidonic acid is synthesized from linoleic acid in eukaryotes. This is the means by which animals synthesize fatty acids with double bonds at positions other than C-9.

24.1r Regulatory Control of Fatty Acid Metabolism Is an Interplay of Allosteric Modifiers and Phosphorylation–Dephosphorylation Cycles

The activities of the enzymes of fatty acid synthesis fluctuate in response to changes in physiological state. Fatty acid synthesis is also regulated by the direct action of metabolite effectors on key enzymes in the pathway. The control and regulation of fatty acid synthesis is intimately related to regulation of fatty acid breakdown, glycolysis, and the TCA cycle. Acetyl-CoA is an important intermediate metabolite in all these processes. In these terms, it is easy to appreciate the interlocking relationships in Figure 24.16. Malonyl-CoA can act to prevent fatty acyl-CoA derivatives from entering the mitochondria by inhibiting the carnitine acyltransferase of the outer mitochondrial membrane that initiates this transport. In this way, when fatty acid synthesis is turned on (as signaled by higher levels of malonyl-CoA), β -oxidation is inhibited. As described in section 24.1f, citrate is an important allosteric activator of acetyl-CoA carboxylase, and fatty acyl-CoAs are inhibitors. The degree of inhibition is proportional to the chain length of the fatty acyl-CoA; longer chains show a higher affinity for the allosteric inhibition site on acetyl-CoA carboxylase. Palmitoyl-CoA, stearoyl-CoA, and arachidyl-CoA are the most potent inhibitors of the carboxylase.

24.1s Hormonal Signals Regulate ACC and Fatty Acid Biosynthesis

Several hormones act to control fatty acid synthesis, especially via regulation of acetyl-CoA carboxylase. As described in Section 24.1f, citrate activation and palmitoyl-CoA inhibition of acetyl-CoA carboxylase are strongly dependent on the phosphorylation state of the enzyme. This provides a crucial connection to hormonal regulation.

Human Biochemistry

 ω 3 and ω 6—Essential Fatty Acids with Many Functions

Linoleic acid and α -linolenic acid are termed *essential fatty acids* because animals cannot synthesize them and must acquire them in their diet. Linoleic acid is the precursor of arachidonic acid, and both of these are referred to as **ω 6 fatty acids** because, counting from the end (omega, ω) carbon of the chain, the first double bond is at the sixth position (see figure). Similarly, α -linolenic acid is the precursor of *eicosapentaenoic acid* and *docosahexaenoic acid (DHA)*, and these three are termed **ω 3 fatty acids**. Vegetable oils are rich in linoleic acid and thus satisfy the body's ω 6 dietary requirements, whereas fish oils (for example, cod, herring, menhaden, and salmon) are rich in ω 3 fatty acids.

The ω 6 fatty acids are precursors of inflammation mediators, including the prostaglandins, thromboxanes, and leukotrienes (see

Section 24.3). The ω 3 fatty acids have beneficial effects in a variety of organs and biological processes, including growth regulation, platelet activation, and lipoprotein metabolism. The ω 3 fats are generally cardioprotective, anti-inflammatory, and anticarcinogenic.

Interestingly, especially high levels of DHA have been found in rod cell membranes in animal retina and in neural tissue. DHA is approximately 22% of total fatty acids in animal retina and 35% to 40% of the fatty acids in retinal phosphatidylethanolamine. DHA supports neural and visual development, in part because it is a precursor for eicosanoids that regulate numerous cell and organ functions. Infants can synthesize DHA and other polyunsaturated fatty acids, but the rates of synthesis are low. Strong evidence exists for the importance of these fatty acids in infant nutrition.

The “ ω ” numbering system, where the position of the first double bond relative to the methyl (ω) group is indicated (red box), is useful because the ω double-bond position is retained during chain elongation and desaturation. (a) ω 6 fatty acids. (b) ω 3 fatty acids.

Figure 24.16 Regulation of fatty acid synthesis and fatty acid oxidation are coupled as shown. Malonyl-CoA, produced during fatty acid synthesis, inhibits the uptake of fatty acylcarnitine (and thus fatty acid oxidation) by mitochondria. When fatty acyl-CoA levels rise, fatty acid synthesis is inhibited and fatty acid oxidation activity increases. Rising citrate levels (which reflect an abundance of acetyl-CoA) similarly signal the initiation of fatty acid synthesis.

Figure 24.17 Hormonal signals regulate fatty acid synthesis, primarily through actions on acetyl-CoA carboxylase. Availability of fatty acids also depends upon hormonal activation of triacylglycerol lipase.

Many of the enzymes that act to phosphorylate acetyl-CoA carboxylase (see Figure 24.4) are controlled by hormonal signals. Glucagon is a good example (Figure 24.17). As noted in Chapter 22, glucagon binding to membrane receptors activates an intracellular cascade involving activation of adenylyl cyclase. Cyclic AMP produced by the cyclase activates protein kinase A, which then phosphorylates acetyl-CoA carboxylase. Unless citrate levels are high, phosphorylation causes inhibition of fatty acid biosynthesis. The carboxylase (and fatty acid synthesis) can be reactivated by a specific phosphatase, which dephosphorylates the carboxylase. Also indicated in Figure 24.17 is the simultaneous activation by glucagon of triacylglycerol lipases, which hydrolyze triacylglycerols, releasing fatty acids for β -oxidation. Both the inactivation of acetyl-CoA carboxylase and the activation of triacylglycerol lipase are counteracted by insulin, whose receptor acts to stimulate a phosphodiesterase that converts cAMP to AMP.

24.2 | How Are Complex Lipids Synthesized?

Complex lipids consist of backbone structures to which fatty acids are covalently bound. Principal classes include the **glycerolipids**, for which glycerol is the backbone, and **sphingolipids**, which are built on a sphingosine backbone. The two major classes of glycerolipids are **glycerophospholipids** and **triacylglycerols**. The **phospholipids**, which include both glycerophospholipids and sphingomyelins, are crucial components of membrane structure. They are also precursors of hormones such as the *eicosanoids* (for example, *prostaglandins*) and signal molecules (such as the breakdown products of *phosphatidylinositol*).

Different organisms possess greatly different complements of lipids and therefore utilize somewhat different lipid biosynthetic pathways. For example, sphingolipids and triacylglycerols are produced only in eukaryotes. In contrast, bacteria usually have rather simple lipid compositions. Phosphatidylethanolamine accounts for at least 75% of the phospholipids in *E. coli*, with phosphatidylglycerol and cardiolipin accounting for most of the rest. *E. coli* membranes possess no phosphatidylcholine, phosphatidylinositol, sphingolipids, or cholesterol. On the other hand, some bacteria (such as *Pseudomonas*) can synthesize phosphatidylcholine, for example. In this section and the one following, we consider some of the pathways for the synthesis of glycerolipids, sphingolipids, and the eicosanoids, which are derived from phospholipids.

24.2a Glycerolipids Are Synthesized by Phosphorylation and Acylation of Glycerol

A common pathway operates in nearly all organisms for the synthesis of **phosphatidic acid**, the precursor to other glycerolipids. *Glycerokinase* catalyzes the phosphorylation of glycerol to form glycerol-3-phosphate, which is then acylated at both the 1- and 2-positions to yield phosphatidic acid (Figure 24.18). The first acylation, at position 1, is catalyzed by *glycerol-3-phosphate acyltransferase*, an enzyme that in most organisms is specific for saturated fatty acyl groups. Eukaryotic systems can also use **dihydroxyacetone phosphate** as a starting point for synthesis of phosphatidic acid (Figure 24.18). Again a specific acyltransferase adds the first acyl chain, followed by reduction of the backbone keto group by **acyldihydroxyacetone phosphate reductase**, using NADPH as the reductant. Alternatively, dihydroxyacetone phosphate can be reduced to glycerol-3-phosphate by *glycerol-3-phosphate dehydrogenase*.

24.2b Eukaryotes Synthesize Glycerolipids from CDP-Diacylglycerol or Diacylglycerol

In eukaryotes, phosphatidic acid is converted directly either to diacylglycerol or to *cytidine diphosphodiacylglycerol* (or simply *CDP-diacylglycerol*; Figure 24.19). From these two precursors, all other glycerophospholipids in eukaryotes are derived.

Human Biochemistry

Lipins—Phosphatases Essential for Triglyceride Synthesis and Other Functions

Lipins are phosphatidic acid phosphatases (also known as PAPs) widely conserved in eukaryotes. Unlike other enzymes of the triacylglycerol biosynthetic pathway, lipins lack transmembrane domains and are extensively phosphorylated and thus confined to the cytosol until activated. Activation occurs upon PAP binding to a complex of two ER/nuclear transmembrane proteins, Nem1p and Spo7p, followed by removal of the phosphate groups from PAP. The activated lipin-Nem1p-Spo7p complex dephosphorylates phosphatidic acid to produce diacylglycerols, which can be acylated to form triacylglycerols. Lipins are critical for triacylglycerol biosynthesis in most eukaryotes, and they are also essential for maintenance of nuclear structure and organization of the ER membrane.

Many cell types maintain a pool of lipins within the nucleus, where they regulate expression of genes encoding fatty acid-metabolizing enzymes. Nuclear import of certain lipins in response to nutrient depletion induces nuclear envelope remodeling and downregulation of certain transcription factors involved in lipid synthesis.

Reference
Siniossoglou, S., 2015. The many faces of lipins. *ASBMB Today* **14**:14–15.

Figure 24.18 Synthesis of glycerolipids in eukaryotes begins with the formation of phosphatidic acid, which may be formed from dihydroxyacetone phosphate or glycerol as shown.

Diacylglycerol is a precursor for synthesis of triacylglycerol, phosphatidylethanolamine, and phosphatidylcholine. Triacylglycerol is synthesized mainly in adipose tissue, liver, and intestines and serves as the principal energy storage molecule in eukaryotes. Triacylglycerol biosynthesis in liver and adipose tissue occurs via **diacylglycerol acyltransferase**, an enzyme bound to the cytoplasmic face of the ER. A different route is used, however, in intestines. Recall (see Figure 23.3) that triacylglycerols from the diet are broken down to 2-monoacylglycerols by specific lipases. Acyltransferases then acylate 2-monoacylglycerol to produce new triacylglycerols (Figure 24.20).

Figure 24.19 Diacylglycerol and CDP-diacylglycerol are the principal precursors of glycerolipids in eukaryotes. Phosphatidylethanolamine and phosphatidylcholine are formed by reaction of diacylglycerol with CDP-ethanolamine or CDP-choline, respectively.

24.2c Phosphatidylethanolamine Is Synthesized from Diacylglycerol and CDP-Ethanolamine

Phosphatidylethanolamine synthesis begins with phosphorylation of ethanolamine to form phosphoethanolamine (see Figure 24.19). The next reaction involves transfer of a cytidylyl group from CTP to form CDP-ethanolamine and pyrophosphate. As always, PP_i hydrolysis drives this reaction forward. A specific **phosphoethanolamine transferase** then links phosphoethanolamine to the diacylglycerol backbone. Biosynthesis of phosphatidylcholine is entirely analogous because animals can synthesize it directly. All of the choline used in this pathway must be acquired from the diet. On the other hand, yeast, certain bacteria, and animal livers can convert phosphatidylethanolamine to phosphatidylcholine by methylation reactions involving S-adenosylmethionine.

24.2d Exchange of Ethanolamine for Serine Converts Phosphatidylethanolamine to Phosphatidylserine

Mammals synthesize phosphatidylserine (PS) in a calcium ion–dependent reaction involving aminoalcohol exchange (Figure 24.21). The enzyme catalyzing this reaction is associated with the ER and will accept phosphatidylethanolamine (PE) and other phospholipid substrates. A mitochondrial **PS decarboxylase** can subsequently convert PS to PE. No other pathway converting serine to ethanolamine has been found.

24.2e Eukaryotes Synthesize Other Phospholipids Via CDP-Diacylglycerol

Eukaryotes also use CDP-diacylglycerol, derived from phosphatidic acid, as a precursor for several other important phospholipids, including phosphatidylinositol (PI), phosphatidylglycerol (PG), and cardiolipin (Figure 24.22). PI accounts for only about 2% to 8% of the lipids in most animal membranes, but breakdown products of PI, including inositol-1,4,5-trisphosphate and diacylglycerol, are second messengers in a vast array of cellular signaling processes.

Figure 24.21 The interconversion of phosphatidylethanolamine and phosphatidylserine in mammals.

Figure 24.20 Triacylglycerols are formed primarily by the action of acyltransferases on monoacylglycerol and diacylglycerol.

Figure 24.22 CDP-diacylglycerol is a precursor of phosphatidylinositol, phosphatidylglycerol, and cardiolipin in eukaryotes.

24.2f Dihydroxyacetone Phosphate Is a Precursor to the Plasmalogens

Certain glycerophospholipids possess alkyl or alkenyl ether groups at the 1-position in place of an acyl ester group. These glycerether phospholipids are synthesized from dihydroxyacetone phosphate (Figure 24.23). Acylation of dihydroxyacetone phosphate (DHAP) is followed by an exchange reaction, in which the acyl group is removed as a carboxylic acid and a long-chain alcohol adds to the 1-position. This

long-chain alcohol is derived from the corresponding acyl-CoA by means of an acyl-CoA reductase reaction involving oxidation of two molecules of NADH. The 2-*keto* group of the DHAP backbone is then reduced to an alcohol, followed by acylation. The resulting 1-alkyl-2-acylglycero-3-phosphate can react in a manner similar to phosphatidic acid to produce ether analogs of phosphatidylcholine, phosphatidylethanolamine, and so forth (Figure 24.23). In addition, specific **desaturase** enzymes associated with the ER can desaturate the alkyl ether chains of these lipids as shown. The products, which contain α,β -unsaturated ether-linked chains at the C-1 position, are **plasmalogens**; they are abundant in cardiac tissue and in the central nervous system. The desaturases catalyzing these reactions are distinct from but similar to those that introduce unsaturations in fatty acyl-CoAs.

24.2g Platelet-Activating Factor Is Formed by Acetylation of 1-Alkyl-2-Lysophosphatidylcholine

A particularly interesting ether phospholipid with unusual physiological properties, **1-alkyl-2-acetylglycerophosphocholine**, also known as **platelet-activating factor**, possesses an alkyl ether at C-1 and an acetyl group at C-2 (Figure 24.24). The very short chain at C-2 makes this molecule much more water soluble than typical glycerolipids. Platelet-activating factor displays a dramatic ability to dilate blood vessels (and thus reduce blood pressure in hypertensive animals) and to aggregate platelets.

24.2h Sphingolipid Biosynthesis Begins with Condensation of Serine and Palmitoyl-CoA

Sphingolipids, ubiquitous components of eukaryotic cell membranes, are present at high levels in neural tissues. The myelin sheath that insulates nerve axons is particularly rich in sphingomyelin and other related lipids. Prokaryotic organisms normally do not contain sphingolipids. Sphingolipids are built upon sphingosine backbones rather than glycerol. The initial reaction, which involves condensation of serine and palmitoyl-CoA with release of bicarbonate, is catalyzed by **3-ketosphinganine synthase**, a PLP-dependent enzyme (Figure 24.25). Reduction of the ketone product to form sphinganine is catalyzed by **3-ketosphinganine reductase**, with NADPH as a reactant. In the next step, sphinganine is acylated to form *N*-acyl sphinganine, which is then desaturated to form **ceramide**. Sphingosine itself does not appear to be an intermediate in this pathway in mammals.

24.2i Ceramide Is the Precursor for Other Sphingolipids and Cerebrosides

Ceramide is the building block for all other sphingolipids. **Sphingomyelin**, for example, is produced by transfer of phosphocholine from phosphatidylcholine (Figure 24.26). Glycosylation of ceramide by sugar nucleotides yields **cerebrosides**, such as galactosylceramide, which makes up about 15% of the lipids of myelin sheath structures.

Figure 24.24 Platelet-activating factor, formed from 1-alkyl-2-lysophosphatidylcholine by acetylation at C-2, is degraded by the action of acetylhydrolase.

Figure 24.25 Biosynthesis of sphingolipids in animals begins with the 3-ketosphinganine synthase reaction, a PLP-dependent condensation of palmitoyl-CoA and serine. Subsequent reduction of the keto group, acylation, and desaturation (via reduction of an electron acceptor, X) form ceramide, the precursor of other sphingolipids.

Figure 24.26 Glycosylceramides (such as galactosylceramide), gangliosides, and sphingomyelins are synthesized from ceramide in animals.

Cerebrosides that contain one or more sialic acid (*N*-acetylneuraminic acid) moieties are called **gangliosides**. Several dozen gangliosides have been characterized, and the general form of the biosynthetic pathway is illustrated for the case of ganglioside GM₂ (Figure 24.26). Sugar units are added to the developing ganglioside from nucleotide derivatives, including UDP-*N*-acetylglucosamine, UDP-galactose, and UDP-glucose.

24.3 | How Are Eicosanoids Synthesized, and What Are Their Functions?

Eicosanoids are signaling molecules derived from arachidonic acid. They are so named because they are all derived from 20-carbon fatty acids and they are ubiquitous breakdown products of phospholipids. In response to appropriate stimuli, cells activate the breakdown of selected phospholipids (Figure 24.27). Phospholipase A₂ (see Chapter 8) selectively cleaves fatty acids from the C-2 position of phospholipids. Often these are unsaturated fatty acids, among which is arachidonic acid. Arachidonic acid may also be released from phospholipids by the combined actions of phospholipase C (which yields diacylglycerols) and diacylglycerol lipase (which releases fatty acids).

24.3a Eicosanoids Are Local Hormones

Animal cells can modify arachidonic acid and other polyunsaturated fatty acids, in processes often involving cyclization and oxygenation, to produce so-called local hormones that (1) exert their effects at very low concentrations and (2) usually act near their sites of synthesis. These substances include the **prostaglandins (PG)** (Figure 24.27), described in this section, as well as **thromboxanes (Tx)**, **leukotrienes**, and other **hydroxyeicosanoic acids**. Thromboxanes, discovered in blood platelets (*thrombocytes*), are cyclic ethers (TxB₂ is actually a hemiacetal; see Figure 24.27) with a hydroxyl group at C-15.

24.3b Prostaglandins Are Formed from Arachidonate by Oxidation and Cyclization

All prostaglandins are cyclopentanoic acids derived from arachidonic acid. The biosynthesis of prostaglandins is initiated by an enzyme associated with the ER, called **prostaglandin endoperoxide H synthase (PGHS)**, also known as **cyclooxygenase (COX)**. The enzyme catalyzes simultaneous oxidation and cyclization of arachidonic acid. The enzyme is viewed as having two distinct activities, COX and peroxidase (POX), as shown in Figure 24.28.

24.3c A Variety of Stimuli Trigger Arachidonate Release and Eicosanoid Synthesis

The release of arachidonate and the synthesis or interconversion of eicosanoids can be initiated by a variety of stimuli, including histamine, hormones such as epinephrine and bradykinin, proteases such as thrombin, and even serum albumin. An important mechanism of arachidonate release and eicosanoid synthesis involves tissue injury and inflammation. When tissue damage or injury occurs, special inflammatory cells, **monocytes** and **neutrophils**, invade the injured tissue and interact with the resident cells (such as smooth muscle cells and fibroblasts). *This interaction typically leads to arachidonate release and eicosanoid synthesis.* Examples of tissue injury in which eicosanoid synthesis has been characterized include heart attack (myocardial infarction), rheumatoid arthritis, and ulcerative colitis.

Figure 24.27 Arachidonic acid, derived from breakdown of phospholipids (PL), is the precursor of prostaglandins, thromboxanes, and leukotrienes. The letters used to name the prostaglandins are assigned on the basis of similarities in structure and physical properties. The class denoted PGE, for example, consists of β -hydroxyketones that are soluble in ether, whereas PGF denotes 1,3-diols that are soluble in phosphate buffer. PGA denotes prostaglandins possessing α,β -unsaturated ketones. The number following the letters refers to the number of carbon-carbon double bonds. Thus, PGE₂ contains two double bonds.

A Deeper Look

The Molecular Basis for the Action of Nonsteroidal Anti-inflammatory Drugs

Prostaglandins are potent mediators of inflammation. The first and committed step in the production of prostaglandins from arachidonic acid is the bis-oxygenation of arachidonate to prostaglandin PGG_2 . This is followed by reduction to PGH_2 in a peroxidase reaction. Both these reactions are catalyzed by PGHS or COX. This enzyme is inhibited by the family of drugs known as nonsteroidal anti-inflammatory drugs, or NSAIDs. Aspirin, ibuprofen, flurbiprofen, and acetaminophen (trade name Tylenol) are all NSAIDs.

There are two isoforms of COX in animals: COX-1, which carries out normal, physiological production of prostaglandins, and COX-2, which is induced by cytokines, mitogens, and endotoxins in inflammatory cells and is responsible for the production of prostaglandins in inflammation.

The enzyme structure shown in panel (a) is that of residues 33 to 583 of COX-1 from sheep, inactivated by ibuprofen (*cyan*).

The COX active site lies at the end of a long, narrow, hydrophobic tunnel or channel.

The COX-1 structure shown in panel (a) has a molecule of ibuprofen bound in the tunnel. Deep in the tunnel, at the far end, lies Tyr³⁸⁵, a catalytically important residue. Heme-dependent peroxidase activity is implicated in the formation of a proposed Tyr³⁸⁵ radical, which is required for COX activity. Aspirin and other NSAIDs block the synthesis of prostaglandins by filling and blocking the tunnel, preventing the migration of arachidonic acid to Tyr³⁸⁵ in the active site at the back of the tunnel.

Why do the new COX-2 inhibitors bind to (and inhibit) COX-2 but not COX-1? A single amino acid substitution makes all the difference. Panel (b) shows an overlay of COX-1 (1EQG) and COX-2 (1CX2) structures. COX-2 has a valine (*blue*) at position 523, which leaves room for binding of a celebrex-like inhibitor (*orange*). On

PDB id = 1EQG

Superposition of PDB id = 1EQG and 1CX2

the other hand, COX-1 has bulkier isoleucine (*red*) at position 523, which prevents binding of the inhibitor.

COX-2 inhibitors were introduced as pain medications in 1997, and by 2004 nearly half of the 100 million prescriptions written annually for NSAIDs in the United States were COX-2 inhibitors. However, several COX-2 inhibitors were taken off the U.S. market in late 2004 and early 2005, when their use was linked to

heart attacks and strokes in a small percentage of users. Since then, prescriptions for COX-2 inhibitors have dropped by 65%. Interestingly, although COX-2 inhibitors were originally intended to alleviate pain without the risk of adverse gastrointestinal effects, less than 5% of patients that used COX-2 prescriptions at the peak of their popularity were at high risk for these adverse effects.

In 1971, biochemist John Vane was the first to show that **aspirin** (acetylsalicylate; Figure 24.29) exerts most of its effects by inhibiting the biosynthesis of prostaglandins. Its site of action is PGHS. COX activity is destroyed when aspirin *O*-acetylates Ser⁵³⁰ on the enzyme. From this you may begin to infer something about how prostaglandins (and aspirin) function. Prostaglandins are known to enhance inflammation in animal tissues. Aspirin exerts its powerful anti-inflammatory effect by inhibiting this first step in their

Figure 24.28 Prostaglandin endoperoxide synthase (PGHS), the enzyme that converts arachidonic acid to prostaglandin PGH_2 , possesses two distinct activities: cyclooxygenase (COX) and a glutathione-dependent hydroperoxidase (POX). The mechanism of the reaction begins with hydrogen atom abstraction by a tyrosine radical on the enzyme, followed by rearrangement to cyclize and incorporate two oxygen molecules. Reduction of the peroxide at C15 completes the reaction. COX is the site of action of aspirin and other analgesic agents.

Figure 24.29 The structures of several common analgesic agents. (a) Acetaminophen is marketed under the trade name Tylenol. Ibuprofen is sold as Motrin, Nuprin, and Advil. (b) Acetylsalicylate (aspirin) inhibits the COX activity of endoperoxide synthase via acetylation (covalent modification) of Ser⁵³⁰.

synthesis. Aspirin does not have any measurable effect on the peroxidase activity of the synthase. Other nonsteroidal anti-inflammatory agents, such as **ibuprofen** (Figure 24.29) and phenylbutazone, inhibit COX by competing at the active site with arachidonate or with the peroxyacid intermediate (PGG_2 , as in Figure 24.28).

Figure 24.30 The structure of cholesterol, drawn (a) in the traditional planar motif and (b) in a form that more accurately describes the conformation of the ring system.

24.4 | How Is Cholesterol Synthesized?

The most prevalent steroid in animal cells is **cholesterol** (Figure 24.30). Plants contain no cholesterol, but they *do* contain other steroids very similar to cholesterol in structure (see the Human Biochemistry box “Plant Sterols and Stanols—Natural Cholesterol Fighters” in Section 8.7). Cholesterol serves as a crucial component of cell membranes as well as a precursor to bile acids (such as cholate, glycocholate, taurocholate) and steroid hormones (such as testosterone, estradiol, progesterone). Also, vitamin D₃ is derived from *7-dehydrocholesterol*, the immediate precursor of cholesterol. Liver is the primary site of cholesterol biosynthesis.

24.4a Mevalonate Is Synthesized from Acetyl-CoA Via HMG-CoA Synthase

The cholesterol biosynthetic pathway begins in the cytosol with the synthesis of mevalonate from acetyl-CoA (Figure 24.31). The first step is the **β -ketothiolase**-catalyzed Claisen condensation of two molecules of acetyl-CoA to form acetoacetyl-CoA. In the next reaction, acetyl-CoA and acetoacetyl-CoA join to form *3-hydroxy-3-methylglutaryl-CoA*, which is abbreviated *HMG-CoA*. The reaction, a second Claisen condensation, is catalyzed by **HMG-CoA synthase**. The third step in the pathway is the rate-limiting step in cholesterol biosynthesis. Here, HMG-CoA undergoes two NADPH-dependent reductions to produce *3R-mevalonate* (Figure 24.32). The reaction is catalyzed by **HMG-CoA reductase**, a 97 kDa glycoprotein that spans the ER membrane with its active site facing the cytosol. As the rate-limiting step, HMG-CoA reductase is the principal site of regulation in cholesterol synthesis.

Three different regulatory mechanisms are involved:

1. Phosphorylation by cAMP-dependent protein kinase inactivates the reductase. This inactivation can be reversed by two specific phosphatases (Figure 24.33).
2. Degradation of HMG-CoA reductase. This enzyme has a half-life of only 3 hours, and the half-life itself depends on cholesterol levels: High [cholesterol] means a short half-life for HMG-CoA reductase.
3. Gene expression. Cholesterol levels control the amount of mRNA. If [cholesterol] is high, levels of mRNA coding for the reductase are reduced. If [cholesterol] is low, more mRNA is made.

24.4b Why Can't Thiolase Be Used in Fatty Acid Synthesis?

If acetate units can be condensed by the thiolase reaction to yield acetoacetate in the first step of cholesterol synthesis, why couldn't this same reaction also be used in fatty acid synthesis, avoiding all the complexity of the fatty acyl synthase? The answer is that the thiolase reaction is more or less reversible but slightly favors the cleavage reaction. In the cholesterol synthesis pathway, subsequent reactions, including HMG-CoA reductase and the following kinase reactions, pull the thiolase-catalyzed condensation forward. However, in the case of fatty acid synthesis, a succession of eight thiolase condensations would be distinctly unfavorable from an energetic perspective. Given the necessity of repeated reactions in fatty acid synthesis, it makes better energetic sense to use a reaction that is favorable in the desired direction.

Figure 24.31 The biosynthesis of 3R-mevalonate from acetyl-CoA.

Figure 24.32 Two successive NADPH-dependent reductions convert the thioester, HMG-CoA, to a primary alcohol. (a) A reaction mechanism for HMG-CoA reductase. (b) Homotetramer of the catalytic portion of the human HMG-CoA reductase.

24.4c Squalene Is Synthesized from Mevalonate

Squalene, a triterpene formed from mevalonate, is a precursor in the synthesis of cholesterol and all other sterols. The biosynthesis of squalene involves conversion of mevalonate to two key 5-carbon intermediates, *isopentenyl pyrophosphate* and *dimethylallyl pyrophosphate*, which join to yield *farnesyl pyrophosphate* and then squalene. A series of four reactions converts mevalonate to isopentenyl pyrophosphate and then to dimethylallyl pyrophosphate (Figure 24.34). The first three steps each consume an ATP, two for the purpose of forming a pyrophosphate at the 5-position and the third to drive the decarboxylation and double-bond formation in the third step. **Pyrophosphomevalonate decarboxylase** phosphorylates the 3-hydroxyl group, and this is followed by *trans* elimination of the phosphate and carboxyl groups to form the double bond in isopentenyl pyrophosphate. Isomerization of the double bond yields the dimethylallyl pyrophosphate. Condensation of these two 5-carbon intermediates produces *geranyl pyrophosphate*; addition of another 5-carbon isopentenyl group gives *farnesyl pyrophosphate*. Both steps in the production of farnesyl pyrophosphate occur with release of pyrophosphate, hydrolysis of which drives these reactions forward. Note too that the linkage of isoprene units to form farnesyl pyrophosphate occurs in a head-to-tail fashion. This is the general rule in biosynthesis of molecules involving isoprene linkages. The next step—the joining of two farnesyl pyrophosphates to

Figure 24.33 HMG-CoA reductase activity is modulated by a cycle of phosphorylation and dephosphorylation.

Figure 24.34 The conversion of mevalonate to squalene. In the last step, two farnesyl-PP condense to form squalene.

Human Biochemistry

Statins Lower Serum Cholesterol Levels

Chemists and biochemists have long sought a means of lowering serum cholesterol levels to reduce the risk of heart attack and cardiovascular disease. Because HMG-CoA reductase is the rate-limiting step in cholesterol biosynthesis, this enzyme is a likely drug target. *Mevinolin*, also known as *lovastatin* (see accompanying figure), was isolated from a strain of *Aspergillus terreus* and developed at Merck Sharpe & Dohme for this purpose. It is now a widely prescribed cholesterol-lowering drug. Dramatic reductions of serum cholesterol are observed at dosages of 20 to 80 mg per day.

Lovastatin is administered as an inactive lactone. After oral ingestion, it is hydrolyzed to the active *mevinolinic acid*, a competitive

inhibitor of the reductase with a K_i of 0.6 nM. Mevinolinic acid is thought to behave as a transition-state analog (see Chapter 14) of the tetrahedral intermediate formed in the HMG-CoA reductase reaction (see figure).

Derivatives of lovastatin have been found to be even more potent in cholesterol-lowering trials. *Synvinolin* lowers serum cholesterol levels at much lower dosages than lovastatin. Lipitor, shown bound at the active site of HMG-CoA reductase, was the best-selling drug of all time, with total sales exceeding \$125 billion over a 15-year period.

The structures of (a) (inactive) lovastatin, (active) mevinolinic acid, mevalonate, and (b) Lipitor (atorvastatin). (c) HMG-CoA reductase with NADP⁺, HMG, and CoA. (d) Lipitor bound at the HMG-CoA reductase active site.

produce squalene—is a tail-to-tail condensation and represents an important exception to the general rule.

Squalene monooxygenase, an enzyme bound to the ER, converts squalene to *squalene-2,3-epoxide* (Figure 24.35). This reaction employs FAD and NADPH as coenzymes and requires O₂ as well as a cytosolic protein called **soluble protein activator**. A second ER membrane enzyme, **2,3-oxidosqualene lanosterol cyclase**, catalyzes the second reaction, which involves a succession of 1,2 shifts of hydride ions and methyl groups and produces lanosterol.

Figure 24.35 Cholesterol is synthesized from squalene via lanosterol. The primary route from lanosterol involves 20 steps, the last of which converts 7-dehydrocholesterol to cholesterol. An alternative route produces desmosterol as the penultimate intermediate.

24.4d
Conversion of Lanosterol to Cholesterol Requires 20 Additional Steps

Although lanosterol may appear similar to cholesterol in structure, another 20 steps are required to convert lanosterol to cholesterol (Figure 24.35). The enzymes responsible for this are all associated with the ER. The primary pathway involves *7-dehydrocholesterol* as the penultimate intermediate. An alternative pathway, also composed of many steps, produces the intermediate *desmosterol*. Reduction of the double bond at C-24 yields cholesterol. Cholesterol esters—a principal form of circulating cholesterol—are synthesized by **acyl-CoA:cholesterol acyltransferases (ACATs)** on the cytoplasmic face of the ER.

24.5 |
How Are Lipids Transported Throughout the Body?

Lipids are universal energy sources for the organism and must circulate to the sites where they are utilized. When most lipids circulate in the body, they do so in the form of **lipoprotein complexes**. Simple, unesterified fatty acids are bound to serum albumin and other proteins in blood plasma, but phospholipids, triacylglycerols, cholesterol, and cholesterol esters are all transported in the form of lipoproteins. At various sites in the body, lipoproteins interact with specific receptors and enzymes that transfer or modify their lipid cargoes. It is now customary to classify lipoproteins according to their densities (Table 24.1). The densities are related to the relative amounts of lipid and protein in the complexes. Because most proteins have densities of about 1.3 to 1.4 g/mL, and lipid aggregates usually possess densities of about 0.8 g/mL, the more protein and the less lipid in a complex, the denser the lipoprotein. Thus, there are **high-density lipoproteins (HDLs)**, **low-density lipoproteins (LDLs)**, **intermediate-density lipoproteins (IDLs)**, **very-low-density lipoproteins (VLDLs)**, and also **chylomicrons**. Chylomicrons have the lowest protein-to-lipid ratio and thus are the lowest-density lipoproteins. They are also the largest.

24.5a
Lipoprotein Complexes Transport Triacylglycerols and Cholesterol Esters

HDL and VLDL are assembled primarily in the ER of liver cells (with smaller amounts produced in the intestine), whereas chylomicrons form in the intestine. LDL is not synthesized directly but rather is made from VLDL. LDL appears to be the major circulatory complex for cholesterol and cholesterol esters. The primary task of chylomicrons is to transport triacylglycerols. Despite all this, it is extremely important to note that each of these lipoprotein classes contains some of each type of lipid. The relative amounts of HDL and LDL are important in the disposition of cholesterol in the body and in the development of arterial plaques (Figure 24.36). The structures of the various lipoproteins are approximately similar, and they consist of a core of mobile triacylglycerols or cholesterol esters surrounded by a single layer of phospholipid, into

Figure 24.36 Photograph of an arterial plaque. The view is into the artery (*orange*), with the plaque shown in *yellow* at the back.

Table 24.1 Composition and Properties of Human Lipoproteins						
Lipoprotein Class	Density (g/mL)	Diameter (nm)	Composition (% dry weight)			
			Protein	Cholesterol	Phospholipid	Triacylglycerol
HDL	1.063–1.21	5–15	33	30	29	8
LDL	1.019–1.063	18–28	25	50	21	4
IDL	1.006–1.019	25–50	18	29	22	31
VLDL	0.95–1.006	30–80	10	22	18	50
Chylomicrons	<0.95	100–500	1–2	8	7	84

Human Biochemistry

APOC3—An Apolipoprotein That Regulates Plasma Triglyceride Levels

Elevated plasma triglycerides (>150 mg/dL) are a demonstrated risk factor for cardiovascular disease and heart attacks. Lifestyle factors such as smoking, lack of exercise, and weight gain all contribute to high triglyceride levels. However, heritability also plays a role in individual variation in triglyceride levels. For example, one in 20 people in Amish communities are genetically predisposed to triglyceride levels of 50 or less and can enjoy diets high in fat with no ill effects. At the other extreme, familial chylomicronemia syndrome (FCS) is a serious, often life-threatening, hereditary condition affecting one in a million individuals in which triglyceride levels often exceed 2000 mg/dL. Analysis of data from the Exome Sequencing Project of the National Heart, Lung, and Blood Institute has revealed that four loss-of-function mutations in *APOC3*, a gene encoding apolipoprotein C3 (apoC3), are associated with remarkably low plasma triglyceride

levels. Individuals carrying at least one of these mutations were found to have 39% lower triglycerides than noncarriers and a 40% lower risk of coronary heart disease.

Volanesorsen, sold under the brand name Waylivra by Ionis Pharmaceuticals, is an antisense oligonucleotide drug that targets messenger RNA for APOC3. It is approved for use in the European Union. In clinical trials, participants with FCS who were given volanesorsen had an average 77% reduction in the level of triglycerides in the blood.

which is inserted a mixture of cholesterol and proteins (Figure 24.37). Note that the phospholipids are oriented with their polar head groups facing outward to interact with solvent water and that the phospholipids thus shield the hydrophobic lipids inside from the solvent water outside. The proteins also function as recognition sites for the various lipoprotein receptors throughout the body. A number of different apoproteins have been identified in lipoproteins (Table 24.2), and others may exist as well. The apoproteins have an abundance of hydrophobic amino acid residues, as is appropriate for interactions with lipids. A **cholesterol ester transfer protein** also associates with lipoproteins.

24.5b Lipoproteins in Circulation Are Progressively Degraded by Lipoprotein Lipase

The liver and intestines of animals are the primary sources of circulating lipids. Chylomicrons carry triacylglycerol and cholesterol esters from the intestines to other tissues, and VLDLs carry lipid from the liver, as shown in Figure 24.38. At various target sites, particularly in the capillaries of muscle and adipose cells, these particles

Figure 24.38 Lipoprotein components are synthesized predominantly in the ER of liver cells. Following assembly of lipoprotein particles (red dots) in the ER and processing in the Golgi, lipoproteins are packaged in secretory vesicles for export from the cell (via exocytosis) and released into the circulatory system.

are degraded by **lipoprotein lipase**, which hydrolyzes triacylglycerols. Lipase action causes progressive loss of triacylglycerol (and apoprotein) and makes the lipoproteins smaller. This process gradually converts VLDL particles to IDL and then LDL particles, which are either returned to the liver for reprocessing or redirected to adipose tissues and adrenal glands. Every 24 hours, nearly half of all serum LDL is removed from circulation in this way. The LDL binds to specific LDL receptors, which cluster in domains of the plasma membrane known as **coated pits** (invaginations of the membrane discussed in subsequent paragraphs). These domains eventually invaginate to form **coated vesicles** (Figure 24.39), which pinch off from the plasma membrane and form **endosomes** (literally “bodies inside” the cell). In the low pH environment of the

Figure 24.39 Endocytosis and degradation of lipoprotein particles. (ACAT is acyl-CoA cholesterol acyltransferase.)

endosome, the LDL particles dissociate from their receptors. The endosomes then fuse with lysosomes, and the LDLs are degraded by **lysosomal acid lipases**.

HDLs have much longer life spans in the body (5 to 6 days) than other lipoproteins. Newly formed HDL contains virtually no cholesterol ester. However, over time, cholesterol esters are accumulated through the action of **lecithin:cholesterol acyltransferase (LCAT)**, a 59 kDa glycoprotein associated with HDLs. Another associated protein, **cholesterol ester transfer protein**, transfers some of these esters to VLDL and LDL. Alternatively, HDLs function to return cholesterol and cholesterol esters to the liver. This latter process apparently explains the correlation between high HDL levels and reduced risk of cardiovascular disease. (High LDL levels, on the other hand, are correlated with an *increased* risk of coronary artery and cardiovascular disease.)

24.5c The Structure of the LDL Receptor Involves Five Domains

The LDL receptor in plasma membranes (Figure 24.40) consists of 839 amino acid residues and is composed of five domains, two of which contain multiple subdomains. The N-terminal LDL-binding domain (292 residues) contains seven cysteine-rich repeats, denoted R1 to R7. The next segment (417 residues) contains three **epidermal growth factor repeats**, as well as a **β -propeller** module. This is followed in the sequence by a 58-residue segment of O-linked oligosaccharides, a 22-residue membrane-spanning segment, and a 50-residue segment extending into the cytosol. The clustering of receptors prior to the formation of coated vesicles requires the presence of this cytosolic segment. Note that the LDL particle binds specifically to the receptor at the fourth and fifth cysteine-rich repeats (R4 and R5).

Figure 24.40 The structure of the LDL receptor. The amino-terminal binding domain is responsible for recognition and binding of LDL apoprotein. The B-100 apolipoprotein of the LDL particle is presumed to bind to the fourth and fifth cysteine-rich repeats (R4 and R5). The O-linked oligosaccharide-rich domain may act as a molecular spacer, raising the binding domain above the glycocalyx. The cytosolic domain is required for aggregation of LDL receptors during endocytosis.

Figure 24.39 shows the release of LDL particles in endosomes that pinch off from the plasma membrane when cells take up LDLs. What molecular events trigger the release of LDL particles? A collaboration by three Nobel laureates has provided an answer. Johann Deisenhofer, Michael Brown, and Joseph Goldstein determined the structure of the extracellular domain of the LDL receptor at pH 5.3, the typical pH inside endosomes. At this low pH, the receptor polypeptide is folded back on itself, with the β -propellor domain associated with R4 and R5, the two repeats that normally bind the LDL particle (Figure 24.41). The implication is that the β -propellor displaces the LDL particle in the lower pH environment of the endosome. What residues at the interface between the propellor and the R4 and R5 repeats act as the pH sensors? Three histidines at the propellor–R4/R5 interface—His¹⁹⁰, His⁵⁶², and His⁵⁸⁶—are the likely pH-sensing residues. His¹⁹⁰ lies at the tip of a loop on R5, whereas His⁵⁶² and His⁵⁸⁶ are on the surface of the propellor domain (Figure 24.41). These three His residues form a cluster at the three-way junction between R4, R5, and the β -propellor.

24.5d Defects in Lipoprotein Metabolism Can Lead to Elevated Serum Cholesterol

The mechanism of LDL metabolism and the various defects that can occur therein have been studied extensively by Brown and Goldstein. **Familial hypercholesterolemia** is the term given to a variety of inherited metabolic defects that lead to greatly elevated levels of serum cholesterol, much of it in the form of LDL particles. The general genetic defect responsible for familial hypercholesterolemia is the absence or dysfunction of LDL receptors in the body. Only about half the normal level of LDL receptors is found in heterozygous individuals (persons carrying one normal gene and one defective gene). Homozygotes (with two copies of the defective gene) have few, if any, functional LDL receptors. In such cases, LDLs (and cholesterol) cannot be absorbed, and plasma levels of LDL (and cholesterol) are very high. Typical heterozygotes display serum cholesterol levels of 300 to 400 mg/dL, but homozygotes carry serum cholesterol levels of 600 to 800 mg/dL or even higher. There are two possible causes of an absence of LDL receptors—either receptor synthesis does not occur at all, or the newly synthesized protein does not successfully reach the plasma membrane due to faulty processing in the Golgi or faulty transport to the plasma membrane. Even when LDL receptors are made and reach the plasma membrane, they may fail to function for two reasons. They may be unable to form clusters competent in coated pit formation because of folding or sequence anomalies in the carboxy-terminal domain, or they may be unable to bind LDL because of sequence or folding anomalies in the LDL-binding domain.

Figure 24.41 The β -propellor domain of the LDL receptor displaces LDL particles in endosomes. (a) The cysteine-rich repeats R4 and R5 are the site of LDL particle binding. Each repeat contains two loops connected by three disulfide bonds. The second loop in each repeat carries acidic residues (Asp and Glu) and forms a Ca^{2+} -binding site. (b) The β -propellor domain of the LDL receptor. (c) The structure of the LDL receptor extracellular domain at pH 5.3 (similar to that found in endosomes). The β -propellor domain is associated with cysteine-rich domains R4 and R5. A cluster of histidines (His¹⁹⁰, His⁵⁶², and His⁵⁸⁶) and a variety of hydrophobic and charged interactions mediate the association (PDB id = 1N7D).

Human Biochemistry

New Cholesterol-Lowering Drugs Target PCSK9, an LDL Receptor Chaperone

Michael Brown and Joseph Goldstein (recipients of the Nobel Prize in Physiology or Medicine, 1985) established the genetic connection between LDL and heart attacks, showing that loss-of-function mutations in LDL receptors raise serum LDL and increase the risk

of heart attacks. The opposite correlation—that mutations that increase LDL receptor function will lower serum LDL and protect against coronary heart disease and heart attacks—also turns out to be true. These latter mutations occur in a gene that encodes a protein called PCSK9 (for proprotein convertase subtilisin/kexin type 9) that is secreted into the circulation by liver and other organs. PCSK9 binds to liver LDL receptors (LDLRs) and disrupts the recycling mechanism that normally returns the receptors to the cell surface after internalization (Figure 24.39). Thus, the normal function of PCSK9 results in a decrease in the number of LDL receptors and an increase in serum LDL.

Interestingly, PCSK9 is a zymogen precursor that undergoes autocatalytic cleavage, leaving an N-terminal prodomain (see figure) tightly bound in its active site. Although the prodomain is required for proper folding of the rest of the protein, it renders the protease domain inactive. Once secreted from the liver cell, PCSK9 acts as a molecular chaperone that binds to LDL receptors on the cell surface. That is, PCSK9 does not function as an enzyme; it acts as a chaperone! The PCSK9-LDLR complex is taken up by liver cells and directed to lysosomes and degraded.

The function of PCSK9 suggested a novel cholesterol-lowering strategy: If the levels of LDL receptors could be raised, more LDL would be taken from the blood, lowering serum levels of cholesterol. Two new PCSK9 inhibitors have received Food and Drug Administration (FDA) approval as drugs. Both are monoclonal antibodies against PCSK9 (*Praluent* from Sanofi and *Repatha* from Amgen). They attach to PCSK9, preventing it from binding to LDL receptors, thus aborting its role as a chaperone that targets LDL receptors for destruction in the lysosome.

PCSK9 is a 692-residue protein consisting of an N-terminal prodomain, a catalytic domain (residues 153–447) and a C-terminal domain composed of three β -sandwich folds. Autocatalytic cleavage between Gln-152 and Ser-153 leaves the prodomain tightly bound (PDB id = 2PMW). Thr-61 marks the beginning of the inhibitory prodomain.

24.6 | How Are Bile Acids Biosynthesized?

Bile acids, which exist mainly as **bile salts**, are polar carboxylic acid derivatives of cholesterol that are important in the digestion of food, especially the solubilization of ingested fats. The Na^+ and K^+ salts of *glycocholic acid* and *taurocholic acid* are the principal bile salts (Figure 24.42). Glycocholate and taurocholate are conjugates of *cholic acid* with glycine and taurine, respectively. Because they contain both nonpolar and polar domains, these bile salt conjugates are highly effective as detergents. These substances are made in the liver, stored in the gallbladder, and secreted as needed into the intestines.

The formation of bile salts represents the major pathway for cholesterol degradation. The first step involves hydroxylation at C-7 (Figure 24.42). **7 α -Hydroxylase**, which catalyzes the reaction, is a mixed-function oxidase involving *cytochrome P-450*. **Mixed-function oxidases** use O_2 as substrate. One oxygen atom goes to hydroxylate the substrate while the other is reduced to water (Figure 24.43). The function of cytochrome P-450 is to activate O_2 for the hydroxylation reaction. Such hydroxylations are quite common in the synthetic routes for cholesterol, bile acids, and steroid hormones and also in detoxification pathways for aromatic compounds. Several of

Human Biochemistry

Niemann-Pick Type C Disease—A Hydrophobic Handoff Fumbled

Niemann-Pick type C (NPC) is a lipid storage disease that causes a variety of neurological symptoms and arises from abnormal accumulation of cholesterol and other lipids in the lysosomes of cells in the liver, spleen, and brain. In most cases, neurological symptoms begin appearing between the ages of 4 and 10. NPC is always fatal. Although it occurs in all races and populations, a higher incidence of NPC occurs among Ashkenazi Jews, French Canadians in Nova Scotia, Maghrebs in northern Africa, and Hispanic people in New Mexico and Colorado.

Nearly all cases of NPC are caused by mutations in the genes for two proteins, termed NPC1 and NPC2. NPC2 is a soluble protein in the lysosomal lumen. NPC1 is a lysosomal membrane protein containing three luminal domains—an N-terminal domain (NTD), a middle luminal domain (MLD), a C-terminal domain (CTD) and a transmembrane domain (TM). The transmembrane domain includes a sterol-sensing domain (SSD) that is highly conserved in membrane proteins involved in cholesterol metabolism. Cryo-EM studies of the NPC1–NPC2 complex at pH 5.5 (the pH of the lysosomal lumen)

reveal a central tunnel that is enclosed by the MLD and CTD domains and that connects the luminal domains to the SSD. The luminal end of the tunnel opens to the NTD and the rest traverses through the interface between the MLD and CTD domains, all the way down to the membrane-facing surface of the sterol-sensing domain. Cholesterol binds to NPC2 with its 8-carbon side chain buried within a hydrophobic binding pocket and the 3β -hydroxyl group exposed on the surface (see figure). In contrast, NPC1 binds cholesterol in the opposite orientation, with the 3β -hydroxyl deep in the binding site and the side chain partially exposed.

Brown and Goldstein have proposed a hydrophobic handoff model for the interaction of NPC1 and NPC2 that enables cholesterol transfer between these proteins and that is essential for export of cholesterol from the lysosomes. Structural studies suggest a K-turn trajectory for cholesterol delivery. Much resembling a K-turn for steering a vehicle, cholesterol first binds NPC2 exposing its hydroxyl end, reverses into NPC1(NTD), and eventually enters the central tunnel with the hydrophobic side facing the membrane.

The hydrophobic handoff of cholesterol from NPC2 to NPC1. A conformation change in NTD transfers cholesterol to the tunnel of the SSD and then to the cytosol. Adapted from Qian, H., et al., 2020. Structural basis of low-pH-dependent lysosomal cholesterol egress by NPC1 and NPC2. *Cell* **182**:98–111.

Structure of the NPC1–NPC2 complex NPC1 is gold. NPC2 is aqua. Cholesterol is shown in gray. (PDB id = 6W5V).

Figure 24.42 Cholic acid, a bile salt, is synthesized from cholesterol via 7 α -hydroxycholesterol. Conjugation with taurine or glycine produces taurocholic acid and glycocholic acid, respectively. Taurocholate and glycocholate are freely water soluble and are highly effective detergents.

Human Biochemistry

Steroid 5 α -Reductase—A Factor in Male Baldness, Prostatic Hyperplasia, and Prostate Cancer

An enzyme that metabolizes testosterone may be involved in the benign conditions of male-pattern baldness (also known as *androgenic alopecia*) and benign prostatic hyperplasia (prostate gland enlargement), as well as potentially fatal prostate cancers. Steroid 5 α -reductases are membrane-bound enzymes that catalyze the NADPH-dependent reduction of testosterone to dihydrotestosterone (DHT) (see accompanying figure). Two isoforms of 5 α -reductase have been identified. In humans, the

type I enzyme predominates in the sebaceous glands of skin and liver, whereas type II is most abundant in the prostate, seminal vesicles, liver, and epididymis. DHT is a contributory factor in male baldness and prostatic hyperplasia, and it has also been shown to act as a mitogen (a stimulator of cell division). For these reasons, 5 α -reductase inhibitors are potential candidates for treatment of these human conditions.

Finasteride (see figure) is a specific inhibitor of type II 5 α -reductase. It has been used clinically for treatment of benign prostatic hyperplasia, and it is also marketed under the trade name Propecia by Merck as a treatment for male baldness. Type II 5 α -reductase inhibitors may also be potential therapeutic agents for treatment of prostate cancer. Somatic mutations occur in the gene for type II 5 α -reductase during prostate cancer progression.

Because type I 5 α -reductase is the predominant form of the enzyme in human scalp, the mechanism of finasteride's promotion of hair growth in men with androgenic alopecia has been uncertain. However, scientists at Merck have shown that, whereas type I 5 α -reductase predominates in sebaceous ducts of the skin, type II 5 α -reductase is the only form of the enzyme present in hair follicles. Thus, finasteride's therapeutic effects may arise from inhibition of the type II enzyme in the hair follicle itself.

Figure 24.43 The mixed-function oxidase activity of 7 α -hydroxylase.

these are considered in the next section. 7 α -Hydroxycholesterol is the precursor for cholic acid. Conjugation with taurine or glycine converts cholic acid to taurocholic and glycocholic acids, respectively.

24.7 | How Are Steroid Hormones Synthesized and Utilized?

Steroid hormones are crucial signal molecules in mammals, controlling metabolism, salt balance, and sexual function. Their biosynthesis begins with the **desmolase** reaction, which converts cholesterol to pregnenolone (Figure 24.44). Desmolase is found in the mitochondria of tissues that synthesize steroids (mainly the adrenal glands and gonads). Desmolase activity includes two hydroxylases and utilizes cytochrome P-450.

Steroid hormones act in a different manner from most hormones we have considered. In many cases, they do not bind to plasma membrane receptors but rather pass easily across the plasma membrane. Steroids may bind directly to receptors in the nucleus or cytosolic steroid hormone receptors, which then enter the nucleus. In the nucleus, the hormone–receptor complex binds directly to specific nucleotide sequences in DNA, increasing transcription of DNA to RNA.

24.7a Pregnenolone and Progesterone Are the Precursors of All Other Steroid Hormones

Pregnenolone is transported from the mitochondria to the ER, where a hydroxyl oxidation and migration of the double bond yield progesterone. Pregnenolone synthesis in the adrenal cortex is activated by **adrenocorticotrophic hormone** (ACTH), a peptide of 39 amino acid residues secreted by the anterior pituitary gland.

Progesterone is secreted from the corpus luteum during the latter half of the menstrual cycle and prepares the lining of the uterus for attachment of a fertilized ovum. If an ovum attaches, progesterone secretion continues to ensure the successful maintenance of a pregnancy. Progesterone is also the precursor for synthesis of the other **sex hormone steroids** and the **corticosteroids**. Male sex hormone steroids are called **androgens**, and female hormones, **estrogens**. Testosterone is an androgen synthesized in males primarily in the testes (and in much smaller amounts in the adrenal cortex). Androgens are necessary for sperm maturation. Even nongonadal tissue (liver, brain, and skeletal muscle) is susceptible to the effects of androgens.

Testosterone is also produced in the ovaries (and in much smaller amounts in the adrenal glands) of females as a precursor for the estrogens. β -Estradiol is the most prominent estrogen (Figure 24.44).

24.7b Cortisol and Other Corticosteroids Regulate a Variety of Body Processes

Corticosteroids, including the *glucocorticoids* and *mineralocorticoids*, are made by the cortex of the adrenal glands on top of the kidneys. **Cortisol** (Figure 24.44) is representative of the **glucocorticoids**, a class of compounds that (1) stimulate gluconeogenesis and glycogen synthesis in liver (by promoting the synthesis of PEP carboxykinase, fructose-1,6-bisphosphatase, glucose-6-phosphatase, and glycogen synthase); (2) inhibit protein synthesis and stimulate protein degradation in peripheral tissues such as muscle; (3) inhibit allergic and inflammatory responses; (4) exert an immunosuppressive effect, inhibiting DNA replication and mitosis as well as repressing the formation of antibodies and lymphocytes; and (5) inhibit formation of fibroblasts involved in healing wounds and slow the healing of broken bones.

Figure 24.44 The steroid hormones are synthesized from cholesterol, with intermediate formation of pregnenolone and progesterone. Testosterone, the principal male sex hormone steroid, is a precursor to β -estradiol. Cortisol, a glucocorticoid, and aldosterone, a mineralocorticoid, are also derived from progesterone.

Aldosterone, the most potent of the **mineralocorticoids** (Figure 24.44), is involved in the regulation of sodium and potassium balances in tissues. Aldosterone increases the kidney's capacity to absorb Na^+ , Cl^- , and H_2O from the glomerular filtrate in the kidney tubules.

The dramatic effects of androgens on protein biosynthesis have led many athletes to use *synthetic androgens*, which go by the blanket term **anabolic steroids**. Despite numerous warnings from the medical community about side effects, which include kidney and liver disorders, sterility, and heart disease, abuse of such substances is epidemic. **Stanozolol** (Figure 24.45) was one of the agents found in the blood and urine of Ben Johnson following his record-setting performance in the 100-meter dash in the 1988 Olympic Games. Because use of such substances is disallowed, Johnson lost his gold medal and Carl Lewis was declared the official winner.

Figure 24.45 The structure of stanozolol, an anabolic steroid.

Foundational Biochemistry Things You Should Know after Reading Chapter 24.

- Formation of malonyl-CoA activates acetate units for fatty acid synthesis.
- Fatty acid biosynthesis depends on the reductive power of NADPH.
- The citrate–malate–pyruvate shuttle provides cytosolic acetate units and reducing equivalents for fatty acid synthesis.
- Acetate units are committed to fatty acid synthesis by formation of malonyl-CoA.
- Acetyl-CoA carboxylase is biotin dependent and displays ping-pong kinetics.
- Acetyl-CoA carboxylase in animals is a multifunctional protein.
- Phosphorylation of ACC modulates activation by citrate and inhibition by palmitoyl-CoA.
- Acyl carrier proteins carry the intermediates in fatty acid synthesis.
- Fatty acid synthesis takes place in multienzyme complexes in some organisms.
- Decarboxylation drives the condensation of acetyl-CoA and malonyl-CoA in fatty acid synthesis.
- Reduction of the β -carbonyl group of a newly added acetate unit in fatty acid synthesis proceeds via reduction to a hydroxyl group, dehydration to form a double bond, and reduction of the double bond to form a single bond.
- The multiple enzyme domains of eukaryotic fatty acid synthases are arrayed on large protein structures termed megasynthases.
- Palmitate is the primary product of the fatty acid synthase. Longer chains are made through special elongation reactions, both in mitochondria and on the surface of the endoplasmic reticulum.
- Unsaturation reactions occur in eukaryotes in the middle of an aliphatic chain.
- Mammals cannot synthesize most polyunsaturated fatty acids, but arachidonic acid is synthesized from linoleic acid.
- Glucagon and insulin regulate acetyl-CoA carboxylase and fatty acid biosynthesis. Fatty acid synthesis is regulated by allosteric effectors, hormones, and phosphorylation/dephosphorylation.
- Glycerolipids are synthesized by phosphorylation and acylation of glycerol.
- Eukaryotes synthesize glycerolipids from CDP-diacylglycerol or diacylglycerol.
- Phosphatidylethanolamine is synthesized from diacylglycerol and CDP-ethanolamine.
- Exchange of ethanolamine for serine converts phosphatidylethanolamine to phosphatidylserine.
- CDP-diacylglycerol is the precursor for phosphatidylinositol, phosphatidylglycerol and diphosphatidylglycerol (cardiolipin).
- Sphingolipid biosynthesis begins with condensation of serine and palmitoyl-CoA, forming ceramides in four steps. Ceramides are the precursors for other sphingolipids and cerebroside.
- Eicosanoids, including prostaglandins, thromboxanes, and leukotrienes, are derived from arachidonic acid.
- Aspirin and the NSAIDs are inhibitors of the cyclooxygenase that is the first step in the conversion of arachidonic acid to the eicosanoids that facilitate inflammation.
- Cholesterol synthesis begins with formation of mevalonate from acetyl-CoA via the HMG-CoA synthase and HMG-CoA reductase reactions.
- Squalene is synthesized from mevalonate. Cyclization of squalene yields lanosterol, and cholesterol is formed after 20 steps from lanosterol.
- Most lipids, including phospholipids, triacylglycerols, cholesterol, and cholesterol esters, circulate in the body in the form of lipoprotein complexes.
- Lipoproteins are progressively degraded by lipoprotein lipases, converting chylomicrons to VLDLs, then to IDLs and LDLs, which are taken up by LDL receptors in the liver or redirected to adipose tissues and adrenal glands.
- HDLs function to return cholesterol and cholesterol esters to the liver.
- Defects in lipoprotein metabolism can lead to elevated serum cholesterol and resultant cardiovascular damage.
- Bile acids are synthesized via hydroxylation of cholesterol and subsequent steps that form cholic acid, taurocholic acid, and glycocholic acid.
- Pregnenolone and progesterone are the precursors of all other steroid hormones, including testosterone, estradiol, cortisol, and aldosterone.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. Explaining the Stoichiometry of Fatty Acid Synthesis** Carefully count and account for each of the atoms (that is, explain where each one comes from) and charges in the equations for the synthesis of palmitoyl-CoA, the synthesis of malonyl-CoA, and the overall reaction for the synthesis of palmitoyl-CoA from acetyl-CoA.
- 2. Tracing Carbon Atom Incorporation in Fatty Acids** (Integrates with Chapters 18 and 19.) Use the relationships shown in Figure 24.1 to determine which carbons of glucose will be incorporated into palmitic acid. Consider the cases of both citrate that is immediately exported to the cytosol following its synthesis and citrate that enters the TCA cycle.
- 3. Modeling the Regulation of Acetyl-CoA Carboxylase** Based on the information presented in the text and in Figures 24.4 and 24.5, suggest a model for the regulation of acetyl-CoA carboxylase.
- 4. Mechanism of Acetyl-CoA Carboxylase** (Integrates with Chapter 19.) What part of the enzyme mechanism is similar between citrate synthase (see Chapter 19) and acetyl-CoA carboxylase?
- 5. Estimating Active Site Separation in Animal Fatty Acid Synthase** Consider the role of the pantothenic acid groups in animal FAS and the size of the pantothenic acid group itself, and estimate a maximal separation between the malonyl transferase and the β -ketoacyl-ACP synthase active sites.
- 6. Assessing the Stoichiometry of Stearoyl-CoA Desaturase** Carefully study the reaction mechanism for the stearoyl-CoA desaturase in Figure 24.14, and account for all of the electrons flowing through the reactions shown. Also account for all of the hydrogen and oxygen atoms involved in this reaction, and convince yourself that the stoichiometry is correct as shown.

7. **Hormonal Regulation of Fatty Acid Biosynthesis** Glucagon and insulin are hormones released when blood glucose levels are low or high, respectively. Why does it make biochemical sense that glucagon inhibits and insulin activates fatty acid biosynthesis? (Hint: see Figure 24.17.)
8. **Understanding the Stoichiometry of Glycerophospholipid Synthesis** Write a balanced, stoichiometric reaction for the synthesis of phosphatidylethanolamine from glycerol, fatty acyl-CoA, and ethanolamine. Make an estimate of the ΔG° for the overall process.
9. **Triglyceride Biosynthesis and Glycolysis** Describe two biochemical links between the biosynthesis of triacylglycerides and the glycolysis pathway.
10. **Understanding the Stoichiometry of Cholesterol Synthesis** Write a balanced, stoichiometric reaction for the synthesis of cholesterol from acetyl-CoA.
11. **Unspecific Squalene Monooxygenase and Squalene Epoxide** Imagine the possibility that the squalene monooxygenase enzyme is not very specific and that it oxidized a different bond in squalene, as indicated in the figure. What could be the reaction products after the action of monooxygenase and cyclase (see Figure 24.35)?

12. **Tracing Carbon Atom Incorporation in Cholesterol** Trace each of the carbon atoms of mevalonate through the synthesis of cholesterol, and determine the source (that is, the position in the mevalonate structure) of each carbon in the final structure.
13. **Understanding the Functional Role of O-linked Oligosaccharides in the LDL Receptor** Suggest a structural or functional role for the O-linked saccharide domain in the LDL receptor (Figure 24.40).
14. **Assessing the Consequences of Low Cellular Levels of CTP** Identify the lipid synthetic pathways that would be affected by abnormally low levels of CTP.
15. **Determining the ATP Requirements for Fatty Acid Synthesis** Determine the number of ATP equivalents needed to form palmitic acid from acetyl-CoA. (Assume for this calculation that each NADPH is worth 3.5 ATPs.)
16. **Understanding the Mechanism of the 3-Ketosphinganine Synthase Reaction** Write a reasonable mechanism for the 3-ketosphinganine synthase reaction, remembering that it is a pyridoxal phosphate-dependent reaction.
17. **Understanding the Involvement of FAD in the Conversion of Stearic Acid to Oleic Acid** Why is the involvement of FAD important in the conversion of stearic acid to oleic acid?
18. **Understanding the Mechanism of the HMG-CoA Synthase Reaction** Write a suitable mechanism for the HMG-CoA synthase reaction. What is the chemistry that drives this condensation reaction?
19. **Understanding the Mechanism of the β -Ketoacyl-ACP Synthase Reaction** Write a suitable reaction mechanism for the β -ketoacyl-ACP synthase, showing how the involvement of malonyl-CoA drives this reaction forward.
20. **Studying the Structure of the Fatty Acyl Synthase** In the FAS megasynthase structures, the multiple functional sites must lie within reach of the ACP and its bound acyl group substrates. Examine the mammalian FAS structure (see Figure 24.11), and determine the distances between the various functional sites. You could approach this problem either by using a molecular modeling program (such as PyMol at www.pymol.org) or by consulting appropriate references (the following end-of-chapter reference is a good place to start: Maier, T., Leibundgut, M., and Ban, N., 2008. *Science* **321**:1315–1322). Present quantitative evidence that the intersite distances can be traversed appropriately by the ACP group.
21. **Modeling the LDL Receptor** In the LDL receptor structure shown in Figure 24.41c, the β -propeller interaction with domains R4 and R5 is partly stabilized by salt bridges between acidic residues on R4 and R5 that also coordinate Ca^{2+} ions. Use a molecular modeling program or consult the literature to identify at least two such interactions. Two suitable references are Beglova, N., and Blacklow, S. C., 2005. *Trends in Biochemical Sciences* **30**:309–316; and Rudenko, G., Henry, L., et al., 2002. *Science* **298**:2353–2358.
22. **Understanding the Function of the LDL Receptor** Insights into the function of LDL receptors in displacing LDL particles in endosomes have come from an unlikely source: a study of LDL receptor binding by a human rhinovirus HRV2 (a common cold virus). Consult suitable references to learn how this study provided support for the model of LDL particle displacement presented in this chapter. Good references are Blacklow, S. C., 2004. *Nature Structural and Molecular Biology* **11**:388–390; Verdager, N., et al., 2004. *Nature Structural and Molecular Biology* **11**:429–434; and Beglova, N., and Blacklow, S. C., 2005. *Trends in Biochemical Sciences* **30**:309–316.
23. **Detoxification of Oxygen** (Integrates with Chapter 23.) An argument can be made that aerobic biochemistry is nothing more than the catalytic conversion of oxygen, an aggressive oxidizing agent, into harmless water. Which aspects of fatty acid biochemistry support this point of view (apart from their contribution to driving the electron transport/oxidative phosphorylation)? Describe one involvement of fatty acids in the detoxification of oxygen from Chapter 23 and this chapter.
24. Hibernating bears such as grizzlies undergo seasonal metabolic stresses. During late summer, grizzlies gorge, consuming more than 50,000 kilocalories of food and gaining up to 16 pounds every day. Then, hibernating for up to 7 months, they subsist solely on stored body fat, without eating, drinking, urinating, or defecating. What might be the biochemical consequences of these dietary and metabolic changes? What signaling pathways and regulations might be involved? When you have composed your answer, consult the following reference to see how your ideas compare with the research presented: Nelson, O. L., Jansen, H. T., Galbreath, E., et al., 2014. Grizzly bears exhibit augmented insulin sensitivity while obese prior to a reversible insulin resistance during hibernation. *Cell Metabolism* **20**:376–382.
25. Most populations of phospholipids in cell membranes exhibit enrichment in particular fatty acids. For example, the phosphatidylinositol in mammalian membranes is predominantly 1-stearoyl-2-archidonoyl phosphatidylinositol. Assuming that this enrichment occurs after incorporation of PI into the membrane, propose a series of steps or a cycle of reactions that could achieve this enrichment. When you have constructed your model, consult the following reference to see how your model compares with the research presented: Epand, R. M., 2015. Enrichment of acyl chains in the lipids of the phosphatidylinositol cycle. *ASBMB Today* **14**:16–17.
26. **Comparing the Reaction of Fatty Acid Synthesis and the Tricarboxylic Acid Cycle** Consider the synthesis of linoleic acid from palmitic acid, and identify a series of three consecutive reactions that exhibit chemistry similar to three reactions in the tricarboxylic acid cycle.
27. **Writing an Equation to Describe the Synthesis of Behenic Acid** Rewrite the equation in Section 24.1 to describe the synthesis of behenic acid (see Table 8.1).

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

28. Using the PSafe structure for Niemann-Pick C1, describe the structure of the sterol-binding pocket, and explain the interaction involved in cholesterol binding.
29. Using the PSafe structure for HMG-CoA reductase (HMGR), explain how HMGR is regulated. Why do researchers seek ways to inhibit HMGR?
30. Using the PSafe structure for cyclooxygenase-2, explain the mechanisms by which NSAIDs inhibit this enzyme. Discuss several examples.

Think-Pair-Share Question

Imagine yourself as a researcher at a pharmaceutical company. You have been tasked with the development of a drug that could lower triacylglyceride storage in the adipose tissues. Focusing only on triacylglyceride or fatty acid biochemistry (discussed in Chapters 22, 23, or 24), which enzymes, receptors, pathways, or processes could you suggest as potential targets for pharmacological intervention? List at least six possible targets. (Hint: Recall that enzymes can be activated or inhibited; receptors can be stimulated or blocked.)

Nitrogen Acquisition and Amino Acid Metabolism

25

I was determined to know beans.

Henry David Thoreau (1817–1862)
The Writings of Henry David Thoreau, vol. 2,
p. 178, Houghton Mifflin (1906)

David Frazier/Flame/Corbis

- Only plants and certain microorganisms are able to transform the oxidized, inorganic forms of nitrogen available in the inanimate environment into reduced, biologically useful forms. Soybean plants can meet their nitrogen requirements both by assimilating nitrate and, in symbiosis with bacteria, fixing N_2 .

Essential Question

Nitrogen is an essential nutrient for all cells. Amino acids provide nitrogen for the synthesis of other nitrogen-containing biomolecules. Excess amino acids in the diet can be converted into α -keto acids and used for energy production. **What are the biochemical pathways that form ammonium from inorganic nitrogen compounds prevalent in the inanimate environment? How is ammonium incorporated into organic compounds? How are amino acids synthesized and degraded?**

Amino acids and nucleotides, as well as their polymeric forms (proteins and nucleic acids), are nitrogen-containing molecules upon which cell structure and function rely. In these compounds, the nitrogen atoms are typically bound to carbon and hydrogen atoms. That is, the nitrogen atom is in a reduced state. On the other hand, the prevalent forms of nitrogen in the environment are inorganic and oxidized, N_2 (dinitrogen gas) and NO_3^- (nitrate ions) being the most abundant species. The two principal routes for nitrogen acquisition from the inanimate environment, nitrate assimilation and nitrogen fixation, lead to formation of ammonium ions (NH_4^+). Reactions that incorporate NH_4^+ into organic linkage (the reactions of ammonium assimilation) are few, but they serve as the source of N atoms for all biologically significant nitrogen-containing molecules. Among these, glutamine synthetase merits particular attention because it conveys several important lessons in metabolic regulation. This chapter presents the pathways of amino acid biosynthesis and degradation; those involving the sulfur-containing amino acids provide an opportunity to introduce aspects of sulfur metabolism.

25.1 Which Metabolic Pathways Allow Organisms to Live on Inorganic Forms of Nitrogen?

The prevalent forms of inorganic nitrogen in the environment can be interconverted through oxidation–reduction reactions carried out by organisms exploiting them to meet their particular metabolic needs. Collectively, these reactions constitute a

Key Questions

- 25.1 Which Metabolic Pathways Allow Organisms to Live on Inorganic Forms of Nitrogen?
- 25.2 What Is the Metabolic Fate of Ammonium?
- 25.3 What Regulatory Mechanisms Act on *Escherichia coli* Glutamine Synthetase?
- 25.4 How Do Organisms Synthesize Amino Acids?
- 25.5 How Does Amino Acid Catabolism Lead into Pathways of Energy Production?

nitrogen cycle. Ammonium ions, the most reduced of these substances, is the precursor to virtually all N-containing biological molecules.

25.1a Nitrogen Is Cycled between Organisms and the Inanimate Environment

Nitrogen acquisition by biological systems is accompanied by its reduction to ammonium ion (NH_4^+) and the incorporation of NH_4^+ into organic linkage as amino or amido groups (Figure 25.1). The reduction of NO_3^- to NH_4^+ occurs in green plants, various fungi, and certain bacteria in a two-step metabolic pathway known as **nitrate assimilation**. The formation of NH_4^+ from N_2 gas is termed **nitrogen fixation**. N_2 fixation is an exclusively prokaryotic process, although bacteria in symbiotic association with certain green plants also carry out nitrogen fixation. No animals are capable of either nitrogen fixation or nitrate assimilation, so they are totally dependent on plants and microorganisms for the synthesis of organic nitrogenous compounds, such as amino acids and proteins, to satisfy their requirements for this essential element.

Animals release excess nitrogen in a reduced form, either as NH_4^+ or as organic nitrogenous compounds such as urea. The release of N occurs both during life and as a consequence of microbial decomposition following death. Various bacteria return the reduced forms of nitrogen back to the environment by oxidizing them. The oxidation of NH_4^+ to NO_3^- by **nitrifying bacteria**, a group of chemoautotrophs, provides the sole source of chemical energy for the life of these microbes. Nitrate nitrogen also returns to the atmosphere as N_2 as a result of the metabolic activity of **denitrifying bacteria**. These bacteria are capable of using NO_3^- and similar oxidized, inorganic forms of nitrogen as electron acceptors in place of O_2 in oxidative phosphorylation pathways. The NO_3^- is reduced ultimately to *dinitrogen* (N_2). These bacteria thus deplete the levels of *combined nitrogen*, that is, N joined with other elements in chemical compounds. Combined nitrogen is important as natural fertilizer. However, the denitrifying activity of bacteria is exploited in water treatment plants to reduce the load of combined nitrogen that might otherwise enter lakes, streams, and bays.

25.1b Nitrate Assimilation Is the Principal Pathway for Ammonium Biosynthesis

Nitrate assimilation occurs in two steps: the two-electron reduction of nitrate to nitrite, catalyzed by **nitrate reductase** (Equation 25.1), followed by the six-electron reduction of nitrite to ammonium, catalyzed by **nitrite reductase** (Equation 25.2).

Nitrate assimilation is the predominant means by which green plants, algae, and many microorganisms acquire nitrogen. The pathway of nitrate assimilation accounts for more than 99% of the inorganic nitrogen (nitrate or N_2) assimilated into organisms.

Corn nitrate reductase cytochrome domain (FAD shown in yellow) (PDB id = 1CNE)

Fungal nitrate reductase molybdenum cofactor domain (Mo cofactor in gold) (PDB id = 2BIH)

Nitrate reductase has two structural domains, the cytochrome *b* domain (*top*) and the molybdenum cofactor domain (*bottom*).

Figure 25.1 The nitrogen cycle. Organic nitrogenous compounds are formed by the incorporation of NH_4^+ into carbon skeletons. Note that denitrification and nitrogen fixation are anaerobic processes.

Nitrate Reductase Contains Cytochrome b_{557} and Molybdenum Cofactor

A pair of electrons is transferred from NADH via enzyme-associated sulfhydryl groups, FAD, cytochrome b_{557} , and **MoCo** (an essential molybdenum-containing cofactor) to nitrate, reducing it to nitrite. The brackets [] denote the protein-bound prosthetic groups that constitute an e^- transport chain between NADH and nitrate. Nitrate reductases typically are cytosolic 220 kDa dimeric proteins. The structure of the molybdenum cofactor (MoCo) is shown in Figure 25.2a. Molybdenum cofactor is necessary for both nitrate reductase activity and the assembly of nitrate reductase subunits into the active dimeric holoenzyme form. Molybdenum cofactor is also an essential cofactor for a variety of enzymes that catalyze hydroxylase-type reactions, including xanthine dehydrogenase, aldehyde oxidase, and sulfite oxidase.

Nitrite Reductase Contains Siroheme Six electrons are required to reduce NO_2^- to NH_4^+ . Nitrite reductases in photosynthetic organisms obtain these electrons from six molecules of photosynthetically reduced ferredoxin (Fd_{red}).

Photosynthetic nitrite reductases are 63 kDa monomeric proteins having a tetranuclear iron–sulfur cluster and a novel heme, termed **siroheme**, as prosthetic groups. The $[4\text{Fe-4S}]$ cluster and the siroheme act as a coupled e^- transfer center. Nitrite binds directly to siroheme, providing the sixth ligand, much as O_2 binds to the heme of hemoglobin. Nitrite is reduced to ammonium while liganded to siroheme. The structure of siroheme is shown in Figure 25.2b.

Spinach nitrate reductase (iron–sulfur cluster in *gold*, siroheme in *red*) (PDB id = 2AKJ)

Figure 25.2 The novel prosthetic groups of nitrate reductase and nitrite reductase. **(a)** The molybdenum cofactor of nitrate reductase. The fifth ligand for the Mo atom is the sulfur atom of a conserved cysteine residue in the nitrate reductase. The Mo cofactor is a pyranopterin ring system: To form a pterin, a pyrimidine ring (*left*) is fused with a piperazine ring (*center* [a piperazine ring is a six-membered ring, with two nitrogens directly opposite from one another]). Adding a pyran ring (*right* [a pyran ring contains one oxygen and five carbon atoms]) to the pterin yields a pyranopterin. **(b)** Siroheme, an essential prosthetic group of nitrite reductase. Siroheme is novel among hemes in having eight carboxylate-containing side chains. These carboxylate groups may act as H^+ donors during the reduction of NO_2^- to NH_4^+ .

Figure 25.3 Domain organization within the enzymes of nitrate assimilation. The numbers denote residue number along the amino acid sequence of the proteins.

In higher plants, nitrite reductase is found in chloroplasts, where it has ready access to its primary reductant, photosynthetically reduced ferredoxin. Microbial nitrite reductases closely resemble nitrate reductases in having essential —SH groups and FAD prosthetic groups to couple enzyme-mediated NADPH oxidation to nitrite reduction (Figure 25.3).

25.1c Organisms Gain Access to Atmospheric N₂ via the Pathway of Nitrogen Fixation

Nitrogen fixation involves the reduction of nitrogen gas (N₂) via an enzyme system found only in prokaryotic cells. The heart of the nitrogen fixation process is the enzyme known as **nitrogenase**, which catalyzes the reaction

Note that an obligatory reduction of two protons to hydrogen gas accompanies the biological reduction of N₂ to ammonia. Less than 1% of the inorganic N incorporated into organic compounds by organisms can be attributed to nitrogen fixation; however, this process is the only way that organisms can tap into the enormous reservoir of N₂ in the atmosphere.

Although nitrogen fixation is exclusively prokaryotic, N₂-fixing bacteria may be either free living or living as symbionts with higher plants. For example, *Rhizobia* are bacteria that fix nitrogen in symbiotic association with soybeans and other leguminous plants. Because nitrogen in a metabolically useful form is often the limiting nutrient for plant growth, such symbiotic associations can be an important factor in plant productivity.

Despite the wide diversity of bacteria in which nitrogen fixation takes place, all N₂-fixing systems are nearly identical and all have four fundamental requirements: (1) the enzyme *nitrogenase*; (2) a strong reductant, such as reduced ferredoxin; (3) ATP; and (4) O₂-free conditions. In addition, several modes of regulation act to control nitrogen fixation.

The Nitrogenase Complex Is Composed of Two Metalloproteins Two metalloproteins constitute the nitrogenase complex: the **Fe-protein** or nitrogenase reductase and the **MoFe-protein**, which is another name for nitrogenase. **Nitrogenase reductase** is a 60 kDa homodimer possessing a single [4Fe–4S] cluster as a prosthetic group. Nitrogenase reductase is inactivated by small amounts of O₂. Nitrogenase reductase binds MgATP and hydrolyzes two ATPs per electron transferred during nitrogen fixation. Because reduction of N₂ to 2 NH₄⁺ + H₂ requires 8 electrons, 16 ATPs are consumed per N₂ reduced.

This ATP requirement seems paradoxical because the reaction is thermodynamically favorable: The $\mathcal{E}_o'$ for the reaction ($\text{N}_2 + 8 e^- + 10 \text{H}^+ \rightarrow 2 \text{NH}_4^+ + \text{H}_2$) is -0.314 V . Ferredoxin, the most common e^- donor for nitrogen fixation, has an $\mathcal{E}_o'$ that is more negative (see Table 3.3). The solution to the paradox is found in the very strong bonding between the two N atoms in N_2 (Figure 25.4). Substantial energy input is needed to overcome this large activation energy and break the $\text{N}\equiv\text{N}$ triple bond. In this biological system, the energy is provided by ATP.

Nitrogenase, the MoFe-protein, is a 240-kDa $\alpha_2\beta_2$ -type heterotetramer. An $\alpha\beta$ -dimer serves as the functional unit, and each $\alpha\beta$ -dimer contains two types of metal centers: an unusual 8Fe-7S center known as the **P-cluster** (Figure 25.5a) and the novel 7Fe-1Mo-9S cluster known as the **FeMo-cofactor** (Figure 25.5b). Nitrogenase under unusual circumstances may contain an iron-vanadium cofactor instead of the molybdenum-containing one. Like nitrogenase reductase, nitrogenase is very oxygen labile.

The Nitrogenase Reaction In the nitrogenase reaction (Figure 25.6), electrons from reduced ferredoxin pass to nitrogenase reductase, which serves as electron donor to nitrogenase, the enzyme that actually catalyzes N_2 fixation. Electron transfer from nitrogenase reductase to nitrogenase takes place through docking of nitrogenase reductase with an $\alpha\beta$ -subunit pair of nitrogenase (Figure 25.7). Nitrogenase reductase transfers e^- to nitrogenase one electron at a time. $\text{N}\equiv\text{N}$ (or the substrate analog $\text{C}\equiv\text{O}$) binding to FeMoCo displaces one of the nine S atoms in FeMoCo; thus, the FeMoCo structure shown in Figure 25.5b is Fe_7MoS_8 , with the C atom of CO occupying the site where the ninth S atom would be in the substrate-free complex. N_2 is bound within the FeMo-cofactor metal cluster until all electrons and protons are added; no free intermediates, such as $\text{HN}=\text{NH}$ or $\text{H}_2\text{N}-\text{NH}_2$ are released. Electron transfer takes place in the following sequence: Fe-protein $\rightarrow$ P-cluster $\rightarrow$ FeMo-cofactor $\rightarrow$ N_2 .

Figure 25.4 The free energy of activation for the reduction of N_2 to 2NH_3 . The triple bond in N_2 must be broken during nitrogen fixation.

Figure 25.5 Structures of the two types of metal clusters found in nitrogenase. **(a)** The P-cluster consists of two Fe_4S_3 clusters that share an S atom. **(b)** FeMoCo with bound carbon monoxide ($\text{C}\equiv\text{O}$, like N_2 , has a triple bond between its two atoms and acts as a substrate analog of molecular nitrogen). CO is liganded to FeMoCo via two of its iron atoms. The side-chains of $\alpha\text{-Val}^{70}$ and $\alpha\text{-His}^{195}$ just nearby are catalytically important. Fe atoms are shown in orange, S in yellow, Mo in turquoise, C in gray, N in blue, and O in red. Note the key carbide C atom that occupies the center of the FeMoCo complex. Six of the 7 Fe atoms in FeMoCo have Fe-C metal-carbide bonds to this C atom, holding it in place. (Adapted from Figure 1(d) in Spatzal, T., Perez, K. A., Einsle, O., Howard, J. B., and Rees, D. C., 2014. Ligand binding to the Fe-Mo cofactor: Structures of CO-bound and reactivated nitrogenase. *Science* **345**:1620–1623). See also Ohki, Y., et al., 2022. Nitrogen reduction by the Fe sites of synthetic $[\text{Mo}_3\text{S}_4\text{Fe}]$ cubes. *Nature* **607**:86–90.

Figure 25.6 The nitrogenase reaction. Depending on the bacterium, electrons for N_2 reduction may come from light, NADH, hydrogen gas, or pyruvate. The primary e^- donor for the nitrogenase system is reduced ferredoxin.

ATP hydrolysis is coupled to the transfer of an electron from the Fe-protein to the P-cluster. ATP hydrolysis leads to conformational change in the nitrogenase reductase, so it no longer binds to nitrogenase. The ADP:oxidized nitrogenase reductase complex dissociates, making way for another ATP:reduced nitrogenase reductase complex to bind to nitrogenase. Interestingly, nitrogenase reductase is a member of the G-protein family; G proteins are molecular switches whose operation is driven by NTP hydrolysis.

Nitrogenase is a rather slow enzyme: Its optimal rate of e^- transfer is about $12 e^-$ pairs per second per enzyme molecule; that is, it reduces only three molecules of nitrogen gas per second. Because its activity is so weak, nitrogen-fixing cells maintain large amounts of nitrogenase so that their requirements for reduced N can be met. As much as 5% of the cellular protein may be nitrogenase.

Figure 25.7 Ribbon diagram of nitrogenase reductase (the Fe-protein, *blue*):nitrogenase (FeMo protein, *green*) complex. The Fe-protein iron-sulfur cluster is shown in *yellow*, bound ADP in *orange*. The nitrogenase FeMo cofactor is shown in *cyan*, the P-cluster in *red* (PDB id = 1N2C).

Careers in Chemistry

Dr. Squire J. Booker

Dr. Squire J. Booker is the Evan Pugh University Professor of Chemistry, Biochemistry, and Molecular Biology and the Eberly Distinguished Chair in Science at Pennsylvania State University. He directs a lab where they study how enzymes with iron-sulfur clusters catalyze chemical reactions. The focus is on the novel ways that the radical S-adenosylmethionine (SAM) superfamily of enzymes use their [4Fe-4S] cluster to generate a potent oxidant, the 5'-deoxyadenosyl radical, from SAM, and then use it to initiate radical chemistry on a variety of substrates. The Booker Lab seeks to characterize these complex reaction mechanisms to gain insight into the role of these enzymes in human health and disease, as well as to reveal how these enzymes solve difficult chemical problems.

Dr. Booker did his undergraduate studies at Austin College before earning his Ph.D. in Biochemistry at MIT. At both schools, he had to actively seek out African-American role models in science because of their historical underrepresentation. In 2022, Dr. Booker was awarded both the American Society of Biochemistry and Molecular Biology (ASBMB)-Merck Award for his major contributions in biochemistry and molecular biology and the ASBMB Ruth Kirschstein Diversity in Science Award for sustained commitment to breaking down racial barriers. This was the first time ASBMB gave two major awards in the same year to one person.

Figure 25.8 Regulation of nitrogen fixation. (a) ADP inhibits nitrogenase activity and NH_4^+ represses *nif* gene expression. (b) In some organisms, the nitrogenase complex is regulated by covalent modification. ADP-ribosylation of nitrogenase reductase leads to its inactivation. The modifying enzyme catalyzing ADP-ribosylation is dinitrogen reductase ADP-ribosyl transferase (or DraT), and the modifying enzyme catalyzing removal of ADP-ribose is dinitrogen reductase ADP-ribosyl glycohydrolase (or DraG).

The Regulation of Nitrogen Fixation Two regulatory controls for nitrogen fixation are paramount (Figure 25.8): (1) ADP inhibits the activity of nitrogenase; thus, as the ATP/ADP ratio drops, nitrogen fixation is blocked. (2) NH_4^+ represses the expression of the *nif* genes, the genes that encode the proteins of the nitrogen-fixing system. Repression of *nif* gene expression by ammonium, the primary product of nitrogen fixation, is an efficient and effective way of shutting down N_2 fixation when its end product is not needed. In addition, in some systems, covalent modification of nitrogenase reductase leads to its inactivation. Inactivation occurs when Arg¹⁰¹ of nitrogenase reductase receives an ADP-ribosyl group donated by NAD^+ .

25.2 | What Is the Metabolic Fate of Ammonium?

Given the prevalence of N atoms in cellular components, it is surprising that only three enzymatic reactions introduce ammonium into organic molecules. Of these three, *glutamate dehydrogenase* and *glutamine synthetase* are responsible for most of the ammonium assimilated into carbon compounds. The third, *carbamoyl-phosphate synthetase I*, is a mitochondrial enzyme that participates in the urea cycle.

25.2a The Citric Acid Cycle Intermediate α -Ketoglutarate Is Precursor to Both Glutamate and Glutamine

Glutamate dehydrogenase (GDH) catalyzes the reductive amination of α -ketoglutarate to yield glutamate. Reduced pyridine nucleotides (NADH or NADPH) provide the reducing power:

This reaction provides an important interface between nitrogen metabolism and cellular pathways of carbon and energy metabolism because α -ketoglutarate is a citric acid cycle intermediate. In vertebrates, GDH is an α_6 -type multimeric enzyme localized in the mitochondrial matrix that uses NADPH as electron donor when

Figure 25.9 The glutamate dehydrogenase reaction.

operating in the biosynthetic direction (the direction of glutamate synthesis) (Figure 25.9). In mammals, GDH typically acts in the catabolic direction to generate α -ketoglutarate from glutamate. The binding of NADP^+ , the electron acceptor for glutamate oxidation, shows negative cooperativity (see Chapter 15). The catabolic activity is allosterically activated by ADP and inhibited by GTP. Interestingly, mammalian GDH plays a prominent role in amino acid catabolism because it is the only mammalian enzyme that can carry out the oxidative deamination of an amino acid. In plants and bacteria, GDH usually operates in the anabolic direction of glutamate synthesis.

Glutamine synthetase (GS) catalyzes the ATP-dependent amidation of the γ -carboxyl group of glutamate to form glutamine (Figure 25.10). The reaction proceeds via a γ -glutamyl-phosphate intermediate, and GS activity depends on the presence of divalent cations such as Mg^{2+} . **Glutamine** is a major N donor in the biosynthesis of many organic N compounds such as purines, pyrimidines, and other amino acids, and GS activity is tightly regulated, as we shall soon see. The amide-N of glutamine provides the nitrogen atom in these biosyntheses. Glutamine is the most abundant amino acid in humans.

Figure 25.10 (a) The enzymatic reaction catalyzed by glutamine synthetase. (b) The reaction proceeds by (1) activation of the γ -carboxyl group of Glu by ATP, followed by (2) amidation by NH_4^+ .

Carbamoyl-phosphate synthetase I, the third enzyme capable of using ammonium to form an N-containing organic compound, catalyzes an early step in the urea cycle. Two ATPs are consumed, one in the activation of HCO_3^- for reaction with ammonium and the other in the phosphorylation of the carbamate formed (see also Figure 25.22):

N-acetylglutamate is an essential allosteric activator for this enzyme. Both carbamoyl-P and *N*-acetylglutamate are precursors to arginine synthesis and intermediates in the urea cycle.

25.2b The Major Pathways of Ammonium Assimilation Lead to Glutamine Synthesis

In organisms that enjoy environments rich in nitrogen, GDH and GS acting in sequence furnish the principal route of NH_4^+ incorporation (Figure 25.11). However, GDH has a significantly higher K_m for NH_4^+ than does GS. Consequently, in organisms such as green plants that grow under conditions where little NH_4^+ is available, GDH is not effective and GS is the only NH_4^+ -assimilative reaction. Such a situation creates the need for an alternative mode of glutamate synthesis to replenish the glutamate consumed by the GS reaction. This need is filled by **glutamate synthase** (also known as *GOGAT*, the acronym for the other name of this enzyme—**glutamate:oxo-glutarate amino-transferase**). Glutamate synthase catalyzes the reductive amination of α -ketoglutarate using the amide-N of glutamine as the N donor:

Two glutamates are formed—one from amination of α -ketoglutarate and the other from deamidation of Gln (Figure 25.12). These glutamates can now serve as

Figure 25.11 The GDH/GS pathway of ammonium assimilation. The sum of these reactions is the conversion of 1 α -ketoglutarate to 1 glutamine at the expense of 2 NH_4^+ , 1 ATP, and 1 NADPH.

Figure 25.12 The glutamate synthase reaction. (a, top) The overall reaction, showing the various reductants used by different organisms to drive this reductive amination reaction. (b, bottom) The amido group of glutamine that is transferred to α -ketoglutarate is highlighted in blue. (c, right) Molecular graphic of glutamate synthase (PDB id = 1LM1). FAD is shown in blue, the Fe-S cluster in yellow.

Figure 25.13 The GS/GOGAT pathway of ammonium assimilation. **(a)** The glutamine synthetase reaction; **(b)** the GOGAT reaction. The sum of these reactions results in the conversion of one α -ketoglutarate to one glutamine at the expense of two ATP and one NADPH.

ammonium acceptors for glutamine synthesis by GS. Organisms variously use NADH, NADPH, or reduced ferredoxin as reductant. Glutamate synthases are typically large, complex proteins; in *Escherichia coli*, GOGAT is an 800-kDa flavoprotein containing both FMN and FAD, as well as [4Fe–4S] clusters.

Together, GS and GOGAT constitute a second pathway of ammonium assimilation, in which GS is the only NH_4^+ -fixing step; the role of GOGAT is to regenerate glutamate (Figure 25.13). Note that this pathway consumes two equivalents of ATP and one NADPH (or similar reductant) per pair of N atoms introduced into Gln, in contrast to the GDH/GS pathway, in which only one ATP and one NADPH are consumed per pair of NH_4^+ fixed. Clearly, coping with a nitrogen-limited environment has its cost.

25.3 | What Regulatory Mechanisms Act on *Escherichia coli* Glutamine Synthetase?

As indicated earlier, glutamine plays a pivotal role in nitrogen metabolism by donating its amide nitrogen to the biosynthesis of many important organic N compounds. Consistent with its metabolic importance, in prokaryotic cells such as *E. coli*, GS is regulated at three different levels:

1. Its activity is regulated allosterically by *feedback inhibition*.
2. GS is interconverted between active and inactive forms by *covalent modification*.
3. Cellular amounts of GS are carefully controlled at the level of *gene expression* and *protein synthesis*.

Eukaryotic versions of glutamine synthetase show none of these regulatory features.

E. coli GS is a 600-kDa dodecamer (α_{12} -type subunit organization) of identical 52-kDa monomers (each monomer contains 468 amino acid residues). These monomers are arranged as a stack of two hexagons (Figure 25.14). The active sites are located at subunit interfaces within the hexagons; these active sites are recognizable in the X-ray crystallographic structure by the pair of divalent cations that occupy them. Adjacent subunits contribute to each active site, thus accounting for the fact that GS monomers are catalytically inactive.

25.3a Glutamine Synthetase Is Allosterically Regulated

Nine distinct feedback inhibitors (Gly, Ala, Ser, His, Trp, CTP, AMP, carbamoyl-P, and glucosamine-6-P) act on GS. Gly, Ala, and Ser are key indicators of amino acid metabolism in the cell; each of the other six compounds represents an end product of a biosynthetic pathway dependent on Gln (Figure 25.15). AMP competes with ATP for binding at the ATP substrate site. Gly, Ala, and Ser compete with Glu for binding at the active site. Carbamoyl-P binds at a site that overlaps both the Glu site and the site occupied by the $\gamma\text{-PO}_4$ of ATP.

Figure 25.14 The subunit organization of bacterial glutamine synthetase. **(a)** Schematic; **(b)** molecular structure (note the pairs of metal ions [dark blue] that define the active sites; PDB id = 1FPY).

Figure 25.15 The allosteric regulation of glutamine synthetase activity by feedback inhibition.

25.3b Glutamine Synthetase Is Regulated by Covalent Modification

Each GS subunit can be adenylylated at a specific tyrosine residue (Tyr³⁹⁷) in an ATP-dependent reaction (Figure 25.16). Adenylylation inactivates GS. If we define n as the average number of adenylyl groups per GS molecule, GS activity is inversely proportional to n . The number n varies from 0 (no adenylyl groups) to 12 (every subunit in each GS molecule is adenylylated). Adenylylation of GS is catalyzed by the bifunctional *converter enzyme* **ATP-GS-adenylyl transferase**, or simply **adenylyl transferase (AT)**. However, whether or not this covalent modification occurs is determined by a highly regulated cycle (Figure 26.17). The bifunctional AT not only catalyzes adenylylation of GS, it also catalyzes **deadenylylation**—the phosphorolytic removal of the Tyr-linked adenylyl groups as ADP. The direction in which AT operates depends on the nature of a regulatory protein, P_{II}, associated with it. P_{II} is a 44-kDa protein (trimer of 12 to 13 kDa subunits): The state of P_{II} controls the direction in which AT acts. If P_{II} is not uridylylated, that is, if it is in its so-called P_{IIA} form, the AT:P_{IIA} complex acts to adenylylate GS. When P_{II} is uridylylated, that is, in its so-called P_{IID} form, the AT:P_{IID} complex catalyzes the deadenylylation of GS. The active sites of AT:P_{IIA} and AT:P_{IID} are different, consistent with the difference in their catalytic roles. In addition, the AT:P_{IIA} and AT:P_{IID} complexes are allosterically regulated in a reciprocal fashion by the effectors α -KG and Gln. Gln activates AT:P_{IIA} activity and inhibits AT:P_{IID} activity; the effect of α -KG on the activities of these two complexes is diametrically opposite (Figure 25.17). Further, Gln favors conversion of P_{IID} to P_{IIA}, whereas α -ketoglutarate favors the P_{IID} over the P_{IIA} form.

Clearly, the determining factor regarding the degree of adenylylation, n , and hence the relative activity of GS, is the [Gln]/[α -KG] ratio. A high [Gln] level signals cellular nitrogen sufficiency, and GS becomes adenylylated and inactivated. In contrast, a high [α -KG] level is an indication of nitrogen limitation and a need for ammonium fixation by GS. Note that Gln affects all four reactions of the cyclic cascade system, whereas α -KG affects only three. Thus, Gln is ultimately the key effector in this system.

25.3c Glutamine Synthetase Is Regulated through Gene Expression

The gene that encodes the GS subunit in *E. coli* is designated *GlnA*. The *GlnA* gene is actively transcribed to yield GS mRNA for translation and synthesis of GS protein only if a *specific transcriptional enhancer*, **NR_I**, is in its phosphorylated

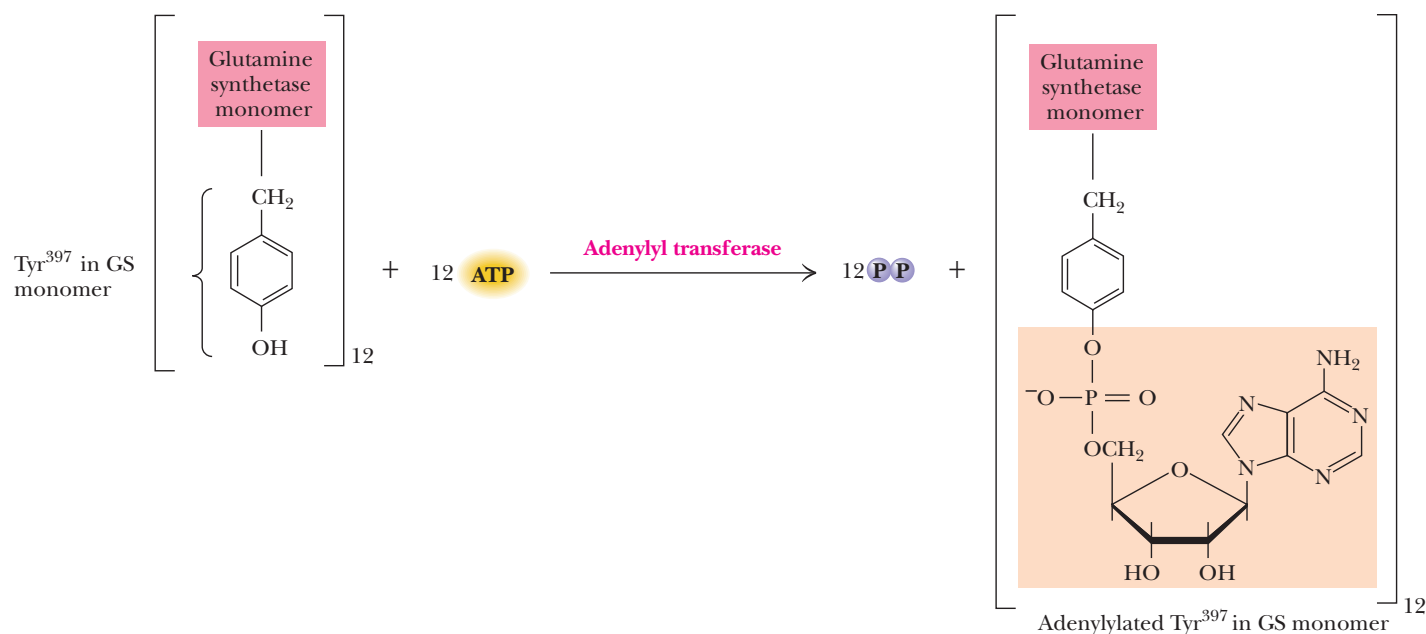

Figure 25.16 Covalent modification of GS: Adenylylation of Tyr³⁹⁷ in the glutamine synthetase polypeptide via an ATP-dependent reaction catalyzed by the converter enzyme adenylyl transferase.

Figure 25.17 The cyclic cascade system regulating the covalent modification of GS.

form, $\text{NR}_I\text{-P}$. In turn, NR_I is phosphorylated in an ATP-dependent reaction catalyzed by NR_{II} , a protein kinase (Figure 25.18). However, if NR_{II} is complexed with P_{IIA} , it acts not as a kinase but as a phosphatase, and the transcriptionally active form of NR_I , namely $\text{NR}_I\text{-P}$, is converted back to NR_I with the result that *GlnA* transcription halts. Recall from the foregoing discussion that a high $[\text{Gln}]/[\alpha\text{-KG}]$ ratio favors P_{IIA} at the expense of P_{IID} . Under such conditions, GS gene expression is not necessary.

25.3d Glutamine in the Human Body

Glutamine is not among the 10 most commonly occurring amino acids in proteins (see Figure 5.17), but it is the most abundant amino acid in human body fluids and tissues. The abundance of glutamine reflects its prominent anabolic role as the source of N atoms in the synthesis of purines and pyrimidines, amino sugars (Chapter 18), and other nitrogen-containing biological molecules.

Mammalian cells grown in culture rely on glucose and glutamine as their principal substrates for energy production, generation of reducing equivalents in the form of NADPH, and the carbon and nitrogen atoms for anabolic growth. Donation of the amide group of glutamine during nucleotide biosynthesis or the creation of other N-containing biomolecules creates glutamate. Oxidative deamination of Glu by GDH or transfer of its α -amino group through transamination (see Figure 25.19) leads to the formation of α -ketoglutarate, thus replenishing a key citric acid cycle intermediate. Thus, carbon for biosynthesis is provided by glutamine through the amphibolic nature of the citric acid cycle.

Glutamine in the Brain Glutamine is by far the most abundant amino acid in the central nervous system. Glutamine synthetase in astrocytes, a star-shaped type of glial cell, aids in meeting the demand for Gln. (Glial cells are cells that support and nourish neurons.) Gln serves as the precursor for both glutamate and γ -aminobutyrate, two neurotransmitters that are synthesized in neurons. Excessive accumulation of Gln in the central nervous system can interfere with brain function.

Figure 25.18 Transcriptional regulation of *GlnA* expression through the reversible phosphorylation of NR_I .

Glutamine and Cancer Cancer cells growing under oxygen-limiting (hypoxic) conditions are dependent on glutamine for anabolic purposes. Glutamine uptake by cancer cells is followed by hydrolysis by **glutaminase** (an amidohydrolase) to produce glutamate and NH_4^+ . Mitochondrial glutamate dehydrogenase converts the glutamate into α -ketoglutarate (Figure 25.9, running in reverse). The α -ketoglutarate can then enter the citric acid cycle, where it can be reductively carboxylated by isocitrate dehydrogenase running in reverse, to form citrate. Citrate is a versatile anabolic precursor that can be used to synthesize many needed metabolites, including acetyl-CoA for lipid synthesis. (Export of mitochondrial citrate to the cytosol makes it available to citrate-ATP lyase, which converts it to OAA and acetyl-CoA [see Figure 24.1]). Certain cancer cell lines are very sensitive to glutamine deprivation. Therapeutic agents that block the use of glutamine for anabolic purposes are potential drugs in cancer chemotherapy.

25.4 | How Do Organisms Synthesize Amino Acids?

Organisms show substantial differences in their capacity to synthesize the 20 amino acids common to proteins. Typically, plants and microorganisms can form all of their nitrogenous metabolites, including all of the amino acids, from inorganic forms of N such as NH_4^+ and NO_3^- . In these organisms, the α -amino group for all amino acids is derived from glutamate, usually via transamination of the corresponding α -keto acid analog of the amino acid (Figure 25.19). In many cases, amino acid biosynthesis is thus a matter of synthesizing the appropriate α -keto acid carbon skeleton, followed by transamination with Glu. The amino acids can be classified according to the source of intermediates for the α -keto acid biosynthesis (Table 25.1). For example, the amino acids Glu, Gln, Pro, and Arg (and, in some instances, Lys) are all members of the α -ketoglutarate family because they are all derived from the citric acid cycle intermediate α -ketoglutarate. We return to this classification scheme later when we discuss the individual biosynthetic pathways.

Table 25.1 The Grouping of Amino Acids into Families According to the Metabolic Intermediates That Serve as Their Progenitors	
α-Ketoglutarate Family	Oxaloacetate Family
Glutamate	Aspartate
Glutamine	Asparagine
Proline	Methionine
Arginine	Threonine
Lysine*	Isoleucine
	Lysine*
Pyruvate Family	3-Phosphoglycerate Family
Alanine	Serine
Valine	Glycine
Leucine	Cysteine
Phosphoenolpyruvate and Erythrose-4-P Family	
The aromatic amino acids	
Phenylalanine	
Tyrosine	
Tryptophan	
The remaining amino acid, <i>histidine</i> , is derived from PRPP (5-phosphoribosyl-1-pyrophosphate) and ATP.	

*Different organisms use different precursors to synthesize lysine.

Human Biochemistry

Human Dietary Requirements for Amino Acids

Humans can synthesize only 10 of the 20 common amino acids (see table); the others must be obtained in the diet (Table 1). Those that can be synthesized are classified as **nonessential**, meaning it is not essential that these amino acids be part of the diet. In effect, humans can synthesize the α -keto acid analogs of nonessential amino acids and form the amino acids by transamination. In contrast, humans are incapable of constructing the carbon skeletons of **essential** amino acids, so they must rely on dietary sources for these essential metabolites. Excess dietary amino acids cannot be stored for future use, nor are they excreted unused. Instead, they are converted to common metabolic intermediates that can be either oxidized by the citric acid cycle to generate metabolic energy or used to form glucose (see Section 25.5).

Since autotrophic cells (and many prokaryotic cells) synthesize all 20 amino acids, several questions arise regarding human dietary requirements for amino acids. First, why is it that humans lack the ability to do what other organisms can do? The answer is that, over evolutionary time, human diets provided adequate amounts of those amino acids classified as essential. Thus, the loss of the metabolic pathways for synthesis of essential amino acids did not impair the fitness of humans. That is, synthesizing essential amino acids became superfluous, and no evolutionary pressure operated on humans to retain the genes for these pathways. A second question now emerges: Are there significant differences between synthesis of amino acids humans can make (the so-called nonessential amino

acids) and those they can't? Table 2 summarizes amino acid biosynthesis from citric acid cycle intermediates in terms of the number of reactions needed to make an amino acid from a TCA cycle intermediate. Nonessential amino acids are shown in blue; essential amino acids in red. Two conclusions stand out: Nonessential amino acids require fewer reaction steps for synthesis than essential amino acids, and nonessential amino acids tend to be more abundantly represented in proteins than essential amino acids. Thus, evolutionary loss was not random: The biosynthetic pathways lost were those for amino acids requiring the most reaction steps.

‡Note that “nonessential” cysteine can be made only from “essential” methionine and “nonessential” tyrosine can be made only from “essential” phenylalanine.

25.4a Amino Acids Are Formed from α -Keto Acids by Transamination

Transamination involves transfer of an α -amino group from an amino acid to the α -keto position of an α -keto acid (Figure 25.19). In the process, the amino donor becomes an α -keto acid and the α -keto acid acceptor becomes an α -amino acid:

The predominant amino acid/ α -keto acid pair in these reactions is glutamate/ α -ketoglutarate, with the net effect that glutamate is the primary amino donor for the synthesis of amino acids. Transamination reactions are catalyzed by **aminotransferases** (the preferred name for enzymes formerly termed *transaminases*). Aminotransferases are named according to their amino acid substrates, as in **glutamate-aspartate aminotransferase**. Aminotransferases are prime examples of enzymes that catalyze double displacement (ping-pong)-type bisubstrate reactions (see Figure 13.23).

A Deeper Look

The Mechanism of the Aminotransferase (Transamination) Reaction

The aminotransferase (transamination) reaction is a workhorse in biological systems. It provides a general means for exchange of nitrogen between amino acids and α -keto acids. Aminotransferases depend on the coenzyme pyridoxal-phosphate (PLP), a vitamin B₆ derivative. The mechanism involves loss of the C $_{\alpha}$ proton of the amino acid, followed by an aldimine-ketimine tautomerization—literally a flip-flop of the Schiff base double bond from the pyridoxal

aldehyde carbon to the α -carbon of the amino acid substrate. This is followed by hydrolysis of the ketimine intermediate to yield the product α -keto acid. Left in the active site is a pyridoxamine phosphate intermediate, which combines with another (substrate) α -keto acid to form a second ketimine, which rearranges to form an aldimine, followed by release as an amino acid. Transaldiminization with a lysine at the active site completes the reaction.

The mechanism of PLP-catalyzed transamination reactions.

Figure 25.19 Glutamate-dependent transamination of α -keto acid carbon skeletons is a primary mechanism for amino acid synthesis. (a) The generic pyridoxal-P dependent aminotransferase reaction. (b) A prime example is the glutamate-aspartate aminotransferase reaction: the transamination of oxaloacetate by glutamate to yield aspartate and α -ketoglutarate.

25.4b The α -Ketoglutarate Family of Amino Acids Includes Glu, Gln, Pro, Arg, and Lys

As indicated in Table 25.1, the amino acids can be grouped into families on the basis of the metabolic intermediates that serve as their precursors. Amino acids derived from α -ketoglutarate include glutamate (Glu), glutamine (Gln), proline (Pro), arginine (Arg), and in fungi and protista such as *Euglena*, lysine (Lys). The routes for Glu and Gln synthesis were described when we considered pathways of ammonium assimilation.

Proline is derived from glutamate via a series of four reactions involving activation, then reduction, of the γ -carboxyl group to an aldehyde (*glutamate-5-semialdehyde*), which spontaneously cyclizes to yield the internal Schiff base, Δ^1 -pyrroline-5-carboxylate (Figure 25.20). NADPH-dependent reduction of the pyrroline double bond gives proline.

Arginine biosynthesis involves enzymatic steps that are also part of the **urea cycle**, a metabolic pathway that allows certain animals (including humans) to excrete any excess nitrogen arising from overconsumption of protein. Net synthesis of arginine depends on the formation of **ornithine**. Interestingly, ornithine is derived from glutamate via a reaction pathway reminiscent of the proline biosynthetic pathway (Figure 25.21). Glutamate is first *N*-acetylated in an acetyl-CoA-dependent reaction to yield *N*-acetylglutamate (Figure 25.21). An ATP-dependent phosphorylation of *N*-acetylglutamate to give *N*-acetylglutamate-5-phosphate primes this substrate for a reduced pyridine nucleotide-dependent reduction to the semialdehyde. *N*-acetylglutamate-5-semialdehyde then is aminated by a glutamate-dependent aminotransferase, giving *N*-acetylornithine, which is deacylated to ornithine. In mammals, ornithine is made from glutamate via a pathway that does not involve an *N*-acetyl block.

Ornithine has three metabolic roles: (1) to serve as a precursor to arginine, (2) to function as an intermediate in the urea cycle, and (3) to act as an intermediate in Arg degradation. In any case, the δ - NH_3^+ of ornithine is carbamoylated in a reaction catalyzed by **ornithine transcarbamoylase**. The carbamoyl group is derived from carbamoyl-P synthesized by **carbamoyl-phosphate synthetase I (CPS-I)**. CPS-I is the mitochondrial CPS isozyme; it uses two ATPs in catalyzing the formation of carbamoyl-P from NH_3

Figure 25.20 The pathway of proline biosynthesis from glutamate. The enzymes are (1) γ -glutamyl kinase, (2) glutamate-5-semialdehyde dehydrogenase, and (4) Δ^1 -pyrroline-5-carboxylate reductase; reaction (3) occurs nonenzymatically.

Figure 25.21 The bacterial pathway of ornithine biosynthesis from glutamate. The enzymes are (1) *N*-acetylglutamate synthase, (2) *N*-acetylglutamate kinase, (3) *N*-acetylglutamate-5-semialdehyde dehydrogenase, (4) *N*-acetylornithine δ -aminotransferase, and (5) *N*-acetylornithine deacetylase.

Figure 25.22 The mechanism of action of CPS-I.

and HCO_3^- , one to activate the bicarbonate ion and the other to phosphorylate the carbamate arising from carboxyphosphate through its reaction with the ammonium ion (Figure 25.22). CPS-I represents the committed step in the urea cycle, and CPS-I is allosterically activated by *N*-acetylglutamate. Because *N*-acetylglutamate is both a precursor to ornithine synthesis and essential to the operation of the urea cycle, it serves to coordinate these related pathways.

The product of the ornithine transcarbamoylase reaction is *citrulline* (Figure 25.23). Ornithine and citrulline are two α -amino acids of metabolic importance that nevertheless are *not* among the 20 α -amino acids commonly found in proteins. Like CPS-I, ornithine transcarbamoylase is a mitochondrial enzyme. The reactions of ornithine synthesis and the rest of the urea cycle enzymes occur in the cytosol.

The pertinent feature of the citrulline side chain is the **ureido group**. In a complex reaction catalyzed by **argininosuccinate synthetase**, this ureido group is first activated by ATP to yield a citrullyl-AMP derivative, followed by displacement of AMP by aspartate to give *argininosuccinate* (Figure 25.23). The formation of arginine is then accomplished by **argininosuccinase**, which catalyzes the nonhydrolytic elimination of fumarate from arginosuccinate. This reaction completes the biosynthesis of Arg.

25.4c The Urea Cycle Acts to Excrete Excess N through Arg Breakdown

The carbon skeleton of arginine is derived principally from α -ketoglutarate, but the N and C atoms composing the **guanidino group** (Figure 25.23) of the Arg side chain come from NH_4^+ , HCO_3^- (as carbamoyl-P), and the α - NH_2 groups of glutamate and aspartate. The circle of the urea cycle is closed when ornithine is regenerated from Arg by the arginase-catalyzed hydrolysis of arginine. Urea is the other product of this reaction and lends its name to the cycle. Note that the N atoms in urea arose from NH_4^+ and the Asp amino group. In terrestrial vertebrates, urea synthesis is required

Figure 25.23 The urea cycle series of reactions: The enzymes are (1) ornithine transcarbamoylase (OTCase), (2a and 2b) argininosuccinate synthetase, (3) argininosuccinase, and (4) arginase.

A Deeper Look

The Urea Cycle as Both an Ammonium and a Bicarbonate Disposal Mechanism

Excretion of excess NH_4^+ as nontoxic urea has traditionally been viewed as the physiological role of the urea cycle. However, the urea cycle also provides a mechanism for the excretion of excess HCO_3^- arising principally from α -carboxyl groups generated during the catabolism of α -amino acids. The following equations illustrate this property:

Sum:

That is, two moles of HCO_3^- are eliminated in the synthesis of each mole of urea: One is incorporated into the product, urea (reaction 1),

and the second is simply protonated and dehydrated to form CO_2 (reaction 2), which is easily excreted. One interpretation of the preceding is that these coupled reactions allow a weak acid (NH_4^+) to protonate the conjugate base of a stronger acid (HCO_3^-). This protonation may appear thermodynamically unfavorable, but recall that in the urea cycle, four equivalents of ATP are consumed per equivalent of urea synthesized: two ATPs in the synthesis of carbamoyl-P, and two more as one ATP is converted to AMP + PP_i in the synthesis of argininosuccinate from citrulline (Figure 25.23). If this interpretation is correct, the urea cycle may be considered an ATP-driven proton pump that transfers H^+ ions from NH_4^+ to HCO_3^- against a thermodynamic barrier. In the process, the potentially toxic waste products, ammonium and bicarbonate, are rendered innocuous and excreted.

to excrete excess nitrogen generated by increased amino acid catabolism—for example, following dietary consumption of more than adequate amounts of protein. Urea formation is basically confined to the liver.

Young adults eating a typical American diet will consume about 70 g (females) to 105 g (males) of protein per day. These amounts are significantly more than the recommended dietary allowance (RDA) of 56 g/day. Because these individuals remain in *nitrogen balance* (neither increasing nor decreasing their net protein levels), their bodies must dispose of the excess N derived from the amino acids in this dietary protein. Glutamate is key to this process because of the position of glutamate dehydrogenase at the interface of amino acid and carbohydrate metabolism and the importance of glutamate to the urea cycle.

Increases in amino acid catabolism lead to elevated glutamate levels and a rise in *N*-acetylglutamate, the allosteric activator of CPS-I. Stimulation of CPS-I raises overall urea cycle activity because activities of the remaining enzymes of the cycle simply respond to increased substrate availability. Removal of potentially toxic NH_4^+ by CPS-I is another important aspect of this regulation. The urea cycle is linked to the citric acid cycle through *fumarate*, a by-product of the action of *argininosuccinase* (Figure 25.23, reaction 3).

Lysine biosynthesis in some fungi and in the protist *Euglena* also stems from α -ketoglutarate, making lysine a member of the α -ketoglutarate family of amino acids in these organisms. (As we shall see, the other organisms capable of lysine synthesis—namely, bacteria, other fungi, algae, and green plants—rely on aspartate [derived from oxaloacetate] as a precursor.) To make lysine from α -ketoglutarate requires a lengthening of the carbon skeleton by one CH_2 unit to yield α -ketoadipate (Figure 25.24). This addition is accomplished by a series of reactions reminiscent of the initial stages of the citric acid cycle. First, a two-carbon acetyl-CoA unit is added to the α -carbon of α -ketoglutarate to form *homocitrate*. Then, in a reaction sequence like that catalyzed by aconitase, *homocitrate* is formed from homocitrate. Oxidative decarboxylation (as in isocitrate dehydrogenase) removes one carbon (the original α -carboxyl group of α -ketoglutarate), leaving α -ketoadipate. A glutamate-dependent aminotransferase enzyme then aminates α -ketoadipate to give α -aminoadipate. Next, the δ - COO^- group is activated in an ATP-dependent adenylation reaction, priming this δ - COO^- group for reduction to an aldehyde by NADPH. α -Aminoadipic-6-semialdehyde is then reductively aminated by addition of glutamate to its aldehydic carbon in an NADPH-dependent reaction leading to the formation of *saccharopine*. Oxidative cleavage of saccharopine by way of an NAD^+ -dependent dehydrogenase activity yields α -ketoglutarate and *lysine*. This pathway is known as the **α -aminoadipic**

Figure 25.24 Lysine biosynthesis in certain fungi and *Euglena*: the α -aminoadipic acid pathway.

acid pathway of lysine biosynthesis. Interestingly, lysine degradation in animals leads to formation of α -aminoadipate by a reverse series of reactions identical to those occurring along the last steps of this biosynthetic pathway.

25.4d The Oxaloacetate Family of Amino Acids Includes Asp, Asn, Lys, Met, Thr, and Ile

The members of the oxaloacetate family of amino acids include aspartate (Asp), asparagine (Asn), lysine (via the diaminopimelic acid pathway), methionine (Met), threonine (Thr), and isoleucine (Ile).

Aspartate is formed from the citric acid cycle intermediate oxaloacetate by transfer of an amino group from glutamate via a PLP-dependent aminotransferase reaction (Figure 25.25). Like glutamate synthesis from α -ketoglutarate, aspartate synthesis is a drain on the citric acid cycle. As we already saw, the Asp amino group serves as the N donor in the conversion of citrulline to arginine. In addition, the entire aspartate molecule is used in the biosynthesis of pyrimidine nucleotides.

Asparagine is formed by amidation of the β -carboxyl group of aspartate. In bacteria, in analogy with glutamine synthesis, the nitrogen added in this amidation comes directly from NH_4^+ . In other organisms, **asparagine synthetase** catalyzes the ATP-dependent transfer of the amido-N of glutamine to aspartate to yield glutamate, AMP, PP_i , and asparagine (Figure 25.26).

Figure 25.25 Aspartate biosynthesis via transamination of oxaloacetate by glutamate.

Figure 25.26 Asparagine biosynthesis from Asp, Gln, and ATP by asparagine synthetase. β -Aspartyl adenylate is an enzyme-bound intermediate.

Threonine, methionine, and lysine biosynthesis in bacteria proceeds from the common precursor aspartate, which is converted first to *aspartyl- β -phosphate* and then to *β -aspartyl-semialdehyde*. The first reaction is an ATP-dependent phosphorylation catalyzed by **aspartokinase** (Figure 25.27, reaction 1). In *E. coli*, there are three isozymes of aspartokinase, designated **aspartokinases I, II, and III**. Each of these isozymes is uniquely controlled by one of the three end-product amino acids. Form I is feedback-inhibited by threonine and form III, by lysine. Form II is not feedback-inhibited, but its synthesis is repressed by methionine.

β -Aspartyl-semialdehyde is formed via NADPH-dependent reduction of *aspartyl- β -phosphate* in a reaction catalyzed by **β -aspartyl-semialdehyde dehydrogenase** (Figure 25.27, reaction 2). From here, the pathway of lysine synthesis diverges. The methyl carbon of pyruvate is condensed with *β -aspartyl-semialdehyde*, and H_2O is eliminated to yield the cyclic compound *2,3-dihydropicolinate* (Figure 25.27, reaction 10). Thus, lysine synthesized by this pathway must be considered a member of both the oxaloacetate and the pyruvate families of amino acids. Lysine is a feedback inhibitor of this branch-point enzyme. *Dihydropicolinate* is then reduced in an NADPH-dependent reaction to *Δ^1 -piperidine-2,6-dicarboxylate* (Figure 25.27, reaction 11). A series of reactions, including a hydrolytic opening of the piperidine ring, a succinylation, a glutamate-dependent amination, and the hydrolytic removal of succinate, results in the formation of the symmetric *L,L- α,ϵ -diaminopimelate* (Figure 25.27, reactions 12 through 14). Epimerization of this intermediate to the *meso* form, followed by decarboxylation, yields the end product *lysine* (Figure 25.27, reactions 15 and 16). Because this pathway proceeds through the symmetric *L,L- α,ϵ -diaminopimelate*, one-half of the CO_2 evolved in the terminal decarboxylase step is derived from the carboxyl group of pyruvate and one-half from the α -carboxyl of Asp.

The other metabolic branch diverging from *β -aspartyl-semialdehyde* leads to *threonine* and *methionine* via *homoserine*, an analog of serine that is formed by the NADPH-dependent reduction of *β -aspartyl-semialdehyde* (Figure 25.27, reaction 3) catalyzed by **homoserine dehydrogenase**. To form **methionine**, the $-OH$ group of homoserine is first succinylated by **homoserine acyltransferase** (Figure 25.27, reaction 6). Methionine is a feedback inhibitor of this enzyme. The succinyl group of *O-succinylhomoserine* is then displaced by cysteine to yield *cystathionine* (Figure 25.27, reaction 7). The sulfur atom in methionine is contributed by a cysteine sulfhydryl. *Cystathionine* is then split to give pyruvate, NH_4^+ , and *homocysteine*, a nonprotein amino acid whose side chain is one $-CH_2-$ group longer than that of Cys (Figure 25.27, reaction 8). Methylation of the homocysteine $-SH$ via methyl transfer from the methyl donor, *N*⁵-methyl-THF gives methionine (Figure 25.27, reaction 9). In higher plants, methionine is synthesized in a slightly different way: Phosphohomoserine (the product of reaction 4 in Figure 25.27) and cysteine are joined to form cystathionine with the release of P_i , bypassing reaction 6 and the *O-succinylhomoserine* intermediate. Reactions 7 and 8 constitute a transsulfurylation pathway that transfers the $-SH$ group of Cys to homoserine through cystathionine as an intermediate. Methylation of homocysteine (reaction 9) yields methionine.

SAM as a Methyl Group Donor *S*-Adenosylmethionine (SAM) acts as a methyl-group donor in methylation reactions. The enzyme ***S*-adenosylmethionine synthase** catalyzes the reaction of methionine with ATP to form *S-adenosylmethionine*, or SAM (Figure 25.28). SAM is a substrate of methyltransferases in a variety of methyl-donor reactions, such as the formation of phosphatidylethanolamine (see Figure 8.6), DNA methylation (see the Human Biochemistry box in Section 11.2), and methylation of Arg and Lys residues in the regulation of DNA-histone interactions in chromatin (see Figure 29.29). Following decarboxylation, SAM is a source of propylamine for the synthesis of polyamines (Figure 25.28).

The remaining amino acids of the oxaloacetate family are threonine and isoleucine. **Threonine**, like methionine, is synthesized from homoserine. Indeed, homoserine is the primary alcohol analog of the secondary alcohol Thr. To move this $-OH$ from C-4 to C-3 requires activation of the hydroxyl through ATP-dependent phosphorylation by

Figure 25.27 Biosynthesis of threonine, methionine, and lysine, members of the aspartate family of amino acids. This β-aspartyl phosphate pathway is found in plants, fungi, and bacteria but absent in mammals. Thus, threonine, methionine, lysine, and isoleucine (which is synthesized from threonine [see Figure 25.29]) are essential amino acids for humans; they have to be obtained from dietary protein.

Figure 25.28 The synthesis of S-adenosylmethionine (SAM) and its fates.

homoserine kinase (see Figure 25.27, reaction 4). As the first reaction unique to Thr biosynthesis, homoserine kinase is feedback inhibited by threonine. The last step is catalyzed by **threonine synthase**, a PLP-dependent enzyme (see Figure 25.27, reaction 5).

Isoleucine is included in the oxaloacetate family of amino acids because four of its six carbons derive from Asp (via threonine) and only two come from pyruvate. Nevertheless, four of the five enzymes necessary for isoleucine synthesis are common to the pathway for biosynthesis of valine, so discussion of isoleucine synthesis is presented under the biosynthesis of the pyruvate family of amino acids.

25.4e The Pyruvate Family of Amino Acids Includes Ala, Val, and Leu

The pyruvate family of amino acids includes alanine (Ala), valine (Val), and leucine (Leu). Transamination of pyruvate, with glutamate as amino donor, gives **alanine**. Because these transamination reactions are readily reversible, alanine degradation occurs via the reverse route, with α -ketoglutarate serving as amino acceptor.

Transamination of pyruvate to alanine is a reaction found in virtually all organisms, but valine, leucine, and isoleucine are essential amino acids, and as such, they are not synthesized in mammals. In the organisms that synthesize them, the pathways of **valine** and **isoleucine** synthesis can be considered together because a set of four enzymes is common to the last four steps of both pathways (Figure 25.29). Both pathways begin with an α -keto acid. Isoleucine can be considered a structural analog of valine that has one extra $-\text{CH}_2-$ unit, and its α -keto acid precursor, namely, α -*keto-butyrate*, is one carbon longer than the valine precursor, pyruvate. Interestingly, α -ketobutyrate is formed from threonine by **threonine deaminase** (Figure 25.29, reaction 1). This PLP-dependent enzyme (also known as *threonine dehydratase* or *serine dehydratase*) is feedback-inhibited by isoleucine, the end product. Note that part of the carbon skeleton for Ile comes from Asp by way of Thr. From here on, the Val and Ile pathways employ the same set of enzymes. The first reaction involves the generation of hydroxyethyl-thiamine pyrophosphate from pyruvate in a reaction analogous to those catalyzed by transketolase and the pyruvate dehydrogenase complex. The two-carbon hydroxyethyl group is transferred from TPP to the respective keto acid acceptor by **aceto-hydroxy acid synthase** (acetolactate synthase) to give α -*acetolactate* or α -*aceto- α -hydroxybutyrate* (Figure 25.29, reaction 2). NAD(P)H-dependent reduction of these α -keto hydroxy acids yields the dihydroxy acids α,β -*dihydroxyisovalerate* and α,β -*dihydroxy- β -methylvalerate* (Figure 25.29, reaction 3). Dehydration of each of these dihydroxy acids by **dihydroxy acid dehydratase** gives the appropriate α -keto acid carbon skeletons α -*ketoisovalerate* and α -*keto- β -methylvalerate* (Figure 25.29, reaction 4). Transamination by the **branched-chain amino acid aminotransferase** (BCAT) yields Val or Ile, respectively (Figure 25.29, reaction 5).

Leucine synthesis depends on these reactions as well, because α -ketoisovalerate is a precursor common to both Val and Leu (Figure 25.30). Although Val and Leu differ by only a single $-\text{CH}_2-$ in their respective side chains, the carboxyl group of α -ketoisovalerate first picks up *two* carbons from acetyl-CoA to give α -*isopropylmalate* in a reaction catalyzed by **isopropylmalate synthase**; the enzyme is sensitive to feedback inhibition by Leu (Figure 25.30, reaction 1). **Isopropylmalate dehydratase** (Figure 25.30, reaction 2) converts the α -isomer to the β -form, which undergoes an NAD^+ -dependent oxidative decarboxylation by **isopropylmalate dehydrogenase** (Figure 25.30, reaction 3), so the carboxyl group of α -ketoisovalerate is lost as CO_2 . Amination of α -ketoisocaproate by **leucine aminotransferase** (Figure 25.30, reaction 4) gives Leu.

25.4f The 3-Phosphoglycerate Family of Amino Acids Includes Ser, Gly, and Cys

Serine, glycine, and cysteine are derived from the glycolytic intermediate 3-phosphoglycerate. The diversion of 3-PG from glycolysis is achieved via **3-phosphoglycerate dehydrogenase** (Figure 25.31, reaction 1). This NAD^+ -dependent oxidation of 3-PG

Figure 25.29 Biosynthesis of valine and isoleucine. Note that the enzymes catalyzing reactions 3, 4, and 5 serve both the Val and Ile synthetic pathways.

yields *3-phosphohydroxypyruvate*—which, as an α -keto acid, is a substrate for transamination by glutamate to give *3-phosphoserine* (Figure 25.31, reaction 2). **Serine phosphatase** then generates **serine** (Figure 25.31, reaction 3). Serine inhibits the first enzyme, 3-PG dehydrogenase, and thereby feedback-regulates its own synthesis.

Figure 25.30 Biosynthesis of leucine.

Figure 25.31 Biosynthesis of serine from 3-phosphoglycerate.

Glycine is made from serine via two related enzymatic processes. In the first (Figure 25.32a), **serine hydroxymethyltransferase**, a PLP-dependent enzyme, catalyzes the transfer of the serine β -carbon to tetrahydrofolate (THF), the principal agent of one-carbon metabolism. Glycine and N^5,N^{10} -methylene-THF are the products. In addition, glycine can be synthesized by a reversal of the **glycine oxidase** reaction (Figure 25.32b). Here, glycine is formed when N^5,N^{10} -methylene-THF condenses with NH_4^+ and CO_2 . Via this route, the β -carbon of serine becomes part of glycine. The conversion of serine to glycine is a prominent means of generating one-carbon derivatives of THF, which are so important for the biosynthesis of purines and the C-5 methyl group of thymine, as well as the amino acid methionine. Glycine itself contributes to both purine and heme synthesis.

Figure 25.32 Biosynthesis of glycine from serine
(a) via serine hydroxymethyltransferase and **(b)** via glycine oxidase.

Cysteine synthesis is accomplished by sulfhydryl transfer to serine (Figure 25.33). In some bacteria, H_2S condenses directly with serine via a PLP-dependent enzyme-catalyzed reaction (Figure 25.33a), but in most microorganisms and green plants, the sulfhydrylation reaction requires an activated form of serine, *O*-acetylserine (Figure 25.33b). *O*-acetylserine is made by **serine acetyltransferase**, with the transfer of an acetyl group from acetyl-CoA to the —OH of Ser. This enzyme is inhibited by Cys. *O*-Acetylserine then undergoes sulfhydrylation by H_2S with elimination of acetate; the enzyme is ***O*-acetylserine sulfhydrylase**.

In humans, cysteine is synthesized from methionine by a reverse transsulfurylation pathway (reactions 7, 8, and 9 in Figure 25.27 constitute the forward transsulfurylation pathway). Because cysteine can be made from methionine via this pathway, cysteine is not considered by nutritionists to be an essential amino acid, even though methionine is. Mutations in the reverse transsulfurylation pathway lead to a rare but potentially fatal disease called homocystinuria, caused by accumulation of both methionine and homocysteine. The disease is treated by putting patients on a low-protein diet to minimize methionine intake and giving them vitamin B_6 supplements.

Sulfide Synthesis from Sulfate Involves S-Containing ATP Derivatives Given the prevailing oxidative nature of our environment and the reactivity and toxicity of H_2S , the source of sulfide for Cys synthesis merits discussion. In microorganisms and plants, sulfide is the product of sulfate assimilation. Sulfate is the common inorganic form of combined sulfur, and its assimilation involves several interesting ATP derivatives. **ATP sulfurylase** (Figure 25.34, reaction 1) catalyzes the formation of adenosine-5'-phosphosulfate (APS). Then, **adenosine-5'-phosphosulfate-3'-phosphokinase** catalyzes the formation of 3'-phosphoadenosine-5'-phosphosulfate (PAPS) from APS and ATP (Figure 25.34, reaction 2). Sulfite is then liberated upon reduction of PAPS by reduced thioredoxin, leaving 3'-phosphoadenosine-5'-phosphate as a product (Figure 25.34, reaction 3). Sulfite (SO_3^-) is then reduced to sulfide (S_2^-) in a multielectron transfer reaction catalyzed by **sulfite oxidase** (Figure 25.34, reaction 4); NADPH is the electron donor. Sulfite reductase, like nitrite reductase, possesses siroheme as a prosthetic group (see Figure 25.2). 3'-Phosphoadenosine-5'-phosphosulfate is an intermediate in sulfate assimilation and a substrate for synthesis of sulfate esters, such as the sulfated polysaccharides found in the glycocalyx of animal cells.

Figure 25.33 Cysteine biosynthesis. (a) Direct sulfhydrylation of serine by H₂S. (b) H₂S-dependent sulfhydrylation of O-acetylserine. (c) In mammals, Cys is synthesized from methionine (via homocysteine) and Ser by a reverse transsulfurylation pathway (blue-shaded reactions). The enzymes are CBS (cystathionine-β-synthase) and CGL (cystathionine-γ-lyase). (Figure part (c) adapted from Figure 2 in Lieu, E. L., Nguyen, T., Rhyne, S., and Kim, J., 2020. Amino acids in cancer. *Experimental and Molecular Medicine* 52:15–30.)

Figure 25.34 Sulfate assimilation and the generation of sulfide for synthesis of organic S compounds.

25.4g The Aromatic Amino Acids Are Synthesized from Chorismate

The aromatic amino acids, phenylalanine, tyrosine, and tryptophan, are derived from a shared pathway that has **chorismic acid** (Figure 25.35) as a key intermediate. Indeed, chorismate is common to the synthesis of cellular compounds having benzene rings, including these amino acids, the fat-soluble vitamins E and K, folic acid, as well as coenzyme Q and plastoquinone (the two quinones necessary to electron transport during respiration and photosynthesis, respectively). **Lignin**, a polymer of nine-carbon aromatic units, is also a derivative of chorismate. Lignin and related compounds can account for as much as 35% of the dry weight of higher plants; clearly, enormous amounts of carbon pass through the chorismate biosynthetic pathway.

Figure 25.35 Some of the aromatic compounds derived from chorismate.

Chorismate Is Synthesized from PEP and Erythrose-4-P Chorismate biosynthesis occurs via the **shikimate pathway** (Figure 25.36). The precursors for this pathway are the common metabolic intermediates *phosphoenolpyruvate* and *erythrose-4-phosphate*. These intermediates are linked to form *3-deoxy-D-arabino-heptulosonate-7-phosphate* (DAHP) by **DAHP synthase** (Figure 25.36, reaction 1). Although this reaction is remote from the ultimate aromatic amino acid end products, it is an important point for regulation of aromatic amino acid biosynthesis. In the next step on the way to chorismate, DAHP is cyclized to form a six-membered saturated ring compound, *5-dehydroquinate* (Figure 25.36, reaction 2), in a reaction catalyzed by **dehydroquinase** (NAD^+ is a coenzyme in this reaction but is not modified by it). A sequence of reactions ensues that introduces unsaturations into the ring through dehydration (Figure 25.36, reaction 3, **5-dehydroquinase**) and reduction (reaction 4, **shikimate dehydrogenase**), yielding *shikimate*. Phosphorylation of shikimate by **shikimate kinase** (reaction 5), then addition of PEP by **3-enolpyruvylshikimate-5-phosphate synthase** (reaction 6), followed by **chorismate synthase** (reaction 7), gives *chorismate*. Thus, two equivalents of PEP are needed to form chorismate from erythrose-4-P.

Phenylalanine and Tyrosine Share Prephenate as a Precursor At chorismate, the pathway separates into three branches, each leading specifically to one of the aromatic amino acids. The branches leading to phenylalanine and tyrosine both pass through *prephenate*

Figure 25.36 The shikimate pathway leading to the synthesis of chorismate.

(Figure 25.37). In some organisms, such as *E. coli*, the branches are truly distinct because prephenate does not occur as a free intermediate but rather remains bound to the bifunctional enzyme that catalyzes the first two reactions after chorismate. In any case, **chorismate mutase** is the first reaction leading to Phe or Tyr (Figure 25.37, reaction 1). In the Phe branch, the $-\text{OH}$ group *para* to the prephenate carboxyl is removed by **prephenate dehydratase** (Figure 25.37, reaction 2). In the Tyr branch, this $-\text{OH}$ is retained; instead, an oxidative decarboxylation of prephenate catalyzed by **prephenate dehydrogenase** (Figure 25.37, reaction 4) yields 4-hydroxyphenylpyruvate. Glutamate-dependent aminotransferases (**phenylalanine aminotransferase** [Figure 25.27, reaction 3] and **tyrosine aminotransferase** [reaction 5]) introduce the amino groups into the two α -keto acids, *phenylpyruvate* and *4-hydroxyphenylpyruvate*, to give Phe and Tyr, respectively. Some mammals can synthesize Tyr from Phe obtained in the diet via **phenylalanine-4-monooxygenase** (also known as **phenylalanine hydroxylase**), using O_2 and *tetrahydrobiopterin*, an analog of tetrahydrofolic acid, as co-substrates (Figure 25.38).

Figure 25.37 The biosynthesis of phenylalanine, tyrosine, and tryptophan from chorismate.

Figure 25.38 The formation of tyrosine from phenylalanine.

Tryptophan Is Synthesized from Chorismate and PRPP The pathway of tryptophan synthesis is perhaps the most thoroughly studied of any biosynthetic sequence, particularly in terms of its genetic organization and expression. Synthesis of Trp from chorismate requires six steps (see Figure 25.37). In most microorganisms, the first enzyme, **anthranilate synthase** (see Figure 25.37, reaction 6), is an $\alpha_2\beta_2$ -type protein, with the β -subunit acting in a glutamine–amidotransferase role to provide the $-\text{NH}_2$ group of anthranilate. Or, given high levels of NH_4^+ , the α -subunit can carry out the formation of anthranilate directly by a process in which the activity of the β -subunit is unnecessary. Furthermore, in certain enteric bacteria, such as *E. coli* and *Salmonella typhimurium*, the second reaction of the pathway, the **phosphoribosyl-anthranilate transferase** reaction (see Figure 25.37, reaction 7), is an activity catalyzed

A Deeper Look

Amino Acid Biosynthesis Inhibitors as Herbicides

Unlike animals, plants can synthesize all 20 of the common amino acids. Inhibitors acting specifically on the plant enzymes that are capable of carrying out the biosynthesis of the essential amino acids (that is, enzymes that animals lack) have been developed. These substances appear to be ideal for use as herbicides because they should show no effect on animals. **Glyphosate**, sold commercially as *Roundup*, is a PEP analog that acts as an uncompetitive inhibitor of 3-enolpyruvylshikimate-5-P synthase (Figure 25.36). **Sulfometuron methyl**, a sulfonylurea herbicide that

inhibits *acetohydroxy acid synthase*, an enzyme common to Val, Leu, and Ile biosynthesis (Figure 25.29), is the active ingredient in *Oust*. **Aminotriazole**, sold as *Amitrole*, blocks His biosynthesis by inhibiting *imidazole glycerol-P dehydratase* (Figure 25.40). **PPT (phosphinothricin)** is a potent inhibitor of *glutamine synthetase*. Although Gln is a nonessential amino acid and glutamine synthetase is a ubiquitous enzyme, PPT is relatively safe for animals because it does not cross the blood–brain barrier and is rapidly cleared by the kidneys.

by the α -subunit of anthranilate synthase. *PRPP* (5-phosphoribosyl-1-pyrophosphate), the substrate of this reaction, is also a precursor for purine biosynthesis (see Chapter 26). *Phosphoribosyl-anthranilate* then undergoes a rearrangement wherein the ribose moiety is isomerized to the ribulose form in *enol-1-(o-carboxyphenylamino)-1-deoxyribulose-5-phosphate* by *N-(5'-phosphoribosyl)-anthranilate isomerase* (see Figure 25.37, reaction 8). Decarboxylation and ring closure ensue to yield the indole nucleus as *indole-3-glycerol phosphate* (**indole-3-glycerol phosphate synthase**, reaction 9). The final two reactions (10 and 11 in Figure 25.37) are both catalyzed by **tryptophan synthase**, an $\alpha_2\beta_2$ -type protein. The α -subunit cleaves indoleglycerol-3-phosphate to form indole and 3-glycerol phosphate. The indole is then passed to the β -subunit, which adds serine in a PLP-dependent reaction.

X-ray crystallographic analysis of *S. typhimurium* tryptophan synthase shows that the active sites of the α - and β -subunits are separated from each other by 2.5 nm but are connected by a hydrophobic tunnel wide enough to accommodate indole (Figure 25.39). Indole, the product of the reaction catalyzed by the α -subunit (see Figure 25.37, reaction 10), can be transferred directly to the β -subunit, which catalyzes condensation with serine to yield Trp (see Figure 25.37, reaction 11). Thus, indole is not lost from the enzyme complex and diluted in the surrounding milieu. This phenomenon of direct transfer of enzyme-bound metabolic intermediates, or tunneling, increases the efficiency of the overall pathway by preventing loss and dilution of the intermediate. In addition, molecular tunnels protect reactive intermediates (some of which might be harmful) from potentially unproductive side reactions in the intracellular environment. Also, by directing the intermediate from one active site to another, these tunnels favor a particular reaction sequence. Molecular tunnels are found in many enzymes.

25.4h Histidine Biosynthesis and Purine Biosynthesis Are Connected by Common Intermediates

Like aromatic amino acid biosynthesis, **histidine** biosynthesis shares metabolic intermediates with the pathway of purine nucleotide synthesis. The pathway involves ten separate steps, the first being an unusual reaction that links ATP and PRPP (Figure 25.40). Five carbon atoms from PRPP and one from ATP end up in histidine. Step 5 involves some novel chemistry: The substrate, *phosphoribulosylformimino-5-aminoimidazole-4-carboxamide ribonucleotide*, picks up an amino group (from the amide of glutamine) in a reaction accompanied by cleavage and ring closure to yield two imidazole compounds—the histidine precursor, *imidazole glycerol phosphate*, and a purine nucleotide precursor, *5-aminoimidazole-4-carboxamide ribonucleotide* (AICAR). Note that AICAR as a purine nucleotide precursor can ultimately replenish the ATP consumed in

Figure 25.39 Tryptophan synthase ribbon diagram. The α -subunit is in blue, and the β -subunit is in orange (N-terminal domain) and red (C-terminal domain). The tunnel connecting them is outlined by the yellow dots and is shown with several indole molecules (green) packed in head-to-tail fashion. The labels “IPP” and “PLP” point to the active sites of the α - and β -subunits, respectively, in which a competitive inhibitor (indole propanol phosphate, IPP) and the coenzyme PLP are bound. (Adapted from Hyde, C. C., et al., 1988. Three-dimensional structure of the tryptophan synthase multienzyme complex from *Salmonella typhimurium*. *Journal of Biological Chemistry* **263**:17857–17871.)

Figure 25.40 The pathway of histidine biosynthesis. The following enzymes catalyze each reaction: (1) ATP-phosphoribosyl transferase, (2) pyrophosphohydrolase, (3) phosphoribosyl-AMP cyclohydrolase, (4) phosphoribosylformimino-5-aminoimidazole carboxamide ribonucleotide isomerase, (5) imidazole glycerol phosphate synthase, (6) imidazole glycerol-P dehydratase, (7) L-histidinol phosphate aminotransferase, (8) histidinol phosphate phosphatase, and (9) histidinol dehydrogenase.

reaction 1. Nine enzymes act in histidine's ten synthetic steps. Reactions 9 and 10, the successive NAD^+ -dependent oxidations of an alcohol to an aldehyde and then to a carboxylic acid, are catalyzed by the same dehydrogenase.

25.5 | How Does Amino Acid Catabolism Lead into Pathways of Energy Production?

In human adults, close to 90% of the energy requirement is met by oxidation of carbohydrates and fats; the remainder comes from oxidation of the carbon skeletons of amino acids derived from dietary protein. The dietary amount of free amino acids is trivial under most circumstances. The primary physiological purpose of amino acids is to serve as the building blocks for protein biosynthesis. However, if excess protein is consumed in the diet or if the amount of amino acids released during normal turnover of cellular proteins exceeds the requirements for new protein synthesis, the amino acid surplus must be catabolized. Also, if carbohydrate intake is insufficient (as during fasting or starvation) or if carbohydrates cannot be appropriately metabolized due to disease (as in *diabetes mellitus*), body protein becomes an important fuel for metabolic energy.

25.5a The 20 Common Amino Acids Are Degraded by 20 Different Pathways That Converge to Just 7 Metabolic Intermediates

Because the 20 common amino acids of proteins are distinctive in terms of their carbon skeletons, each amino acid requires its own unique degradative pathway. Dietary recommendations indicate that protein should provide humans with about 30% of their daily caloric intake, so no single amino acid contributes significantly to energy needs. Degradation of the carbon skeletons of the 20 common α -amino acids converges to just 7 metabolic intermediates: *acetyl-CoA*, *succinyl-CoA*, *pyruvate*, α -*ketoglutarate*, *fumarate*, *oxaloacetate*, and *acetoacetate* (Table 25.2). Because succinyl-CoA, pyruvate, α -ketoglutarate, fumarate, and oxaloacetate can serve as precursors for glucose synthesis, amino acids giving rise to these intermediates are termed **glucogenic**. Those degraded to yield acetyl-CoA or acetoacetate are termed **ketogenic**, because these substances can be used to synthesize fatty acids or ketone bodies. Some amino acids are both glucogenic and ketogenic (Figure 25.41). Only leucine and lysine are solely ketogenic.

The C-3 Family of Amino Acids: Alanine, Serine, and Cysteine The carbon skeletons of alanine, serine, and cysteine all converge to *pyruvate* (Figure 25.42). Transamination of alanine yields pyruvate:

Table 25.2 Grouping of Amino Acids According to Their Degradation Product*

Family	C-3	C-4	C-5	Succinyl-CoA	Fumarate	Acetyl-CoA	Acetoacetate
Degradation product	Pyruvate	Oxaloacetate	α -Ketoglutarate	Succinyl-CoA	Fumarate	Acetyl-CoA	Acetoacetate
Amino acids	Alanine Serine Cysteine Glycine Threonine Tryptophan	Aspartate Asparagine	Glutamate Glutamine Proline Arginine Histidine	Valine Isoleucine Methionine	Phenylalanine Tyrosine Aspartate‡	Leucine Isoleucine Threonine	Leucine Lysine Phenylalanine Tyrosine Tryptophan

*Five of the amino acid degradation product families lead to metabolic intermediates that can serve as substrates for gluconeogenesis, namely pyruvate, oxaloacetate, α -ketoglutarate, succinyl-CoA, and fumarate. The other two families lead to acetyl-CoA or acetoacetate, and these intermediates cannot be used as substrates for gluconeogenesis. Thus, amino acids in these degradation families contribute to ketone body formation.

‡Aspartate is readily deaminated to form oxaloacetate, but aspartate also leads to fumarate by virtue of the urea cycle (Figure 25.3, reaction 3) and reactions in the purine biosynthetic pathway (see Figure 26.3, reaction 9, and Figure 26.5).

Figure 25.41 Metabolic degradation of the common amino acids. Glucogenic amino acids are shown in *pink*, ketogenic in *blue*. Note that degradation of 12 of the 20 amino acids leads to a citric acid cycle intermediate.

Figure 25.42 Formation of pyruvate from alanine, serine, cysteine, glycine, tryptophan, or threonine.

Deamination of serine by **serine dehydratase** also yields pyruvate. Cysteine is converted to pyruvate via a number of paths.

The carbon skeletons of three other amino acids also become pyruvate. *Glycine* is convertible to serine and thus to pyruvate. The three carbon atoms of *tryptophan* that are not part of its indole ring appear as alanine (and, hence, pyruvate) upon tryptophan degradation. *Threonine* by one of its degradation routes is cleaved to glycine and acetaldehyde. The glycine is then converted to pyruvate via serine; the acetaldehyde is oxidized to acetyl-CoA (Figure 25.42).

The C-4 Family of Amino Acids: Aspartate and Asparagine Transamination of aspartate gives *oxaloacetate*:

Hydrolysis of asparagine by **asparaginase** yields aspartate and NH_4^+ . Alternatively, participation of aspartate in the urea cycle and purine biosynthesis converts its carbon skeleton to a different citric acid cycle intermediate, namely, *fumarate* (Figure 25.23).

The C-5 Family of Amino Acids Is Converted to α -Ketoglutarate via Glutamate The five-carbon citric acid cycle intermediate α -ketoglutarate is always a product of transamination reactions involving *glutamate*. Thus, glutamate and any amino acid convertible to glutamate are classified within the C-5 family. These amino acids include glutamine, proline, arginine, and histidine (Figure 25.43).

Figure 25.43 The degradation of the C-5 family of amino acids leads to α -ketoglutarate via glutamate. The histidine carbons, numbered 1 through 5, become carbons 1 through 5 of glutamate, as indicated.

Degradation of Valine, Isoleucine, and Methionine Leads to Succinyl-CoA The breakdown of valine, isoleucine, and methionine converges at *propionyl-CoA* (Figure 25.44). Methionine first becomes *S*-adenosylmethionine and then homocysteine (see Figure 25.28). The carboxyl groups from all three are lost as CO_2 . The two distal carbon atoms of isoleucine become acetyl-CoA. Propionyl-CoA subsequently is converted to methylmalonyl-CoA and thence to *succinyl-CoA* via the same reactions mediating the oxidation of fatty acids that have odd numbers of carbon atoms (see Section 23.3).

Leucine Is Degraded to Acetyl-CoA and Acetoacetate Leucine is one of only two purely ketogenic amino acids; the other is lysine. Deamination of leucine via a transamination reaction yields α -*ketoisocaproate*, which is oxidatively decarboxylated to *isovaleryl-CoA* (Figure 25.45). Subsequent reactions, one of which is a biotin-dependent carboxylation, give β -hydroxy- β -methylglutaryl-CoA, which is then cleaved to yield *acetyl-CoA* and *acetoacetate*, a ketone body (see Figure 23.26). Neither of these products is convertible to glucose.

Degradation of the Branched-Chain Amino Acids Follows a Common Pathway Valine, leucine, and isoleucine are the three amino acids with branched aliphatic side chains, and all three are essential amino acids. Unlike the other 17 amino acids, which are broken down principally in the liver, Val, Ile, and Leu are also degraded

Figure 25.44 Valine, isoleucine, and methionine are converted via propionyl-CoA to succinyl-CoA for entry into the citric acid cycle. The shaded carbon atoms of the three amino acids give rise to propionyl-CoA.

Figure 25.45 Leucine is degraded to acetyl-CoA and acetoacetate.

in adipose tissue and skeletal muscle. The first three reactions in their catabolism are identical (Figure 25.46). These reactions, a transamination, followed by an oxidative decarboxylation to form a coenzyme A derivative, and then another dehydrogenation, are localized in the mitochondrial matrix. The liver has low levels of the first enzyme, branched-chain amino acid aminotransferase (BRAT), thus explaining branched-chain amino acid (BCAA) degradation in other tissues. The oxidative

Figure 25.46 The first three steps for degradation of valine, isoleucine, and leucine follow a common pathway. Reaction 1 is catalyzed by the branched-chain amino acid aminotransferase; reaction 2 is catalyzed by the branched-chain α -keto acid dehydrogenase (BCKDH); and reaction 3 is catalyzed by the acyl-CoA dehydrogenase of the fatty acid β -oxidation pathway (see Figure 23.9, reaction 1). The carbons leading to succinyl-CoA via propionyl-CoA are shown within blue-shaded regions; those leading to acetyl-CoA in orange-shaded regions; and those to acetoacetate in green-shaded regions.

decarboxylation is carried out by the branched-chain α -keto acid dehydrogenase (BCKDH), an enzyme complex with striking similarity to the mitochondrial pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes discussed in Chapter 19 (see Figure 19.4 and Table 19.2). Hereditary defects in BCKDH leads to **maple sugar urine disease**. The α -keto acid derivatives of these amino acids accumulate in the blood and ultimately, in the urine, where their presence causes the urine to smell like maple syrup. Such defects lead to abnormal development, intellectual disability, and shortened lifespan, even if dietary intake of branched-chain amino acids (BCAAs) is restricted.

Lysine Degradation Lysine degradation proceeds by several pathways, but the *saccharopine pathway* found in liver predominates (Figure 25.47). This degradative route proceeds backward along the lysine biosynthetic pathway through saccharopine and α -aminoadipate to α -ketoadipate (see Figure 25.24). Next, α -ketoadipate undergoes oxidative decarboxylation to *glutaryl-CoA*, which is then transformed into *acetoacetyl-CoA* and ultimately into the ketone body, *acetoacetate*.

Phenylalanine and Tyrosine Are Degraded to Acetoacetate and Fumarate The first reaction in phenylalanine degradation is the hydroxylation reaction of *tyrosine* biosynthesis (see Figure 25.38). Both these amino acids thus share a common degradative pathway. Transamination of Tyr yields the α -keto acid *p*-hydroxyphenylpyruvate (Figure 25.48, reaction 1). ***p*-Hydroxyphenylpyruvate dioxygenase**, a vitamin C-dependent enzyme, then carries out a ring hydroxylation-oxidative decarboxylation to yield homogentisate (Figure 25.48, reaction 2). Ring opening and isomerization (Figure 25.48, reactions 3 and 4) give *4-fumaryl-acetoacetate*, which is hydrolyzed to *acetoacetate* and *fumarate* (reaction 6).

Tryptophan Degradation Tryptophan is the least abundant amino acid, so its catabolism to produce cellular energy is insignificant. However, tryptophan is a crucial precursor for synthesis of a variety of important substances, including the neurotransmitter **serotonin** (5-hydroxytryptamine) and the hormone **melatonin** (*N*-acetyl-5-methoxytryptamine). As noted earlier in the section on the degradation of the C-3 family of amino acids, degradation of the nonindole carbons of tryptophan yields pyruvate. The *indole ring* of Trp is converted by a series of reactions to α -ketoadipate and ultimately *acetoacetate* by the same reactions shown in Figure 25.47 for lysine. The first reaction in tryptophan degradation is catalyzed by **tryptophan-2,3-dioxygenase** and results in the formation of *N*-formyl-kynurenine; and then **kynurenine** (Figure 25.49). If not degraded to α -ketoadipate, kynurenine leads to the formation of a wide range of secondary metabolites, including **quinolinate** (2,3-pyridinedicarboxylate), which is a precursor to the B vitamin, **niacin**, and thus, to NAD^+ and NADP^+ synthesis. Interestingly, quinolinate is also a neurotoxic substance. Activation of the kynurenine pathway leading to quinolinate has been implicated in the neurodegeneration seen during aging, Alzheimer's disease, Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis.

Figure 25.47 Lysine degradation via the saccharopine, α -ketoadipate pathway culminates in the formation of the ketone body, acetoacetate.

Figure 25.48 Phenylalanine and tyrosine degradation.

Figure 25.49 In the initial reaction of tryptophan degradation, tryptophan is oxidized by tryptophan-2,3-dioxygenase to yield *N*-formylkynurenine. Kynurenine is then formed by the action of *N*-formylkynurenine formamidase. The metabolite quinolinate can be produced from tryptophan if kynurenine is not metabolized to α -ketoadipate.

Human Biochemistry

Amino Acid Metabolism and Cancer

Cancer is characterized by rapidly dividing cells with high energy demands. To meet the demands of growth, cancer cells extensively reorganize their metabolism. Glucose in the blood plasma (at more than 5 mM) is one source of energy and raw material for cancer cells, which elevate their glycolytic activity as a way of generating ATP for energy as well as metabolites for growth. Amino acids in blood plasma are another key resource for cancer-cell growth and proliferation, serving as the building blocks for synthesis of cancer-cell proteins but also as alternative fuels and as sources of carbon for anabolic pathways. In many cancers, amino acid metabolism is deregulated. The total concentration of amino acids in blood plasma exceeds 2 mM, with glutamine representing about 40% of that total. Glutamine is exploited by cancer cells following deamination and anaplerotic metabolism (see Chapter 19) to α -ketoglutarate, which enters the citric acid cycle (see Chapter 19). Branched-chain amino acids (BCAAs) such as isoleucine, leucine, and valine function as fuel sources through conversion to succinyl-CoA and as carbon sources for new lipid synthesis through formation of acetyl-CoA. The two key enzymes in BCAA metabolism, branched-chain aminotransferase (BCAT) and branched-chain keto acid dehydrogenase complex are overexpressed in many cancer types and the degree of overexpression correlates with malignancy. Aspartate, glutamate, glutamine, and glycine are pre-

cursors to purine and pyrimidine biosynthesis; nucleotide synthesis is absolutely essential for rapidly proliferating cells. Glycine, serine, and methionine contribute to formation of methyl groups necessary for purine as well as thymine synthesis.

Compared to normal cells, certain cancers show specific amino acid requirements or unique metabolic limitations and these dependencies make them vulnerable to targeted therapies. For example, both normal lymphocytes (a type of white blood cell) and the malignant lymphocytes of acute lymphoblastic leukemia (ALL) are highly dependent on the uptake of asparagine from the blood, since they do not express sufficient levels of asparagine synthetase. A successful strategy employed for many years is introduction of recombinant bacterial L-asparaginase into the plasma of ALL patients to lower Asn levels. Limiting exogenous asparagine or inhibiting its synthesis also reduces metastasis in breast cancer, resulting in cancer-cell death. Strategies addressing other cancers include limiting plasma levels of methionine, inhibiting glutaminase to block redirection of Gln into energy production or biosynthesis, and inhibiting BCAT to limit use of BCAAs as sources of carbon or fuel. As knowledge accumulates regarding the characteristic metabolic alterations defining different cancer-cell types, possibilities for therapeutic interventions will become even more promising.

25.5b Animals Differ in the Form of Nitrogen That They Excrete

Animals often enjoy a dietary surplus of nitrogen. Excess nitrogen liberated upon metabolic degradation of amino acids is excreted by animals in three different ways, based on the availability of water. Aquatic animals simply release free ammonia to the surrounding water; such animals are termed **ammonotelic** (from the Greek *telos*, meaning “end”). On the other hand, terrestrial and aerial species employ mechanisms that convert ammonium to less toxic waste compounds that require little H₂O for excretion. Many terrestrial vertebrates, including humans, are **ureotelic**, meaning that

Human Biochemistry

Hereditary Defects in Phe Catabolism Underlie Alkaptonuria and Phenylketonuria

Alkaptonuria and phenylketonuria are two human genetic diseases arising from specific enzyme defects in phenylalanine degradation. **Alkaptonuria** is characterized by urinary excretion of large amounts of homogentisate and results from a deficiency in **homogentisate dioxygenase** (step 3, Figure 25.48). Air oxidation of homogentisate causes urine to turn dark on standing, but the only malady suffered by carriers of this disease is a tendency toward arthritis later in life.

In contrast, **phenylketonurics**, whose urine contains excessive *phenylpyruvate* (see accompanying figure), suffer severe intellectual disability if the defect is not recognized immediately after birth and treated by putting the victim on a diet low in phenylalanine. These individuals are deficient in phenylalanine hydroxylase (Figure 25.38),

and the excess phenylalanine that accumulates is transaminated to phenylpyruvate and excreted.

they excrete excess N as **urea**, a highly water-soluble nonionic substance. Urea is formed by ureoteles via the urea cycle (see Figure 25.23). The **uricotelic** organisms are those animals using the third means of N excretion, conversion to **uric acid**, a rather insoluble purine analog. Birds and reptiles are uricoteles. Uric acid metabolism is discussed in the next chapter. Some animals can switch from ammonotelic to ureotelic to uricotelic metabolism, depending on water availability.

Foundational Biochemistry Things You Should Know after Reading Chapter 25.

- Nitrogen is cycled between organisms and the inanimate environment.
- The two principal forms of inorganic nitrogen in the environment are N_2 and nitrate.
- Nitrate assimilation is the principal pathway for ammonium biosynthesis and nitrogen acquisition in the biosphere.
- Nitrate assimilation is a two-step pathway consisting of nitrate reductase and nitrite reductase.
- Organisms gain access to atmospheric N_2 via the pathway of nitrogen fixation.
- The nitrogenase enzyme complex that reduces N_2 to $2 NH_4^+$ is composed of two metalloproteins.
- Ammonium is introduced into organic linkage principally through three enzymatic reactions: glutamate dehydrogenase, glutamine synthetase, and carbamoyl-P synthetase I.
- The major pathways of ammonium assimilation, the GDH/GS route and the GOGAT/GS route, both lead to glutamine synthesis.
- *E. coli* glutamine synthetase is regulated allosterically by feedback inhibition through the action of nine metabolites that are key indicators of cellular nitrogen status.
- Glutamine synthetase is regulated by covalent modification through adenylation of a Tyr side chain.
- Glutamine synthetase levels are regulated through controls on the expression of *GlnA*, the gene encoding the GS subunit.
- Glutamine is the most abundant amino acid in human body fluids and the brain.
- Amino acids are formed from α -keto acids by transamination.
- Aminotransferases (transaminases) are pyridoxal-P-dependent enzymes.
- Amino acids can be grouped into families according to the metabolic intermediate that serves as their progenitor.
- The amino acid progenitors are α -ketoglutarate, oxaloacetate, pyruvate, 3-phosphoglycerate, PEP, and erythrose-4-P.
- Humans can synthesize only 10 of the 20 common amino acids.
- Those amino acids that humans cannot synthesize are called essential amino acids.
- With only one minor exception, the pathways for essential amino acid synthesis contain more steps than the corresponding pathways for nonessential amino acid synthesis.
- The α -ketoglutarate family of amino acids includes glutamate, glutamine, proline, arginine, and lysine.
- The urea cycle acts to synthesize Arg and to excrete excess N through synthesis of urea, which is disposed of in the urine.
- The urea cycle can be viewed as both an ammonium and a bicarbonate disposal mechanism.
- The oxaloacetate family of amino acids includes Asp, Asn, Lys, Met, Thr, and Ile.
- Methionine, as S-adenosyl methionine (SAM), is the methyl donor in a variety of methylation reactions, including DNA methylation and histone modification.
- The pyruvate family of amino acids includes Ala, Val, and Leu.
- The 3-phosphoglycerate family of amino acids includes Ser, Gly, and Cys.
- The —SH group of cysteine comes from H_2S .
- H_2S synthesis from sulfate involves S-containing ATP derivatives.
- The aromatic amino acids are synthesized from chorismate.
- Chorismate is synthesized from PEP and erythrose-4-P.
- Chorismate is also a precursor for coenzyme Q, plastoquinone, vitamin E, and lignin.
- Anthranilate is an intermediate between chorismate and Trp in the tryptophan biosynthetic pathway.
- The pathways of essential amino acid biosynthesis are key targets of herbicides.
- Histidine biosynthesis and purine biosynthesis are connected by common intermediates.
- Dietary protein is an important source of fuel for energy production.
- The 20 common amino acids are degraded by 20 different pathways that converge to just seven metabolic intermediates: α -ketoglutarate, oxaloacetate, pyruvate, succinyl-CoA, fumarate, acetyl-CoA, and acetoacetate.
- Those amino acids that lead to α -ketoglutarate, oxaloacetate, pyruvate, succinyl-CoA, or fumarate are considered glucogenic amino acids because these intermediates can serve as substrates for gluconeogenesis.
- Those amino acids that lead to acetyl-CoA or acetoacetate are ketogenic amino acids because they lead to the formation of ketone bodies.
- Only Leu and Lys are solely ketogenic.
- Ala, Ser, and Cys are degraded to pyruvate, as is Gly.
- Thr is degraded to pyruvate and acetyl-CoA.
- Asp and Asn are degraded to oxaloacetate.

- Glu, Gln, Pro, Arg, and His are degraded to α -ketoglutarate.
- Degradation of Val, Ile, and Met leads to succinyl-CoA.
- Leu is degraded to acetyl-CoA and acetoacetate.
- Degradation of the branched-chain amino acids (Val, Leu, and Ile) follows a common pathway, a key reaction of which is the branched-chain α -keto acid dehydrogenase.
- Lys is degraded to acetoacetate.
- Phe and Tyr are degraded to fumarate and acetoacetate.
- Hereditary defects in Phe catabolism lead to alkaptonuria or phenylketonuria.
- Trp is degraded to pyruvate and acetoacetate.
- Trp is a precursor to the neurotransmitter serotonin, the hormone melatonin, and quinolinate, from which the B vitamin niacin can be formed.
- Amino acids in blood plasma are a key resource for cancer cells.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. The Oxidation States of Nitrogen** What is the oxidation number of N in nitrate, nitrite, NO, N_2O , and N_2 ?
- 2. The Energetic Cost of Nitrogen Acquisition from the Environment** How many ATP equivalents are consumed per N atom of ammonium formed by (a) the nitrate assimilation pathway and (b) the nitrogen fixation pathway? (Assume for this problem NADH, NADPH, and reduced ferredoxin are each worth three ATPs.)
- 3. Structure of Nitrogenase** Figure 25.5 shows the structures of metal clusters found in nitrogenase. One such cluster contains six iron atoms bonded to a single carbon atom. Carbon typically makes four chemical bonds. Explain how carbon could form six bonds.
- 4. Glutamate Dehydrogenase** Glutamate dehydrogenase catalyzes the reductive amination of α -ketoglutarate (see Figure 25.9). What is being reduced in this reaction?
- 5. Regulation of Glutamine Synthetase by Covalent Modification** Suppose at certain specific metabolite concentrations in vivo the cyclic cascade regulating *E. coli* glutamine synthetase has reached a dynamic equilibrium where the average state of GS adenylation is poised at $n = 6$. Predict what change in n will occur if:
 - a. [ATP] increases.
 - b. $\text{P}_{\text{IIA}}/\text{P}_{\text{IID}}$ increases.
 - c. $[\alpha\text{-KG}]/[\text{Gln}]$ increases.
 - d. $[\text{P}_i]$ decreases.
- 6. The Energetic Cost of Nitrogen Excretion via the Urea Cycle** How many ATP equivalents are consumed in the production of one urea equivalent by the urea cycle?
- 7. Why a High-Protein Diet Requires Greater Water Intake** Why are persons on a high-protein diet (such as the Atkins diet) advised to drink lots of water?
- 8. Succinylation in Biosynthesis of Lysine** A succinylation step is involved in the biosynthesis pathway of lysine, as shown in Figure 25.27. The formation of a carbon-nitrogen bond is an endergonic reaction. What provides the energy to drive this particular step in the pathway?
- 9. The Energetic Cost of Lysine Synthesis** How many ATP equivalents are consumed in the biosynthesis of lysine from aspartate by the pathway shown in Figure 25.27?
- 10. PEP as a Precursor for Aromatic Amino Acid Biosynthesis** If PEP labeled with ^{14}C in the 2-position serves as the precursor to chorismate synthesis, which C atoms in chorismate are radioactive?
- 11. Gluconeogenesis from Aspartate** (Integrates with Chapter 22.) Write a balanced equation for the synthesis of glucose (by gluconeogenesis) from aspartate.
- 12. Synthesis of Amino Acids from α -Keto Acids** For each of the 20 common amino acids, give the name of the enzyme that catalyzes the reaction providing its α -amino group.
- 13. Amino Acid Biosynthesis and TCA Cycle** (Integrates with Chapter 19) For which two amino acids is their biosynthetic pathway very similar to the first half of the TCA cycle?
- 14. The Essential Coenzyme in Amino Acid Metabolism** Which vitamin is central in amino acid metabolism? Why?
- 15. Vitamins and Coenzymes in Homocysteine Metabolism** Vitamins B_6 , B_{12} , and folate may be recommended for individuals with high blood serum levels of homocysteine (a condition called *hyperhomocysteinemia*). How might these vitamins ameliorate hyperhomocysteinemia?
- 16. Vitamins and Coenzymes in Branched-Chain Amino Acid Degradation** (Integrates with Chapter 19.) On the basis of the following information, predict a reaction mechanism for the mammalian branched-chain α -keto acid dehydrogenase complex (the BCKAD complex). This complex carries out the oxidative decarboxylation of the α -keto acids derived from valine, leucine, and isoleucine.
 - a. One form of maple syrup urine disease responds well to administration of thiamine.
 - b. Lipoic acid is an essential coenzyme.
 - c. The enzyme complex contains a flavoprotein.
- 17. Dietary Concerns in Phenylketonuria** People with phenylketonuria must avoid foods containing the low-calorie sweetener *Aspartame*, also known as *NutraSweet*. Find the structure of *Aspartame* in the Merck Index (or other scientific source), and state why these people must avoid this substance.
- 18. How the Herbicide Roundup Affects Plant Metabolism** Glyphosate (otherwise known as *Roundup*) is an analog of PEP. It acts as a noncompetitive inhibitor of 3-enolpyruvylshikimate-5-P synthase; it has the following structure in its fully protonated state:

$$\text{HOOC}-\text{CH}_2-\text{NH}-\text{CH}_2-\text{PO}_3\text{H}_2$$
 Consult Figures 25.35 and 25.36, and construct a list of the diverse metabolic consequences that might be experienced by a plant cell exposed to glyphosate.
- 19. Glycine Synthesis from Glucose** (Integrates with Chapter 18.) When cells convert glucose to glycine, which carbon atoms of glucose are represented in glycine?
- 20. Glucogenic Amino Acids** Review Figure 25.41 and explain why leucine and lysine cannot serve as precursors for gluconeogenesis.
- 21. A Deficiency on 3-Phosphoglycerate Dehydrogenase Can Affect Amino Acid Metabolism** Although serine is a nonessential amino acid, serine deficiency syndrome has been observed in humans. One such form of the syndrome is traceable to a deficiency in 3-phosphoglycerate dehydrogenase (see Figure 25.31). Individuals with this syndrome are serine-deficient and impaired in their ability to synthesize another common amino acid, as well as a class of lipids. Describe why.

- 22. Use the Protein Data Bank to Explore the Structure and Function of Glutamate Synthase** Go to <https://www.rcsb.org/>, and examine the PDB file 1LM1 for glutamate synthase. Find its iron–sulfur cluster and FMN prosthetic group. Discover how this enzyme is organized into an N-terminal domain that functions in ammonia removal from glutamine (the glutaminase domain) and the α -ketoglutarate-binding site near the Fe/S and flavin prosthetic groups. Consult van den Heuvel, R. H. H., et al., 2002. Structural studies on the synchronization of catalytic centers in glutamate synthase. *Journal of Biological Chemistry* **277**:24579–24583, to see how these two sites are connected by a tunnel for passage of ammonia from glutamine to α -ketoglutarate.
- 23. The Energy Cost of Using Dietary Protein as Food** The thermic effect of food is a term used to describe the energy cost of processing the food we eat, digesting it, and either turning it into precursors for needed biosynthesis, usable energy in the form of ATP, or storing the excess intake as fat. The thermic effect is usually approximated at 10% of the total calories consumed, but the thermic effect of fat is only 2% to 3% of total fat calories and the thermic effect of protein is 30% or more of calories consumed as protein. Why do you suppose dietary protein has a much higher thermic effect than either dietary carbohydrate or fat?
- 24.** From the dodecameric (α_{12}) structure of glutamine synthetase shown in Figure 25.14, predict the relative enzymatic activity of GS monomers (isolated α -subunits).
- 25.** Consider the synthesis and degradation of tyrosine as shown in Figures 25.37, 25.38, and 25.48 to determine where the carbon atoms in PEP and erythrose-4-P would end up in acetoacetate and fumarate.
- PSAFE Problems**
(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net/>.)
- 26.** Examine the PSAFE Model for glutamine synthetase, and describe the formation of the GS dodecamer.
- 27.** Using the PSAFE Model for glutamate oxaloacetate transaminase I as a guide, write a double-displacement (“ping-pong”) catalytic mechanism for this enzyme.

Think-Pair-Share Question

The biosynthesis of amino acids involves the consumption of ATP and reducing power in the form of NADPH or NADH, as is typical for anabolic reactions. For the list of amino acid biosynthesis reactions shown, describe the reduction step(s) (there can be more than one) and indicate the changes in oxidation numbers of the atom(s) involved.

- Biosynthesis of proline (Figure 25.20).
- Biosynthesis of ornithine (Figure 25.21).
- Biosynthesis of lysine in fungi (Figure 25.24).
- Biosynthesis of threonine (Figure 25.27).
- Biosynthesis of valine (Figure 25.29).
- Biosynthesis of leucine (Figure 25.30).

and Properties of Peruvian Guano (1850)*

- ▶ Pigeon drinking at Gaia Fountain, Siena, Italy. The basic features of purine biosynthesis were elucidated initially from metabolic studies of nitrogen metabolism in pigeons. Pigeons excrete excess N as uric acid, a purine analog.

Essential Question

Virtually all cells are capable of synthesizing purine and pyrimidine nucleotides. These compounds then serve as essential intermediates in metabolism and as the building blocks for DNA and RNA synthesis. **How do cells synthesize purines and pyrimidines?**

Nucleotides are ubiquitous constituents of life, actively participating in the majority of biochemical reactions. Recall that ATP is the energy currency of the cell, that uracil nucleotide derivatives of carbohydrates are common intermediates in cellular transformations of carbohydrates (see Chapter 22), and that biosynthesis of phospholipids proceeds via cytosine nucleotide derivatives (see Chapter 24). In Chapter 30, we will see that GTP serves as the immediate energy source driving the endergonic reactions of protein synthesis. Many of the coenzymes (such as coenzyme A, NAD, NADP, and FAD) are derivatives of nucleotides. Nucleotides also act in metabolic regulation, as in the response of key enzymes of intermediary metabolism to the relative concentrations of AMP, ADP, and ATP (PFK is a prime example here; see also Chapter 18). Furthermore, cyclic derivatives of purine nucleotides such as cAMP and cGMP have no other role in metabolism than regulation. Last but not least, nucleotides are the monomeric units of nucleic acids. Deoxynucleoside triphosphates (dNTPs) and nucleoside triphosphates (NTPs) serve as the immediate substrates for the biosynthesis of DNA and RNA, respectively.

26.1 | How Do Cells Synthesize Nucleotides?

Nearly all organisms can make the purine and pyrimidine nucleotides via so-called de novo biosynthetic pathways. (*De novo* means “anew”; a less literal but more apt translation might be “from scratch” because de novo pathways are metabolic sequences that form complex end products from rather simple precursors.) Many organisms also have salvage pathways to recover purine and pyrimidine compounds obtained in the diet or released during nucleic acid turnover and degradation. Whereas the ribose of nucleotides

Human PRPP synthetase (PDB id = 2H06). PRPP synthetase initiates the pathway for purine synthesis.

Figure 26.1 Nitrogen waste is excreted by birds principally as the purine analog, uric acid.

B. subtilis glutamine phosphoribosyl pyrophosphate amidotransferase (iron clusters in red, AMP in orange) (PDB id = 1GPH). Gln PRPP synthetase catalyzes the committed step in purine synthesis.

can be catabolized to generate energy, the nitrogenous bases do *not* serve as energy sources; their catabolism does not lead to products used by pathways of ATP synthesis.

Compared to slowly dividing cells, rapidly proliferating cells synthesize larger amounts of DNA and RNA per unit time. To meet the increased demand for nucleic acid synthesis, substantially greater quantities of nucleotides must be produced. The pathways of nucleotide biosynthesis thus become attractive targets for the clinical control of rapidly dividing cells such as cancers or infectious bacteria. Many antibiotics and anticancer drugs are inhibitors of purine or pyrimidine nucleotide biosynthesis.

26.2 | How Do Cells Synthesize Purines?

Substantial insight into the *de novo* pathway for purine biosynthesis was provided in 1948 by John Buchanan, who cleverly exploited the fact that birds excrete excess nitrogen principally in the form of uric acid, a water-insoluble purine analog. Buchanan fed isotopically labeled compounds to pigeons and then examined the distribution of the labeled atoms in *uric acid* (Figure 26.1). By tracing the metabolic source of the various atoms in this end product, he showed that the nine atoms of the purine ring system (Figure 26.2) are contributed by aspartic acid (N-1), glutamine (N-3 and N-9), glycine (C-4, C-5, and N-7), CO₂ (C-6), and THF one-carbon derivatives (C-2 and C-8). THF is tetrahydrofolate, a coenzyme serving as a one-carbon transfer agent, not only in purine ring synthesis but also in amino acid metabolism (see Figures 25.27 and 25.32) and in synthesis of the pyrimidine thymine (see Figure 26.26). The formation and function of THF is summarized in A Deeper Look box “Tetrahydrofolate and One-Carbon Units.”

26.2a IMP Is the Immediate Precursor to GMP and AMP

The *de novo* synthesis of purines occurs in an interesting manner: The atoms forming the purine ring are successively added to *ribose-5-phosphate*; thus, purines are directly synthesized as nucleotide derivatives by assembling the atoms that comprise the purine ring system directly on the ribose. Beginning with ribose-5-P and ending with IMP, the pathway consists of 11 enzymatic steps (Figure 26.1). In step 1, ribose-5-phosphate is activated via the direct transfer of a pyrophosphoryl group from ATP to C-1 of the ribose, yielding *5-phosphoribosyl- α -pyrophosphate* (PRPP) (Figure 26.3). The enzyme is **ribose-5-phosphate pyrophosphokinase** (also known as **PRPP synthetase**). PRPP is the limiting substance in purine biosynthesis. The two major purine nucleoside diphosphates, ADP and GDP, are negative effectors of ribose-5-phosphate pyrophosphokinase. However, because PRPP serves additional metabolic needs, the next reaction is actually the committed step in the pathway. Because of this, some discussions of purine biosynthesis number the enzymes starting with Step 2.

Step 2 is catalyzed by **glutamine phosphoribosyl pyrophosphate amidotransferase**. The anomeric carbon atom of the substrate PRPP is in the α -configuration; the product is a β -glycoside (recall that all the biologically important nucleotides are β -glycosides). The N atom of this *N*-glycoside becomes N-9 of the nine-membered purine ring; it is the first atom added in the construction of this ring. Glutamine PRPP amidotransferase is subject to feedback inhibition by GMP, GDP, and GTP as well as AMP, ADP, and ATP. The G series of nucleotides interacts at a guanine-specific allosteric site on the enzyme, whereas the adenine nucleotides act at an A-specific site. The pattern of inhibition by these nucleotides is such that residual enzyme activity remains until sufficient amounts

Figure 26.2 The metabolic origin of the nine atoms in the purine ring system.

Figure 26.3 The de novo pathway for purine synthesis. The atoms added in each step are highlighted in color. Note the change in ribose-5-P representation after step 4. IMP (inosine monophosphate or inosinic acid) serves as a precursor to AMP and GMP.

A Deeper Look

Tetrahydrofolate and One-Carbon Units

Folic acid, a B vitamin found in green plants, fresh fruits, yeast, and liver, takes its name from *folium*, Latin for “leaf.” Folic acid is a *pterin* (the 2-amino-4-oxo derivative of pteridine); pterins are named from the Greek word *pté ryj*, for “wing,” because these substances were first identified as the pigments in insect wings. Mammals cannot synthesize pterins and thus cannot make folates; they derive folates from their diet or from microorganisms in their intestines. (See the Human Biochemistry box “Folate Analogs as Antimicrobial and Anticancer Agents” for the complete structure of folate.)

Folates are acceptors and donors of one-carbon units for all oxidation levels of carbon except CO_2 (for which biotin is the relevant carrier). The active form is **tetrahydrofolate (THF)**. THF is formed through two successive reductions of folate by *dihydrofolate reductase* (panel a of figure). One-carbon units in three different oxidation states may be bound to THF at the N^5 or N^{10} nitrogens (table shown on page 925 and panel b of figure). The one-carbon unit carried by THF can come from formate (HCOO^-), the α -carbon of glycine, the β -carbon of serine (see Figure 25.32), or the 3-position carbon in the imidazole ring of histidine. NADPH-dependent reactions interconvert the oxidation states of the various THF-bound one-carbon units.

(Continued)

Oxidation States of Carbon in One-Carbon Units Carried by Tetrahydrofolate			
Oxidation Number*	Oxidation Level	One-Carbon Form [†]	Tetrahydrofolate Form
−2	Methanol (most reduced)	—CH ₃	N ⁵ -Methyl-THF
0	Formaldehyde	—CH ₂ —	N ⁵ ,N ¹⁰ -Methylene-THF
2	Formate (most oxidized)	—CH=O	N ⁵ -Formyl-THF
		—CH=O	N ¹⁰ -Formyl-THF
		—CH=NH	N ⁵ -Formimino-THF
		—CH=	N ⁵ ,N ¹⁰ -Methenyl-THF

*Calculated by assigning valence bond electrons to the more electronegative atom and then counting the charge on the quasi ion. A carbon assigned four valence electrons would have an oxidation number of 0. The carbon in N⁵-methyl-THF is assigned six electrons from the three C—H bonds and thus has an oxidation number of −2.

[†]Note: All vacant bonds in the structures shown are to atoms more electronegative than C.

of both adenine and guanine nucleotides are synthesized. Glutamine phosphoribosyl pyrophosphate amidotransferase is also sensitive to inhibition by the glutamine analog **azaserine** (Figure 26.4). Azaserine has been used as an antitumor agent because it irreversibly inactivates glutamine-dependent enzymes by reacting with nucleophilic groups at the glutamine-binding site. Two such enzymes are found at steps 2 and 5 of the purine biosynthetic pathway.

Step 3 is carried out by **glycinamide ribonucleotide synthetase (GAR synthetase)** via its ATP-dependent condensation of the glycine carboxyl group with the amine of 5-phosphoribosyl-β-amine (see Figure 26.3). The reaction proceeds in two stages. First, the glycine carboxyl group is activated via ATP-dependent phosphorylation. Next, an amide bond is formed between the activated carboxyl group of glycine and the β-amine. Glycine contributes C-4, C-5, and N-7 of the purine.

Step 4 is the first of two THF-dependent reactions in the purine pathway of eukaryotes. (In *E. coli* and related organisms, formate, not N¹⁰-formyl-THF, is the source of formyl groups, both here in and in step 10. In prokaryotes, these reactions depend on ATP for formate activation.) **GAR transformylase** transfers the N¹⁰-formyl group of N¹⁰-formyl-THF to the free amino group of GAR to yield α-N-formylglycinamide ribonucleotide (FGAR). Thus, C-8 of the purine is “formyl-ly” introduced. Although all of the atoms of the imidazole portion of the purine ring are now present, the ring is not closed until Reaction 6.

Step 5 is catalyzed by **FGAR amidotransferase** (also known as *FGAM synthetase*). ATP-dependent transfer of the glutamine amido group to the C-4-carbonyl of FGAR yields formylglycinamidine ribonucleotide (FGAM). The imino-N becomes N-3 of the purine.

Step 6 is an ATP-dependent dehydration that leads to formation of the imidazole ring. ATP is used to phosphorylate the oxygen atom of the formyl group, activating it for the ring closure step that follows. Because the product is 5-aminoimidazole ribonucleotide, or AIR, this enzyme is called **AIR synthetase**. In higher organisms, the enzymatic activities for steps 3, 4, and 6 (GAR synthetase, GAR transformylase, and AIR synthetase) reside on a single multifunctional polypeptide.

In step 7, carbon dioxide is added at the C-4 position of the imidazole ring by **AIR carboxylase** in an ATP-dependent reaction; the carbon of CO₂ will become C-6 of the purine ring. The product is carboxyaminoimidazole ribonucleotide (CAIR).

In step 8, the amino-N of aspartate provides N-1 through linkage to the C-6 carboxyl function of CAIR. ATP hydrolysis drives the condensation of Asp with CAIR. The product is N-succinyl-5-aminoimidazole-4-carboxamide ribonucleotide (SAICAR). **SAICAR synthetase** catalyzes the reaction. The enzymatic activities for steps 7 and 8 reside on a single, bifunctional polypeptide in eukaryotes known as PAICS, an acronym for phosphoribosylaminoimidazole carboxylase and phosphoribosylaminoimidazolesuccinocarboxamide synthetase, which are alternative names for AIR carboxylase and SAICAR synthetase.

Azaserine

Glutamine

Figure 26.4 The structure of azaserine. Azaserine acts as an irreversible inhibitor of glutamine-dependent enzymes by covalently attaching to nucleophilic groups in the glutamine-binding site.

Human Biochemistry

SAICAR Is a Key Signal for Metabolic Reprogramming in Cancer Cells

Cancer cells show two distinctive hallmarks: altered metabolism and enhanced proliferation. How cancer cells coordinate their various metabolic pathways to sustain high growth rates is a subject of intensive biomedical investigation. A key player is pyruvate kinase isoform M2 (PK M2)—see the Critical Developments in Biochemistry box “The Warburg Effect and Cancer” in Chapter 18. Interestingly, recent studies have demonstrated that the purine biosynthetic intermediate SAICAR is an allosteric activator of PK M2. SAICAR levels rise in glucose-starved cancer cells (from as little as 0.02 mM to as much as 0.7 mM). The effective SAICAR concentration for half-maximal activation of PK M2 is 0.3 mM. The k_{cat} of the PK M2 reaction increases by 2- to 3-fold upon SAICAR binding and its K_m for PEP drops 20-fold (from 2 mM to 0.1 mM). This activation of PK M2 allows the cells to redirect their metabolism away from the use of glycolytic intermediates for anabolic purposes if glucose is not abundant, rebalancing the flow of metabolites

to maintain pathways of energy production. Even more surprisingly, PK M2 is a protein kinase that uses PEP, not ATP, to phosphorylate more than 100 different human proteins (see also the Human Biochemistry box “Pyruvate Kinase M₂ Moonlights as a Protein Kinase in Cancer,” in Section 18.4). Most of these proteins are themselves protein kinases that are involved in the regulation of cell growth and division. Thus, SAICAR, by activating PK M2, is serving as a key signal to reprogram metabolism in cancer cells under nutrient-limited conditions.

- Keller, K. E., Doctor, Z. M., Dwyer, Z. W., and Lee, Y.-S., 2014. SAICAR induces protein kinase activity of PK M2 that is necessary for sustained proliferative signaling of cancer cells. *Molecular Cell* **53**:700–709.

Step 9 removes the four carbons of Asp as fumarate in a nonhydrolytic cleavage. The product is *5-aminoimidazole-4-carboxamide ribonucleotide (AICAR)*; the enzyme is **adenylosuccinase** (*adenylosuccinate lyase*). Adenylosuccinase acts again in that part of the purine pathway leading from IMP to AMP and takes its name from this latter reaction (see following). AICAR is also a by-product of the histidine biosynthetic pathway (see Figure 25.40), but because ATP is the precursor to AICAR in that pathway, no net purine synthesis is achieved.

Step 10 adds the formyl carbon of *N*¹⁰-formyl-THF as the ninth and last atom necessary for forming the purine nucleus. The enzyme that mediates this reaction is called **AICAR transformylase**; the products are THF and *N-formylaminoimidazole-4-carboxamide ribonucleotide (FAICAR)*.

Step 11 involves dehydration and ring closure to form the purine nucleotide **IMP (inosine-5'-monophosphate or inosinic acid)**; this completes the initial phase of purine biosynthesis. The enzyme catalyzing this reaction is **IMP cyclohydrolase** (also known as *IMP synthase* and *inosinase*). Unlike step 6, this ring closure does not require ATP. In bacteria and eukaryotes, but not archaea, the enzymatic activities catalyzing steps 10 and 11 (AICAR transformylase and inosinase) activities reside on a bifunctional polypeptide that dimerizes.

Thus, in higher organisms, 6 of the 11 enzymatic activities for purine synthesis are localized to 3 polypeptides: The enzymes for steps 3, 4, and 6 are found on a trifunctional polypeptide, and those for steps 7 and 8 and for 10 and 11 are found on bifunctional polypeptides. In total then, 6 proteins achieve the 11 steps necessary for IMP formation, starting from PRPP. Benkovic and his colleagues have shown in a cultured human cell line that these six proteins cluster together in the cytosol to form multiprotein complexes when the cells are purine-depleted. This association is dynamic, because when the cell medium is supplemented with purines, the clustered proteins disperse. Benkovic and his colleagues have called these clusters *purinosomes*, since they represent the agents of de novo purine biosynthesis (Figure 26.5). Further, adenylosuccinate synthetase, IMP dehydrogenase, and GMP synthetase, enzymes downstream from IMP, which lead to AMP and GMP, respectively, are also part of the purinosome. (Adenylosuccinate synthetase and IMP dehydrogenase are described in the paragraphs under *AMP and GMP Are Synthesized from IMP*, which follows). The purinosome is an excellent example of metabolic channeling, the transfer of metabolites between different enzymic sites on a multifunctional polypeptide chain (discussed further in Section 26.5a).

Note that six ATPs are required in the purine biosynthetic pathway from ribose-5-phosphate to IMP: one each at steps 1, 3, 5, 6, 7, and 8. However, seven high-energy phosphate bonds (equal to seven ATP equivalents) are consumed because α -PRPP formation in step 1 followed by PP_i release in step 2 represents the loss of two ATP equivalents.

Careers in Chemistry

Dr. Allison C. Augustus-Wallace

Dr. Allison C. Augustus-Wallace earned her B.S. of Biochemistry as well as her M.S. in Natural Sciences-Biochemistry at Louisiana State University. This was followed by the earning of her M.S. in Healthcare Management from the University of New Orleans before receiving her Ph.D. from Louisiana State University Health Science Center-New Orleans, School of Graduate Studies, Dept. of Biochemistry and Molecular Biology.

Dr. Augustus-Wallace was born and reared in Baton Rouge, Louisiana by her devoted parents, Dr. Henry Augustus, III and Mrs. Sarah L. Rowe-Augustus, M.Ed., M.S. (both deceased), with her three siblings and large and loving family. She now

lives in Mandeville, LA with her adoring husband, Mr. Hugh V. Wallace, III, M.Ed. M.S., who is a Principal in Tangipahoa Parish, LA. She is a member of the faculty of the LSU Health Sciences Center-New Orleans as an Associate Professor-Research and Director of Undergraduate Academic Pathway Programs for Diversity, in the School of Medicine's Office of Diversity and Community Engagement. There, she works tirelessly to provide greater educational access to historically marginalized groups in the fields of medicine and biomedical research, encouraging these individuals to promote health equity in their respective communities.

The purinosome metabolon

Figure 26.5 Purinosomes—the dynamic metabolons that synthesize purines. Purinosomes are protein complexes that collectively bear all of the enzymatic activities needed to synthesize purine nucleotides from PRPP. The six proteins shown are PPAT (phosphoribosyl pyrophosphate amidotransferase; step 2), GART (GAR synthetase/GAR transformylase/AIR synthetase; steps 3, 4, and 6), PFAMS (phosphoribosylformylglycinamide synthase; step 5), PAICS (AIR carboxylase/SAICAR synthetase; steps 7 and 8), ADSL (adenylosuccinate lyase; step 9), and ATIC (AICAR transformylase/IMP synthase; steps 10 and 11). As shown, purinosomes localize near mitochondria, the sources of formate and glycine, two essential substrates for this pathway. (Though they are also part of the purinosome, not shown in the figure are the three additional proteins—adenylosuccinate synthetase, IMP dehydrogenase, and GMP synthetase—necessary for AMP and GMP synthesis from IMP.) (Adapted from the figure in Alexandrov, T., 2020. Probing metabolism in time and space. *Science* 368:241–242.)

Human Biochemistry

Folate Analogs as Antimicrobial and Anticancer Agents

The dependence of *de novo* purine biosynthesis on folic acid compounds at steps 4 and 10 means that antagonists of folic acid metabolism indirectly inhibit purine formation and, in turn, nucleic acid synthesis, cell growth, and cell division. Clearly, rapidly dividing cells such as malignancies or infective bacteria are more susceptible to these antagonists than slower-growing normal cells. Among the folic acid antagonists are *sulfonamides* (see accompanying figure, part a). Folic acid is a vitamin for animals and is obtained in the diet. In contrast, bacteria synthesize folic acid from precursors, including *p*-aminobenzoic acid (PABA), and thus are more susceptible to sulfonamides than are animal cells.

Formation of THF, the functional folate form, depends on reduction of folate (and dihydrofolate or DHF) by dihydrofolate

reductase, or DHFR (see A Deeper Look box “Tetrahydrofolate and One-Carbon Units”). Methotrexate (amethopterin), aminopterin, and trimethoprim are three analogs of folic acid (see accompanying figure, part b). The first two have been used in cancer chemotherapy and the treatment of autoimmune disorders. Each binds to DHFR with about 1000-fold greater affinity than folate or DHF, thus acting as a virtually irreversible inhibitor of THF formation. Trimethoprim acts more effectively on bacterial DHFR and is prescribed for infections of the urinary tract. Next-generation folate-analog inhibitors of DHFR include lipophilic molecules that can passively diffuse across cell membranes. These molecules are being used to develop new anti-cancer drugs as well as antibiotics targeted at bacterial and parasitic infections.

(a) Sulfa drugs, or sulfonamides, owe their antibiotic properties to their similarity to *p*-aminobenzoate (PABA), an important precursor in folic acid synthesis. Sulfonamides block folic acid formation by competing with PABA. (b) Precursors and analogs of folic acid employed as antimetabolites include methotrexate, aminopterin, and trimethoprim, as well as sulfonamides.

26.2b AMP and GMP Are Synthesized from IMP

IMP is the precursor to both AMP and GMP. These major purine nucleotides are formed via distinct two-step metabolic pathways that diverge from IMP. The branch leading to AMP (adenosine 5'-monophosphate) involves the displacement of the 6-O group of inosine with aspartate (Figure 26.6) in a GTP-dependent reaction, followed

Figure 26.6 The synthesis of AMP and GMP from IMP. **(a)** AMP synthesis: The two reactions of AMP synthesis mimic steps 8 and 9 in the purine pathway leading to IMP. **(b)** GMP synthesis.

by the nonhydrolytic removal of the four-carbon skeleton of Asp as fumarate; the Asp amino group remains as the 6-amino group of AMP. **Adenylosuccinate synthetase** and **adenylosuccinase** are the two enzymes catalyzing these reactions. Recall that adenylosuccinase also acted at step 9 in the pathway from ribose-5-phosphate to IMP. Fumarate production provides a connection between purine synthesis and the citric acid cycle.

The formation of GMP from IMP requires oxidation at C-2 of the purine ring, followed by a glutamine-dependent amidotransferase reaction that replaces the oxygen on C-2 with an amino group to yield 2-amino,6-oxo purine nucleoside monophosphate, or as this compound is commonly known, *guanosine monophosphate* (Figure 26.6). The enzymes in the GMP branch are **IMP dehydrogenase** and **GMP synthetase**. Note that, starting from ribose-5-phosphate, eight ATP equivalents are consumed in the synthesis of AMP and nine in the synthesis of GMP.

26.2c The Purine Biosynthetic Pathway Is Regulated at Several Steps

The regulatory network that controls purine synthesis is schematically represented in Figure 26.7. The purine biosynthetic pathway from ribose-5-phosphate to IMP is allosterically regulated at the first two steps. Ribose-5-phosphate pyrophosphokinase, although not the committed step in purine synthesis, is subject to feedback inhibition by ADP and GDP. The enzyme catalyzing the next step, glutamine phosphoribosyl pyrophosphate amidotransferase (Gln PRPP amidotransferase) has two allosteric sites, one where the A series of nucleoside phosphates (AMP, ADP, and ATP) binds and feedback-inhibits, and another where the corresponding G series binds and inhibits. Furthermore, PRPP is a feed-forward activator of this enzyme. Thus, the rate of IMP formation by this pathway is governed by the levels of the final end products, the adenine and guanine nucleotides.

The purine pathway splits at IMP. The first enzyme in the AMP branch, adenylosuccinate synthetase, is competitively inhibited by AMP. Its counterpart in the GMP branch, IMP dehydrogenase, is inhibited in a similar fashion by GMP. Thus, the fate of IMP is determined by the relative levels of AMP and GMP, so any deficiency in the

Human adenylosuccinate lyase (AMP in red; PDB id = 2J91)

GMP synthetase tetramer with Mg^{2+} (yellow) adjacent to AMP (red; PDB id = 1GPM).

amount of either of the principal purine nucleotides is self-correcting. This reciprocity of regulation is an effective mechanism for balancing the formation of AMP and GMP to satisfy cellular needs. Note also that reciprocity is even manifested at the level of energy input: GTP provides the energy to drive AMP synthesis, whereas ATP serves this role in GMP synthesis (Figure 26.7).

Further, IMP dehydrogenase has another function: It not only serves in purine nucleotide biosynthesis and allosteric regulation, but it is also a DNA-binding protein involved in the regulation of gene expression in eukaryotic cells. Depending on metabolic state and/or cellular stress, IMP dehydrogenase moves from the cytosol into the nucleus, where it acts in a transcriptional repressor role to ensure that cell proliferation is coupled to metabolic sufficiency.

26.2d ATP-Dependent Kinases Form Nucleoside Diphosphates and Triphosphates from the Nucleoside Monophosphates

The products of de novo purine biosynthesis are the nucleoside monophosphates AMP and GMP. These nucleotides are converted by successive phosphorylation reactions into their metabolically prominent triphosphate forms, ATP and GTP. The first phosphorylation, to give the nucleoside diphosphate forms, is carried out by two base-specific, ATP-dependent kinases, **adenylate kinase** and **guanylate kinase**.

These nucleoside monophosphate kinases also act on deoxynucleoside monophosphates to give dADP or dGDP.

Oxidative phosphorylation (see Chapter 20) is primarily responsible for the conversion of ADP into ATP. ATP then serves as the phosphoryl donor for synthesis of the other nucleoside triphosphates from their corresponding NDPs in a reaction catalyzed by **nucleoside diphosphate kinase**, a nonspecific enzyme. For example,

Because this enzymatic reaction is readily reversible and nonspecific with respect to both phosphoryl acceptor and donor, in effect any NDP can be phosphorylated by any NTP. The preponderance of ATP over all other nucleoside triphosphates means that, in quantitative terms, it is the principal nucleoside diphosphate kinase substrate. The enzyme does not discriminate between the ribose moieties of nucleotides and thus functions in phosphoryl transfers involving deoxy-NDPs and deoxy-NTPs as well.

26.3 | Can Cells Salvage Purines?

Nucleic acid turnover (synthesis and degradation) is an ongoing metabolic process in most cells. Messenger RNA in particular is actively synthesized and degraded. These degradative processes can lead to the release of free purines in the form of adenine, guanine, and hypoxanthine (the base in IMP). Purines represent a metabolic investment by cells. So-called salvage pathways exist to recover them in useful form. Also, purine salvage is the only way to form purine nucleotides in some parasitic organisms, such as protozoans like *Giardia*. Salvage reactions involve resynthesis of nucleotides from bases via **phosphoribosyltransferases**.

The subsequent hydrolysis of PP_i to inorganic phosphate by pyrophosphatases renders the phosphoribosyltransferase reaction effectively irreversible.

The purine phosphoribosyltransferases are **adenine phosphoribosyltransferase (APRT)**, which mediates AMP formation, and **hypoxanthine-guanine phosphoribosyltransferase (HGPRT)**, which can act on either hypoxanthine to form IMP or guanine to form GMP (Figure 26.8).

Human HGPRT (Mg^{2+} in yellow, α -PRPP in blue, purine analog in red; PDB id = 1D6N).

26.4 | How Are Purines Degraded?

Because nucleic acids are ubiquitous in cellular material, significant amounts are ingested in the diet. Nucleic acids are degraded in the digestive tract to nucleotides by various nucleases and phosphodiesterases. Nucleotides are then converted to nucleosides by base-specific nucleotidases and nonspecific phosphatases.

Figure 26.8 Purine salvage by the HGPRT reaction.

Human Biochemistry

Lesch–Nyhan Syndrome—HGPRT Deficiency Leads to a Severe Clinical Disorder

The symptoms of **Lesch–Nyhan syndrome** are tragic: a crippling, gouty arthritis due to excessive uric acid accumulation (uric acid is a purine degradation product, discussed in Section 26.4) and, worse, severe malfunctions in the nervous system that lead to intellectual disability, spasticity, aggressive behavior, and self-mutilation. Lesch–Nyhan syndrome results from a complete deficiency in HGPRT activity. The structural gene for HGPRT is located on the X chromosome, and the disease is a congenital, recessive, sex-linked trait manifested only in males. The severe consequences of HGPRT deficiency argue that purine salvage has greater metabolic importance than simply the energy-saving recovery of bases. Although HGPRT might seem to play a minor role in purine metabolism, its absence has profound consequences: De novo purine biosynthesis is dramatically increased, and uric acid levels in the blood are elevated. Presumably, these changes ensue because lack of consumption of PRPP by HGPRT elevates its availability for glutamine-PRPP amidotransferase, enhancing overall de novo purine synthesis and, ultimately, uric acid production (see accompanying figure). The dramatically elevated uric acid levels lead to the particular neurological aberrations characteristic of the syndrome. Fortunately, deficiencies in HGPRT activity in fetal cells can be detected following amniocentesis. However, no medication alleviates the neurological and behavioral consequences of this disease.

Nucleosides are hydrolyzed by nucleosidases or nucleoside phosphorylases to release the purine base:

The pentoses liberated in these reactions provide the only source of metabolic energy available from purine nucleotide degradation.

Feeding experiments using radioactively labeled nucleic acids as metabolic tracers have demonstrated that little of the nucleotide ingested in the diet is incorporated into cellular nucleic acids. Dietary purines are converted to uric acid in the gut and excreted, and pyrimidine nucleosides are inefficiently absorbed into the bloodstream. These findings confirm the de novo pathways of nucleotide biosynthesis as the primary source of nucleic acid precursors. Ingested bases are, for the most part, excreted. Nevertheless, cellular nucleic acids do undergo degradation in the course of the continuous recycling of cellular constituents.

Adenosine deaminase. Bound inhibitor (purple) identifies the active site; Zn^{2+} ion (cyan; PDB id = 1WXY).

26.4a The Major Pathways of Purine Catabolism Lead to Uric Acid

The major pathways of purine catabolism in animals lead to uric acid formation (Figure 26.9). The various nucleotides are first converted to nucleosides by **intracellular nucleosidases**. These nucleosidases are under strict metabolic regulation to ensure that their substrates, which act as intermediates in many vital processes, are not depleted below critical levels. Nucleosides are then degraded by the enzyme **purine nucleoside phosphorylase (PNP)** to release the purine base and ribose-1-P. Note that neither adenosine nor deoxyadenosine is a substrate for PNP. Instead, these nucleosides are first converted to inosine by **adenosine deaminase**. The PNP products are merged into **xanthine** by **guanine deaminase** and **xanthine oxidase**, and xanthine is then oxidized to uric acid by this latter enzyme.

Human Biochemistry

Severe Combined Immunodeficiency Syndrome—A Lack of Adenosine Deaminase Is One Cause of This Inherited Disease

Severe combined immunodeficiency syndrome, or **SCID**, is a group of related inherited disorders characterized by the lack of an immune response to infectious disease. This immunological insufficiency is attributable to the inability of B and T lymphocytes to proliferate and produce antibodies in response to an antigenic challenge. About 30% of SCID patients suffer from a deficiency in the enzyme *adenosine deaminase* (*ADA*). ADA deficiency is also implicated in a variety of other diseases, including AIDS, anemia, and various lymphomas and leukemias. **Gene therapy**, the repair of a genetic deficiency through introduction of a functional recombinant version of the gene, has been performed on individuals with

SCID due to a defective *ADA* gene (see Section 12.5). *ADA* is a Zn^{2+} -dependent enzyme, and Zn^{2+} deficiency can also lead to reduced immune function.

In the absence of *ADA*, deoxyadenosine is not deaminated to deoxyinosine as normal (see Figure 26.9). Instead, it is salvaged by a nucleoside kinase, which converts it to dAMP. Phosphorylation of dAMP leads to dATP, a potent feedback inhibitor of deoxynucleotide biosynthesis (discussed in Section 26.7). Without deoxyribonucleotides, DNA cannot be replicated and cells cannot divide (see accompanying figure). Rapidly proliferating cell types such as lymphocytes are particularly susceptible if DNA synthesis is impaired.

26.4b The Purine Nucleoside Cycle in Skeletal Muscle Serves as an Anaplerotic Pathway

Deamination of AMP to IMP by **AMP deaminase** (Figure 26.9) followed by resynthesis of AMP from IMP by the de novo purine pathway enzymes, *adenylosuccinate synthetase* and *adenylosuccinate lyase*, constitutes a purine nucleoside cycle (Figure 26.10). This cycle has the net effect of converting aspartate to fumarate plus NH_4^+ . Although this cycle might seem like senseless energy consumption, it plays an important role in energy metabolism in skeletal muscle: The fumarate that it generates replenishes the levels of citric acid cycle intermediates lost in amphibolic side reactions (see Chapter 19). Skeletal muscle lacks the usual complement of anaplerotic enzymes and relies on enhanced levels of AMP deaminase, adenylosuccinate synthetase, and adenylosuccinate lyase to compensate.

26.4c Xanthine Oxidase

Xanthine oxidase (Figure 26.9) is present in large amounts in liver, intestinal mucosa, and milk. It oxidizes hypoxanthine to xanthine and xanthine to uric acid. Xanthine oxidase is a rather indiscriminate enzyme, using molecular oxygen to oxidize a wide variety of purines, pteridines, and aldehydes, producing H_2O_2 as a product. Xanthine oxidase possesses FAD, nonheme Fe-S centers, and *molybdenum cofactor* (a molybdenum-containing pterin complex very similar to the one shown in Figure 25.2) as electron-transferring prosthetic groups. In humans and other primates, uric acid is the end product of purine catabolism and is excreted in the urine. Birds, terrestrial reptiles, and many insects also excrete uric acid, but in these organisms, uric acid represents the major nitrogen excretory compound because, unlike mammals, they do not also produce urea (see Section 25.4d). Instead, the catabolism of all nitrogenous compounds, including amino acids, is channeled into uric acid. This route of nitrogen catabolism allows these animals to conserve water by excreting crystals of uric acid in paste-like solid form.

Figure 26.9 The major pathways for purine catabolism convert the common purine nucleotides to uric acid.

26.4d Gout Is a Disease Caused by an Excess of Uric Acid

Gout is the clinical term describing the physiological consequences accompanying excessive uric acid accumulation in body fluids. Uric acid and urate salts are rather insoluble in water and tend to precipitate from solution if produced in excess. The most common symptom of gout is arthritic pain in the joints as a result of urate deposition in cartilaginous tissue. The joint of the big toe is particularly susceptible. Urate crystals may also appear as kidney stones and lead to painful obstruction of the urinary tract. **Hyperuricemia**, chronic elevation of blood uric acid levels, occurs in about 3% of the population as a consequence of impaired excretion of uric acid or overproduction of purines. Purine-rich foods such as caviar (fish eggs rich in nucleic acids)

Figure 26.10 The purine nucleoside cycle for anaplerotic replenishment of citric acid cycle intermediates in skeletal muscle.

may exacerbate the condition. The biochemical causes of gout are varied. A common treatment for gout is *allopurinol* (Figure 26.11). This hypoxanthine analog binds tightly to xanthine oxidase, thereby inhibiting its activity and preventing uric acid formation. Hypoxanthine and xanthine do not accumulate to harmful concentrations because they are more soluble and thus more easily excreted.

26.4e Different Animals Oxidize Uric Acid to Form Various Excretory Products

The subsequent metabolism of uric acid in organisms that don't excrete it is shown in Figure 26.12. In molluscs and in mammals other than primates, uric acid is oxidized by **urate oxidase** to *allantoin* and excreted. In bony fishes (teleosts), uric acid degradation proceeds through yet another step wherein allantoin is hydrolyzed to *allantoic acid* by **allantoinase** before excretion. Cartilaginous fish (sharks and rays) and amphibians further degrade allantoic acid via the enzyme **allantoicase** to liberate glyoxylic acid and 2 equivalents of *urea*. Even simpler animals, such as most marine invertebrates (crustacea and so forth), use **urease** to hydrolyze urea to CO_2 and ammonia. In contrast to animals that must rid themselves of potentially harmful nitrogen waste products, microorganisms often are limited in growth by nitrogen availability. Many possess an identical pathway of uric acid degradation, using it instead to liberate NH_3 from uric acid so that it can be assimilated into organic-N compounds essential to their survival.

Figure 26.11 Allopurinol, an analog of hypoxanthine, is a potent inhibitor of xanthine oxidase.

26.5 | How Do Cells Synthesize Pyrimidines?

In contrast to purines, pyrimidines are not synthesized as nucleotide derivatives. Instead, the pyrimidine ring system is constructed before a ribose-5-P moiety is attached. Also, only two precursors, carbamoyl-P and aspartate, contribute atoms to the six-membered pyrimidine ring (Figure 26.13), compared to seven precursors for the nine purine atoms.

Figure 26.12 The catabolism of uric acid to allantoin, allantoinic acid, urea, or ammonia in various animals.

26.5a The Pyrimidine Biosynthetic Pathway from Carbamoyl-P and Aspartate to UMP

Mammals have two enzymes for carbamoyl phosphate synthesis. Carbamoyl phosphate for pyrimidine biosynthesis is formed by **carbamoyl phosphate synthetase II (CPS-II)**, a cytosolic enzyme. Recall that carbamoyl phosphate synthetase I is a mitochondrial enzyme dedicated to the urea cycle and arginine biosynthesis (see Figures 25.22 and 25.23). The substrates of carbamoyl phosphate synthetase II are HCO_3^- , H_2O , glutamine, and two ATPs (Figure 26.14). Thus, the N atom in carbamoyl phosphate made by CPS-II comes from the amide group of glutamine. The first ATP is used to form carboxy phosphate, an activated form of CO_2 (Figure 26.14, step 1). The glutamine amide displaces phosphate from carboxy phosphate to give carbamate (step 2). Phosphorylation of carbamate by the second ATP in the overall reaction yields carbamoyl phosphate (step 3). Because carbamoyl phosphate made by CPS-II in mammals has no fate other than incorporation into pyrimidines, mammalian CPS-II can be viewed as the committed step in the pyrimidine de novo pathway (Figure 26.15, step 1). Bacteria and plants have only one CPS, and its carbamoyl phosphate product is incorporated into arginine as well as pyrimidines. Thus, the committed step in bacterial pyrimidine synthesis is the next reaction, which is mediated by **aspartate transcarbamoylase (ATCase)**.

ATCase catalyzes the condensation of carbamoyl phosphate with aspartate to form carbamoyl aspartate (Figure 26.15, step 2). No ATP input is required at this step because carbamoyl phosphate is an activated carbamoyl group.

Step 3 of pyrimidine synthesis involves ring closure and dehydration via linkage of the $-\text{NH}_2$ group introduced by carbamoyl phosphate with the $\beta\text{-COO}^-$ of aspartate; this reaction is mediated by the enzyme **dihydroorotase**. The product of the reaction is **dihydroorotate (DHO)**, a six-membered ring compound. Dihydroorotate is not a true pyrimidine, but its oxidation yields **orotate**, which is. This oxidation (step 4) is catalyzed by **dihydroorotate dehydrogenase**. Bacterial dihydroorotate dehydrogenases are NAD^+ -linked flavoproteins which are somewhat unusual in possessing both FAD and FMN; these enzymes also have nonheme Fe-S centers as additional redox prosthetic groups. The eukaryotic version of dihydroorotate dehydrogenase is a protein component of the inner mitochondrial membrane; its immediate e^- acceptor is a quinone, and oxidation of the reduced quinone by the mitochondrial e^- transport chain can drive ATP synthesis via oxidative phosphorylation. At this stage, ribose-5-phosphate is joined to N-1 of orotate in appropriate $N\text{-}\beta$ -glycosidic configuration, giving the pyrimidine nucleotide **orotidine-5'-monophosphate**, or **OMP** (step 5, Figure 26.15). The ribose phosphate donor is PRPP; the enzyme is **orotate phosphoribosyltransferase**. The next reaction is catalyzed by **OMP decarboxylase**. Decarboxylation of OMP gives UMP (uridine-5'-monophosphate, or uridylic acid), one of the two common pyrimidine ribonucleotides.

26.5b UMP Synthesis Leads to Formation of the Two Most Prominent Ribonucleotides—UTP and CTP

The two prominent pyrimidine ribonucleotide products are derived from UMP via the same unbranched pathway. First, UDP is formed from UMP via an ATP-dependent **nucleoside monophosphate kinase**.

Figure 26.13 The metabolic origin of the six atoms of the pyrimidine ring.

Figure 26.14 The carbamoyl phosphate synthetase II (CPS-II) reaction converts bicarbonate and glutamine into carbamoyl-P and glutamate at the expense of two ATP.

Figure 26.15 The de novo pyrimidine biosynthetic pathway synthesizes UMP from carbamoyl-P, aspartate, and PRPP.

Figure 26.16 CTP synthetase catalyzes the ATP-dependent transfer of the amido group of Gln to UTP, forming CTP.

Then, UTP is formed by *nucleoside diphosphate kinase*.

Amination of UTP at the 6-position gives CTP. The enzyme **CTP synthetase** is a glutamine amidotransferase (Figure 26.16). ATP hydrolysis provides the energy to drive the reaction. Human CTP synthetase, like acetyl-CoA carboxylase (Chapter 24), is one of many metabolic enzymes known to assemble into filamentous structures. UTP and ATP favor such assembly and CTP and ADP reverse their effects. CTP synthetase filaments are enzymatically more active than the CTP synthetase tetramers from which they are formed.

26.5c Pyrimidine Biosynthesis Is Regulated at ATCase in Bacteria and at CPS-II in Animals

Pyrimidine biosynthesis in bacteria is allosterically regulated at aspartate transcarbamoylase (ATCase). *Escherichia coli* ATCase is feedback inhibited by the end product, CTP. ATP, which can be viewed as a signal of both energy availability and purine sufficiency, is an allosteric activator of ATCase. CTP and ATP compete for a common allosteric site on the enzyme. In many bacteria, UTP, not CTP, acts as the ATCase feedback inhibitor.

In animals, CPS-II catalyzes the committed step in pyrimidine synthesis and serves as the focal point for allosteric regulation. UTP is a feedback inhibitor of the CPS-II activity of CAD, whereas PRPP is an allosteric activator. Figure 26.17 compares the regulatory circuits governing pyrimidine synthesis in bacteria and animals.

Figure 26.17 A comparison of the regulatory circuits that control pyrimidine synthesis in *E. coli* and animals.

26.5d “Metabolic Channeling” by Multifunctional Enzymes of Mammalian Pyrimidine Biosynthesis

CPS-II (Figure 26.15), glutamine 5-phosphoribosyl- α -pyrophosphate amidotransferase (see Figure 26.3), and CTP synthetase (Figure 26.16) are enzymes with metabolite tunnels (see also Figure 25.39). In a subtle distinction, **metabolic channeling** refers to the transfer of metabolites between different enzymic sites on a **multifunctional polypeptide chain** as seen in Figure 26.5 for purinosomes.

In bacteria, the six enzymes of de novo pyrimidine biosynthesis exist as distinct proteins, each independently catalyzing its specific step in the overall pathway. In contrast, in mammals, the six enzymatic activities are distributed among only three proteins, two of which are multifunctional polypeptides. The first three steps of pyrimidine synthesis, CPS-II, aspartate transcarbamoylase, and dihydroorotase, are all localized on a single 250-kDa multifunctional polypeptide called CAD, from the first letters of its three enzymatic activities. CAD polypeptides assemble to form hexameric, 1.5 megadalton particles. Step 4 in Figure 26.15 is catalyzed by DHO dehydrogenase, a separate enzyme associated with the outer surface of the inner mitochondrial membrane, but the enzymatic activities mediating steps 5 and 6, namely, orotate phosphoribosyltransferase and OMP decarboxylase in mammals, are also found on a single cytosolic polypeptide known as **UMP synthase**.

Such multifunctional enzymes confer an advantage: The product of one reaction in a pathway is the substrate for the next. In multifunctional enzymes, such products remain bound and are channeled directly to the next active site, rather than dissociated into the surrounding medium for diffusion to the next enzyme. This metabolic channeling is more efficient for a variety of reasons: Transit time for movement from one active site to the next is shortened, substrates are not diluted into the solvent phase, chemically reactive intermediates are protected from decomposition in the aqueous milieu, no pools of intermediates accumulate, and intermediates are shielded from interactions with other enzymes that might metabolize them. The end result is that metabolic channeling can increase the catalytic efficiency of a reaction sequence by as much as two orders of magnitude while minimizing the overall concentration of the metabolic intermediates involved.

26.6 | How Are Pyrimidines Degraded?

In some organisms, free pyrimidines are salvaged and recycled to form nucleotides via phosphoribosyltransferase reactions similar to those discussed earlier for purines. In humans, however, pyrimidines are recycled from nucleosides, but free pyrimidine bases are not salvaged. Pyrimidine catabolism results in degradation of the pyrimidine ring to products reminiscent of the original substrates, aspartate, CO_2 , and ammonia (Figure 26.18). β -Alanine can be recycled into the synthesis of coenzyme A. Catabolism of the pyrimidine base, thymine (5-methyluracil), yields β -aminoisobutyric acid instead of β -alanine.

Interestingly, exercise induces the release of β -aminoisobutyric acid (or BAIBA) from muscle. BAIBA leads to activation of fatty acid oxidation in the liver and promotes the formation of brown adipose tissue from white fat. Levels of BAIBA in the blood are inversely correlated with metabolic risk factors. It has been known for a long time that exercise protects against metabolic diseases. It is now proposed that BAIBA mediates this protective effect.

Pathways presented thus far in this chapter account for the synthesis of the four principal ribonucleotides: ATP, GTP, UTP, and CTP. These compounds serve important coenzymic functions in metabolism and are the immediate precursors for ribonucleic acid (RNA) synthesis. Roughly 90% of the total nucleic acid in cells is RNA, with the remainder being deoxyribonucleic acid (DNA). DNA differs from RNA in being a polymer of deoxyribonucleotides, one of which is deoxythymidylic acid. We now turn to the synthesis of these compounds.

Figure 26.18 Pyrimidine degradation.

Figure 26.19 Deoxyribonucleotide synthesis involves reduction at the 2'-position of the ribose ring of nucleoside diphosphates.

Structure of the human ribonucleotide reductase R1 dimer. One monomer is shown in yellow, the other in cyan. The catalytic, or C, sites are occupied by GDP (orange); the specificity, or S, sites are occupied by TTP (green); and the activity, or A, sites are occupied by ATP (purple). This molecular graphic is a composite of PDB id = 3HND and PDB id = 3HNE. (Adapted from Figure 1 in Fairman, J. W., et al., 2011. Structural basis for regulation of human ribonucleotide reductase by nucleotide-induced oligomerization. *Nature Structural and Molecular Biology* 18:316–323.)

26.7 How Cells Form the Deoxyribonucleotides That Are Necessary for DNA Synthesis?

The deoxyribonucleotides have only one metabolic purpose: to serve as precursors for DNA synthesis. In most organisms, ribonucleoside diphosphates (NDPs) are the substrates for deoxyribonucleotide formation. Reduction at the 2'-position of the ribose ring in NDPs produces 2'-deoxy forms of these nucleotides (Figure 26.19). This reaction involves replacement of the 2'-OH by a hydride ion (H^-) and is catalyzed by an enzyme known as **ribonucleotide reductase**. Enzymatic ribonucleotide reduction involves a free radical mechanism, and three classes of ribonucleotide reductases are known, differing from each other in their mechanisms of free radical generation. Class I enzymes, found in *E. coli* and virtually all eukaryotes, are Fe-dependent and generate the required free radical on a specific tyrosyl side chain.

26.7a *E. coli* Ribonucleotide Reductase Has Three Different Nucleotide-Binding Sites

The enzyme system for dNDP formation consists of four proteins, two of which constitute the ribonucleotide reductase proper, an enzyme of the $\alpha_2\beta_2$ type. The other two proteins, **thioredoxin** and **thioredoxin reductase**, function in the delivery of reducing equivalents, as we shall see shortly. The two proteins of ribonucleotide reductase are designated **R1** (86 kDa) and **R2** (43.5 kDa), and each is a homodimer in the holoenzyme (Figure 26.20). The R1 homodimer carries two types of regulatory sites in addition to the catalytic site (the active site). Substrates (ADP, CDP, GDP, and UDP) bind at the catalytic site. One regulatory site—the **substrate specificity site**—binds ATP, dATP, dGTP, or dTTP, and which of these nucleotides is bound there determines which nucleoside diphosphate is bound at the catalytic site. The other regulatory site, the **overall activity site**, binds either the activator ATP or the negative effector dATP; the nucleotide bound here determines whether the enzyme is active or inactive. Activity depends also on residues Cys⁴³⁹, Cys²²⁵, and Cys⁴⁶² in R1. The R2 homodimer is the source of the free radical that initiates the ribonucleotide reductase reaction. Its two Fe atoms generate this free radical on R2 Tyr¹²², which in turn generates a thiyl free radical (Cys-S $\cdot$) on Cys⁴³⁹. Cys⁴³⁹-S $\cdot$ initiates ribonucleotide reduction by abstracting the 3'-H from the ribose ring of the nucleoside diphosphate substrate (Figure 26.21) and forming a free radical on C-3'. Subsequent dehydration forms the deoxyribonucleotide product.

Figure 26.20 *E. coli* ribonucleotide reductase is an $\alpha_2\beta_2$ tetramer organized as a dimer of R1 and R2 dimers.

Figure 26.21 The free radical mechanism of ribonucleotide reduction. H_a designates the C-3' hydrogen, and H_b , the C-2' hydrogen atom. The polypeptide chain of R1 is represented by the green band carrying the Cys residues of R1 involved in the reaction mechanism.

26.7b Thioredoxin Provides the Reducing Power for Ribonucleotide Reductase

NADPH is the ultimate source of reducing equivalents for ribonucleotide reduction, but the immediate source is reduced **thioredoxin**, a small (12 kDa) protein with reactive Cys-sulfhydryl groups situated near one another in the sequence Cys-Gly-Pro-Cys. These Cys residues are able to undergo reversible oxidation–reduction between (—S—S—) and (—SH HS—) and, in their reduced form, serve as primary electron donors to regenerate the reactive —SH pair of the ribonucleotide reductase active site (Figure 26.21). In turn, the sulfhydryls of thioredoxin must be restored to the (—SH HS—) state for another catalytic cycle. **Thioredoxin reductase**, an α_2 -type enzyme composed of 58-kDa flavoprotein subunits, mediates the NADPH-dependent reduction of thioredoxin (Figure 26.22). Thioredoxin functions in a number of metabolic roles besides deoxyribonucleotide synthesis, the common denominator of which is reversible sulfide: sulfhydryl transitions.

The substrates for ribonucleotide reductase are CDP, UDP, GDP, and ADP, and the corresponding products are dCDP, dUDP, dGDP, and dADP. Because CDP is not an intermediate in pyrimidine nucleotide synthesis, it must arise by dephosphorylation of CTP, for instance, via nucleoside diphosphate kinase action. Although uridine nucleotides do not occur in DNA, UDP is a substrate. The formation of dUDP is justified because it is a precursor to dTTP, a necessary substrate for DNA synthesis (see following discussion).

Figure 26.22 NADPH is the ultimate source of reducing power for ribonucleotide reduction. **(a)** The (—S—S—)/(—SH HS—) oxidation–reduction cycle involving ribonucleotide reductase, thioredoxin, thioredoxin reductase, and NADPH. **(b)** Thioredoxin reductase (α_2 dimer) with bound ligands: FAD (gold) and NADP analog (blue). Each α -subunit is associated with a thioredoxin molecule (yellow; PDB id = 1F6M).

26.7c Both the Specificity and the Catalytic Activity of Ribonucleotide Reductase Are Regulated by Nucleotide Binding

Ribonucleotide reductase activity must be modulated in two ways to maintain an appropriate balance of the four deoxynucleotides essential to DNA synthesis, namely, dATP, dGTP, dCTP, and dTTP. First, the overall activity of the enzyme must be turned on and off in response to the need for dNTPs. Second, the relative amounts of each NDP substrate transformed into dNDP must be controlled so that the right balance of dATP:dGTP:dCTP:dTTP is produced. The two different allosteric sites on ribonucleotide reductase, discrete from the substrate-binding catalytic site, are designed to serve these purposes. As noted previously, these two allosteric sites are designated the *overall activity site* and the *substrate specificity site*. Only ATP and dATP are able to bind at the overall activity site. ATP is an allosteric activator and dATP is an allosteric inhibitor, and they compete for the same site. If ATP is bound, the enzyme is active, whereas if its deoxy counterpart, dATP, occupies this site, the enzyme is inactive. Although ATP is more abundant than dATP, dATP binds to ribonucleotide reductase with 100-fold greater affinity. When dATP binds, R1 dimers aggregate to form inactive hexamers; ATP binding reverses this oligomerization.

The second allosteric site, the substrate specificity site, can bind either ATP, dTTP, dGTP, or dATP, and the substrate specificity of the enzyme is determined by which of these nucleotides occupies this site. If ATP is in the substrate specificity site, ribonucleotide reductase preferentially binds pyrimidine nucleotides (UDP or CDP) at its active site and reduces them to dUDP and dCDP. With dTTP in the specificity-determining site, GDP is the preferred substrate. When dGTP binds to the specificity site, ADP becomes the favored substrate for reduction. The rationale for these varying affinities is as follows (Figure 26.23): High [ATP] is consistent with cell growth and division and, consequently, the need for DNA synthesis. Thus, ATP binds in the overall activity site of ribonucleotide reductase, turning it on and promoting production of dNTPs for DNA synthesis. Under these conditions, ATP is also likely to occupy the substrate specificity site, so UDP and CDP are bound at the catalytic site and reduced to dUDP and dCDP. Both of these pyrimidine deoxynucleoside diphosphates are precursors to dTTP. Thus, elevation of dUDP and dCDP levels leads to an increase in [dTTP]. High dTTP levels increase the likelihood that it will occupy the substrate specificity site, in which case GDP becomes the preferred substrate and dGTP levels rise. Upon dGTP association with the substrate specificity site, ADP is the favored substrate, leading to ADP reduction and the eventual accumulation of dATP. Binding of dATP to the overall activity site then shuts the enzyme down. In summary, the relative affinities of the three classes of nucleotide-binding sites in ribonucleotide reductase for the various substrates, activators, and inhibitors are such that the formation of dNDPs proceeds in an orderly and balanced fashion. As these dNDPs are formed in amounts consistent with cellular needs, their phosphorylation by nucleoside diphosphate kinases produces dNTPs, the actual substrates of DNA synthesis.

Figure 26.23 Regulation of deoxynucleotide biosynthesis: the rationale for the various affinities displayed by the two nucleotide-binding regulatory sites on ribonucleotide reductase.

26.8 | How Are Thymine Nucleotides Synthesized?

The synthesis of thymine nucleotides proceeds from other pyrimidine deoxyribonucleotides. Cells have no requirement for free thymine ribonucleotides and do not synthesize them. Small amounts of thymine ribonucleotides do occur in tRNA (tRNA is notable for having unusual nucleotides), but these Ts arise via methylation of U residues already incorporated into the tRNA. Both dUDP and dCDP can lead to formation of dUMP, the immediate precursor for dTMP synthesis (Figure 26.24). Interestingly, formation of dUMP from dUDP passes through dUTP, which is then cleaved by **dUTPase**, a pyrophosphatase that removes PP_i from dUTP. The action of dUTPase prevents dUTP from serving as a substrate in DNA synthesis. An alternative route to dUMP formation starts with dCDP, which is dephosphorylated to dCMP and then deaminated by **dCMP deaminase** (Figure 26.25), leaving dUMP. dCMP deaminase provides a second point for allosteric regulation of dNTP synthesis; it is allosterically activated by dCTP and feedback-inhibited by dTTP. Of the four dNTPs, only dCTP does not interact with either of the regulatory sites on ribonucleotide reductase (see Figure 26.20). Instead, it acts upon dCMP deaminase.

Synthesis of dTMP from dUMP is catalyzed by **thymidylate synthase** (Figure 26.26). This enzyme methylates dUMP at the 5-position to create dTMP; the methyl donor is the one-carbon folic acid derivative N^5,N^{10} -methylene-THF. The reaction is actually a reductive methylation in which the one-carbon unit is transferred at the methylene level of reduction and then reduced to the methyl level. The THF cofactor is oxidized at the expense of methylene reduction to yield DHF. DHFR then reduces DHF back to THF for service again as a one-carbon vehicle (see panel a of the figure in A Deeper Look box “Tetrahydrofolate and One-Carbon Units” in Section 26.2). Thymidylate synthase sits at a junction connecting dNTP synthesis with folate metabolism. It has become a preferred target for inhibitors designed to disrupt DNA synthesis. An indirect approach is to employ folic acid precursors or analogs as antimetabolites of dTMP synthesis (see panel b of the figure in A Deeper Look box “Folate Analogs as Antimicrobial and Anticancer Agents” in Section 26.2). Purine synthesis is affected as well because it is also dependent on THF (see Figure 26.3).

Figure 26.24 Pathways of dTMP synthesis. dTMP production is dependent on dUMP formation from dCDP and dUDP.

Figure 26.25 Deamination of dCMP forms dUMP. (a) The dCMP deaminase reaction. (b) Trimeric dCMP deaminase. Each chain has a bound dCTP molecule (purple) and a Mg^{2+} ion (orange; PDB id = 1XS4).

Figure 26.26 Thymidylate is synthesized from UMP and N^5, N^{10} methylene-THF. (a) The thymidylate synthase reaction. The 5- CH_3 group is ultimately derived from the β -carbon of serine. (b) Thymidylate synthase dimer. Each monomer has a bound folate analog (green) and dUMP (light blue; PDB id = 1JUI).

Human Biochemistry

Fluoro-Substituted Pyrimidines in Cancer Chemotherapy, Fungal Infections, and Malaria

5-Fluorouracil (5-FU; see part a of the figure) is a thymine analog. It is converted in vivo to 5'-fluorouridylyl by a PRPP-dependent phosphoribosyltransferase and passes through the reactions of dNTP synthesis, culminating ultimately as 2'-deoxy-5-fluorouridylic acid, a potent inhibitor of dTMP synthase (see A Deeper Look box "Fluoro-Substituted Analogs Are Good Trojan Horse Inhibitors" in Section 26.8). 5-FU is used as a chemotherapeutic agent in the treatment of human cancers. Similarly, 5-fluorocytosine (see part b) is used as an antifungal drug because fungi, unlike mammals, can convert it to 2'-deoxy-5-fluorouridylyl. Furthermore, malarial parasites can use exogenous orotate to make pyrimidines for nucleic acid synthesis, whereas mammals cannot. Thus, 5-fluoroorotate (see part c) is an effective antimalarial drug because it is selectively toxic to these parasites.

A Deeper Look

Fluoro-Substituted Analogs Are Good Trojan Horse Inhibitors

Carbon–fluorine bonds are exceedingly rare in nature, and fluorine is an uncommon constituent of biological molecules. F has three properties attractive to drug designers: (1) It is the smallest replacement for an H atom in organic synthesis, (2) fluorine is the most electronegative element, and (3) the F—C bond is relatively unreactive. This steric compactness and potential for strong inductive effects through its electronegativity renders F a useful substituent in the construction of inhibitory analogs of enzyme substrates. One interesting strategy is to devise fluorinated precursors that are taken up and processed by normal metabolic pathways to generate a potent antimetabolite. A classic example is fluoroacetate. FCH_2COO^- is exceptionally toxic because it is readily converted to fluorocitrate by citrate synthase of the citric acid cycle (see Chapter 19). In turn, fluorocitrate is a powerful inhibitor of aconitase. The metabolic transformation of an otherwise innocuous compound into a poisonous derivative is termed **lethal synthesis**. 5-Fluorouracil and 5-fluorocytosine are also examples of this strategy.

Unlike hydrogen, which is often abstracted from substrates as H^+ , electronegative fluorine cannot be readily eliminated as the corresponding F^+ . Thus, enzyme inhibitors can be fashioned in which F replaces H at positions where catalysis involves H removal as H^+ . Thymidylate synthase catalyzes removal of H from dUMP as H^+ through a covalent catalysis mechanism. A thiol group on this enzyme normally attacks the 6-position of the uracil moiety of 2'-deoxyuridylic acid so that C-5 can act as a carbanion in attack on the methylene carbon of N^5,N^{10} -methylene-THF (see accompanying figure). Regeneration of free enzyme then occurs through loss of the C-5 H atom as H^+ and dissociation of product dTMP. If F replaces H at C-5 as in 2'-deoxy-5-fluorouridylate (FdUMP), the enzyme is immobilized in a very stable ternary [enzyme:FdUMP:methylene-THF] complex and effectively inactivated. Enzyme inhibitors like FdUMP whose adverse properties are elicited only through direct participation in the catalytic cycle are variously called **mechanism-based inhibitors**, **suicide substrates**, or **Trojan horse substrates**.

The effect of the 5-fluoro substitution on the mechanism of action of thymidylate synthase. An enzyme thiol group (from a Cys side chain) ordinarily attacks the 6-position of dUMP so that C-5 can react as a carbanion with N^5,N^{10} -methylene-THF. Normally, free enzyme is regenerated following release of the hydrogen at C-5 as a proton. Because release of fluorine as F^+ cannot occur, the ternary (three-part) complex of [enzyme:fluorouridylate:methylene-THF] is stable and persists, preventing enzyme turnover. (The N^5,N^{10} -methylene-THF structure is given in abbreviated form.)

Foundational Biochemistry Things You Should Know after Reading Chapter 26.

- Nucleotides are key participants in metabolism and essential building blocks for RNA and DNA synthesis.
- Nearly all organisms can carry out de novo synthesis of purine and pyrimidine nucleotides.
- The nine atoms that compose the purine ring come from five different precursors: glutamine, glycine, CO_2 , aspartate, and N^{10} -formyl-THF.
- The atoms that form the purine ring are assembled on a ribose-5-P platform.
- THF, the active coenzyme form of the B vitamin folate, is a coenzyme in one-carbon transfer reactions.
- Folate analogs are used as drugs in cancer chemotherapy and as antimicrobial agents.
- IMP is the first purine nucleotide made by the de novo pathway of purine biosynthesis.
- Only seven proteins are needed to carry out the 11 reactions of purine biosynthesis, because some of these reactions are catalyzed by multifunctional polypeptides.

- AMP and GMP are synthesized from IMP by distinct two-step metabolic pathways.
- In humans, purinosomes catalyze de novo purine biosynthesis.
- The purine biosynthetic pathway is regulated through feedback inhibition of ribose-5-P pyrophosphokinase (reaction 1) and glutamine-PRPP amidotransferase (reaction 2).
- ATP-dependent kinases form NDPs and NTPs from NMPs.
- Purine salvage pathways capture purines released in catabolism and relink them to ribose-5-P through the action of purine phosphoribosyltransferases.
- Some parasitic organisms rely on purine salvage to obtain purine nucleotides.
- The major pathways of purine catabolism lead to uric acid.
- The purine nucleoside cycle in skeletal muscle acts as an anaplerotic route to replenish citric acid cycle intermediates.
- Xanthine oxidase is a molybdo-enzyme that oxidizes hypoxanthine and xanthine to uric acid.
- Gout is a disease caused by excess uric acid.
- Different animals oxidize uric acid to form various excretory products.
- Pyrimidines are synthesized de novo from carbamoyl-P and aspartate.
- In contrast to purine biosynthesis, pyrimidines are synthesized as the free base, orotate, and then ribose-5-P is added, using PRPP as the substrate.
- Both purine and pyrimidine biosynthesis in mammals are prime examples of metabolic channeling by multifunctional enzymes.
- UMP is the precursor to both UTP and CTP.
- Pyrimidine biosynthesis is regulated at carbamoyl-P synthetase II in mammals and at aspartate transcarbamoylase in bacteria.
- Pyrimidines are degraded to form β -alanine, NH_3 , and CO_2 . The carbons of β -alanine are the ones contributed by aspartate during pyrimidine synthesis.
- Deoxyribonucleotide synthesis involves reduction at the 2'-position of the ribose ring of NDPs; the reducing power comes from NADPH.
- Deoxyribonucleotides are synthesized through the action of ribonucleotide reductase.
- Eukaryotic ribonucleotide reductase has three nucleotide-binding sites: the catalytic (or C) site, the specificity (or S) site, and the activity (or A) site.
- The S site and the A site of ribonucleotide reductase are allosteric sites.
- Thioredoxin, reduced by NADPH through the action of thioredoxin reductase, is the direct reductant for ribonucleotide reductase.
- Reduction of NDPs to dNDPs by ribonucleotide reductase proceeds via a free radical mechanism.
- ATP is an allosteric activator of ribonucleotide reductase and dATP is an allosteric inhibitor.
- The substrate for dTMP synthesis is dUMP.
- Two dNDPs lead to formation of dUMP: dUDP and dCDP.
- Thymidylate synthase catalyzes the formation of dTMP from dUMP, using N^5, N^{10} -methylene-THF as methyl donor.
- 5-Fluoro-substituted pyrimidines are useful drugs in the treatment of cancer, fungal infections, and malaria.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. Metabolic Origin of the Atoms in Purine and Pyrimidine Rings** Draw the purine and pyrimidine ring structures, indicating the metabolic source of each atom in the rings.
- 2. The Energy Cost of Nucleotide Biosynthesis** Starting with glutamine, aspartate, glycine, CO_2 , and N^{10} -formyl-THF, how many ATP equivalents are expended in the synthesis of (a) ATP, (b) GTP, (c) UTP, and (d) CTP?
- 3. Biosynthesis of AMP or GMP** Consider the structures shown and organize them in the order they may appear in the biosynthetic pathway for AMP or GMP.

- 4. ATP Consumption in Biosynthesis of AMP and GMP** As shown in Figures 26.3 and 26.5, the biosynthesis of adenine consumes many ATP equivalents. How, then, can a net amount of adenine ever be generated?
- 5. Allosteric Regulation of Purine and Pyrimidine Biosynthesis** Draw a diagram illustrating the key points of regulation in (a) the biosynthesis of IMP, AMP, and GMP; (b) *E. coli* pyrimidine biosynthesis; and (c) mammalian pyrimidine biosynthesis.
- 6. Inhibition of Purine and Pyrimidine Metabolism by Pharmacological Agents** Indicate which reactions of purine or pyrimidine metabolism are affected by the inhibitors (a) azaserine, (b) methotrexate, (c) sulfonamides, (d) allopurinol, and (e) 5-fluorouracil.
- 7. The Metabolic Role of dUDP** Since dUTP is not a normal component of DNA, why do you suppose ribonucleotide reductase has the capacity to convert UDP to dUDP?
- 8. Allosteric Regulation of Ribonucleotide Reductase by ATP and Deoxynucleotides** Describe the underlying rationale for the regulatory effects exerted on ribonucleotide reductase by ATP, dATP, dTTP, and dGTP.
- 9. Features of Ribonucleotide Reductase** (Integrates with Chapters 21 and 22)
 - a. The generation of a tyrosyl radical is crucial in the mechanism of ribonucleotide reductase. What other crucially important biochemical reaction requires the presence of a tyrosyl radical in the active site of an enzyme?
 - b. Apart from being a source of ATP, what are the (dual) important functions of glucose in the generation of deoxynucleotides for the synthesis of DNA?

10. **Nucleotide Catabolism as a Source of Metabolic Energy** (Integrates with Chapters 18–20 and 22.) By what pathway(s) does the ribose released upon nucleotide degradation enter intermediary metabolism and become converted to cellular energy? How many ATP equivalents can be recovered from one equivalent of ribose?
11. **Convergence of Purine and Histidine Biosynthesis** (Integrates with Chapter 25.) At which steps does the purine biosynthetic pathway resemble the pathway for biosynthesis of the amino acid histidine?
12. **The Mechanism of Action of Purine Biosynthetic Enzymes** Write reasonable chemical mechanisms for steps 6, 8, and 9 in purine biosynthesis (see Figure 26.3).
13. **The Anaplerotic Purine Nucleoside Cycle of Skeletal Muscle** Write a balanced equation for the conversion of aspartate to fumarate by the purine nucleoside cycle in skeletal muscle.
14. **The Catabolism of Uric Acid** Write a balanced equation for the oxidation of uric acid to glyoxylic acid, CO_2 , and NH_3 , showing each step in the process and naming all of the enzymes involved.
15. **The Allosteric Kinetics of Aspartate Transcarbamoylase** (Integrates with Chapter 15.) *E. coli* aspartate transcarbamoylase (ATCase) displays classic allosteric behavior. This $\alpha_6\beta_6$ enzyme is activated by ATP and feedback-inhibited by CTP. In analogy with the behavior of glycogen phosphorylase shown in Figure 15.15, illustrate the allosteric v versus [aspartate] curves for ATCase (a) in the absence of effectors, (b) in the presence of CTP, and (c) in the presence of ATP.
16. **The Functional Organization of a Heteromeric Allosteric Enzyme** (Integrates with Chapter 15.) Unlike its allosteric counterpart glycogen phosphorylase (an α_2 enzyme), *E. coli* ATCase has a heteromeric ($\alpha_6\beta_6$) organization. The α -subunits bind aspartate and are considered catalytic subunits, whereas the β -subunits bind CTP or ATP and are considered regulatory subunits. How would you describe the subunit organization of ATCase from a functional point of view?
17. **The Energy Cost of dTTP Synthesis** (Integrates with Chapter 20.) Starting from HCO_3^- , glutamine, aspartate, and ribose-5-P, how many ATP equivalents are consumed in the synthesis of dTTP in a eukaryotic cell, assuming dihydroorotate oxidation is coupled to oxidative phosphorylation? How does this result compare with the ATP costs of purine nucleotide biosynthesis calculated in problem 2?
18. **The Chemistry of dTMP Synthesis and the Substrate-Binding Site of Thymidylate Synthase** Write a balanced equation for the synthesis of dTMP from UMP and N^5,N^{10} -methylene-THF. Thymidylate synthase has four active-site arginine residues (Arg^{23} , $\text{Arg}^{178'}$, $\text{Arg}^{179'}$, and Arg^{218}) involved in substrate binding. Postulate a role for the side chains of these Arg residues.
19. **Representatives of the PRT Family of Enzymes in Purine Synthesis** Enzymes that bind phosphoribosyl-5-phosphate (PRPP) have a common structural fold, the PRT fold, which unites them as a structural family. PRT here refers to the phosphoribosyl transferase activity displayed by some family members. Typically, in such reactions, PP_i is displaced from PRPP by a nitrogen-containing nucleophile. Several such reactions occur in purine metabolism. Identify two such reactions where the enzyme involved is likely to be a PRT family member.
20. **Explore the Structure of DHFR Reductase** The crystal structure of *E. coli* dihydrofolate reductase (DFR) with NADP^+ and folate bound can be found in the Protein Data Bank (<https://www.rcsb.org>) as file 7DFR. Go to this website, enter “7DFR” in the search line, and click on one of the viewers under “Display options” when the 7DFR page comes up. Explore the graphic of the DFR structure to visualize how its substrates are bound. (If you hold down the left button on your mouse and move the cursor over the image, you can rotate the structure to view it from different perspectives.) Note in particular the spatial relationship between the nicotinamide ring of NADP^+ and the pterin ring of folate. How might substrate juxtaposition facilitate DFR reductase function? Note also the location of polar groups on the two substrates in relation to the DFR structure.
21. **Explore the Structure of Aspartate Transcarbamoylase, an Allosteric Enzyme** *E. coli* aspartate transcarbamoylase is an allosteric enzyme (see problem 12) composed of six catalytic (C) subunits and six regulatory (R) subunits. Protein Data Bank file 1RAA shows one-third of the ATCase holoenzyme (two C subunits and two R subunits; CTP molecules are bound to the R subunits). Explore this structure using one of the display options. What secondary structural motif dominates the R-subunit structure? Protein Data Bank file 2IPO also shows one-third of the ATCase holoenzyme (two C subunits and two R subunits), but in this structure molecules of the substrate analog *N*-(2-phosphonoacetyl)-L-asparagine are bound to the C subunits. Explore this structure using one of the display options. Note the distance separating the ATCase active site from its allosteric site. Interpret what you see in terms of the Monod–Wyman–Changeux model for allosteric regulation (see Chapter 15). Which of these structures corresponds to the MWC R-state, and which corresponds to the T-state?
22. **Folic Acid and Pregnancy** Pregnant women are recommended to take in extra amounts of folic acid to benefit the growing fetus. Give at least one reason why this recommendation is made.
23. **Nucleotide Biosynthesis and Anticancer Agents** Analogs of folate or fluoro-substituted pyrimidines can be used as anticancer agents. Such agents act as potent inhibitors of key enzymes functioning in the nucleotide biosynthetic pathways. However, chemotherapy with any such agent does lead to serious side effects. Explain why these side effects would occur and why, despite the side effects, the chemotherapeutic agents are still useful.
24. **Allosteric Regulation of Purine Biosynthesis** Examine Figure 26.6, and predict the relative rates of the regulated reactions in the purine biosynthetic pathway from ribose-5-P to GMP and AMP under conditions in which GMP levels are very high.
25. **Glucose as a Source of Carbon in THF-Mediated 1-Carbon Transfers** Decide from Figures 18.1, 25.31, 26.26, and the Deeper Look box “Tetrahydrofolate and One-Carbon Units” in Section 26.2 which carbon atom(s) in glucose would be most likely to end up as the 5- CH_3 carbon in dTMP.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

26. Using the PSafe Module for CTP synthetase, describe how glutamine binding occurs, and explain how His^{57} regulates ammonium diffusion.
27. Using the PSafe Module for HGPRT, discuss the putative function of the flexible loop. Describe the difference between the loop-open and loop-closed conformations.

Think-Pair-Share Question

Briefly review all previous chapters and come up with as many functions of adenine in biochemistry as you can.

Essential Questions

Cells are systems in a dynamic steady state, maintained by a constant flux of nutrients that serve as energy sources or as raw material for the maintenance of cellular structures. Catabolism and anabolism are ongoing, concomitant processes. **What principles underlie the integration of catabolism and energy production with anabolism and energy consumption? How is metabolism integrated in complex organisms with multiple organ systems?**

In the preceding chapters, we have explored the major metabolic pathways—glycolysis, the citric acid cycle, electron transport and oxidative phosphorylation, photosynthesis, gluconeogenesis, fatty acid oxidation, lipid biosynthesis, amino acid metabolism, and nucleotide metabolism. Several of these pathways are catabolic and serve to generate chemical energy useful to the cell; others are anabolic and use this energy to drive the synthesis of essential biomolecules. Despite their opposing purposes, these reactions typically occur at the same time as nutrient molecules are broken down to provide the building blocks and energy for ongoing biosynthesis. Cells maintain a dynamic steady state through processes that involve considerable metabolic flux. The metabolism that takes place in just a single cell is so complex that it resists detailed quantitative description. However, an appreciation of overall relationships can be achieved by stepping back and considering intermediary metabolism at a systems level of organization.

27.1 Can Systems Analysis Simplify the Complexity of Metabolism?

The metabolism of a typical heterotrophic cell can be portrayed by a schematic diagram consisting of three interconnected functional blocks: (1) catabolism, (2) anabolism, and (3) macromolecular synthesis and growth (Figure 27.1).

Key Questions

- 27.1 Can Systems Analysis Simplify the Complexity of Metabolism?
- 27.2 What Underlying Principle Relates ATP Coupling to the Thermodynamics of Metabolism?
- 27.3 Is There a Good Index of Cellular Energy Status?
- 27.4 How Is Overall Energy Balance Regulated in Cells?
- 27.5 How Is Metabolism Integrated in a Multicellular Organism?
- 27.6 What Regulates Our Eating Behavior?
- 27.7 Can You Really Live Longer by Eating Less?

Figure 27.1 Block diagram of intermediary metabolism. The beige-shaded box (*top*) illustrates metabolic blocks found in photosynthetic organisms.

1. Catabolism Energy-yielding nutrients are oxidized to CO_2 and H_2O in catabolism, and most of the electrons liberated are passed to oxygen via an electron-transport pathway coupled to oxidative phosphorylation, resulting in the formation of ATP. Some electrons go to reduce NADP^+ to NADPH, the source of reducing power for anabolism. Glycolysis, the citric acid cycle, electron transport and oxidative phosphorylation, and the pentose phosphate pathway are the principal pathways within this block. The metabolic intermediates in these pathways also serve as substrates for processes within the anabolic block.

2. Anabolism The biosynthetic reactions that form the many cellular molecules collectively comprise anabolism. For thermodynamic reasons, the chemistry of anabolism is more complex than that of catabolism (that is, it takes more energy [and often more steps] to synthesize a molecule than can be produced from its degradation). Metabolic intermediates derived from glycolysis and the citric acid cycle are the precursors for this synthesis, with NADPH supplying the reducing power and ATP, the coupling energy.

3. Macromolecular Synthesis and Growth The organic molecules produced in anabolism are the building blocks for creating macromolecules. Like anabolism, macromolecular synthesis is driven by energy from ATP, although indirectly in some cases: GTP is the principal energy source for protein synthesis, CTP for phospholipid synthesis, and UTP for polysaccharide synthesis. However, keep in mind that ATP is

the principal phosphoryl donor for formation of GTP, CTP, and UTP from GDP, CDP, and UDP, respectively. Macromolecules are the agents of biological function and information—proteins, nucleic acids, lipids that self-assemble into membranes, and so on. Growth can be represented as cellular accumulation of macromolecules and the partitioning of these materials of function and information into daughter cells in the process of cell division.

27.1a Only a Few Intermediates Interconnect the Major Metabolic Systems

Despite the complexity of processes taking place within each block, the connections between blocks involve a limited number of substances. Just ten or so kinds of catabolic intermediates from glycolysis, the pentose phosphate pathway, and the citric acid cycle serve as the raw material for most of anabolism: four kinds of sugar phosphates (triose-P, tetrose-P, pentose-P, and hexose-P), three α -keto acids (pyruvate, oxaloacetate, and α -ketoglutarate), two coenzyme A derivatives (acetyl-CoA and succinyl-CoA), and PEP (phosphoenolpyruvate).

27.1b ATP and NADPH Couple Anabolism and Catabolism

Metabolic intermediates are consumed by anabolic reactions and must be continuously replaced by catabolic processes. In contrast, the energy-rich compounds ATP and NADPH are recycled rather than replaced. When these substances are used in biosynthesis, the products are ADP and NADP^+ , and ATP and NADPH are regenerated during catabolism. ATP and NADPH are unique in that they are the only compounds whose purpose is to couple the energy-yielding processes of catabolism to the energy-consuming reactions of anabolism. Certainly, other coupling agents serve essential roles in metabolism. For example, NADH and $[\text{FADH}_2]$ participate in the transfer of electrons from substrates to O_2 during oxidative phosphorylation. However, these reactions are solely catabolic, and the functions of NADH and $[\text{FADH}_2]$ are fulfilled within the block called catabolism.

27.1c Phototrophs Have an Additional Metabolic System—The Photochemical Apparatus

The systems in Figure 27.1 reviewed thus far are representative only of metabolism as it exists in aerobic heterotrophs. The photosynthetic production of ATP and NADPH in photoautotrophic organisms entails a fourth block, the photochemical system (Figure 27.1). This block consumes H_2O and releases O_2 . When this fourth block operates, energy production within the catabolic block can be largely eliminated. Yet another block, one to account for the fixation of carbon dioxide into carbohydrates, is also required for photoautotrophs. The inputs to this fifth block are the products of the photochemical system (ATP and NADPH) and CO_2 derived from the environment. The carbohydrate products of this block may enter catabolism but not primarily for

Careers in Chemistry

Dr. James M. Ntambi

From Makerere University to the University of Wisconsin-Madison, Dr. James M. Ntambi has been teaching since 1975. Dr. Ntambi's research primarily focuses on the use of animal models to understand the genetic and molecular basis of diabetes and obesity. Specifically, Dr. Ntambi studies the stearoyl-CoA desaturase enzyme system in search of strong etiological links to diabetes, cardiovascular disease, and cancer in humans.

Dr. Ntambi earned his undergraduate degree in Biochemistry and Chemistry from Makerere

University in Uganda and went on to earn his Ph.D. in Biochemistry and Molecular Biology from the Johns Hopkins University School of Medicine. In 2013, Dr. Ntambi received the American Society for Biochemistry and Molecular Biology Award for Exemplary Contributions to Education.

Alongside his research work, Dr. Ntambi has also registered no less than six patents with the U.S. Patent Office that work toward knowledge, treatment, and prevention of non-communicable diseases in human beings.

energy production. In photoautotrophs, carbohydrates are fed into catabolism to generate the metabolic intermediates needed to supply the block of anabolism. Although these diagrams are oversimplifications of the total metabolic processes in heterotrophic or phototrophic cells, they are useful illustrations of functional relationships between the major metabolic subdivisions. This general pattern provides an overall perspective on metabolism, making its purpose easier to understand.

27.2 | What Underlying Principle Relates ATP Coupling to the Thermodynamics of Metabolism?

Stoichiometry is the measurement of the amounts of chemical elements and molecules involved in chemical reactions (from the Greek *stoicheion*, meaning “element,” and *metria*, meaning “measure”).

Virtually every metabolic pathway either consumes or produces ATP. The amount of ATP involved—that is, the stoichiometry of ATP synthesis or hydrolysis—lies at the heart of metabolic relationships. The overall thermodynamic efficiency of any metabolic sequence, be it catabolic or anabolic, is determined by **ATP coupling**. In every case, *the overall reaction mediated by any metabolic pathway is energetically favorable because of its particular ATP stoichiometry*. In the highly exergonic reactions of catabolism, much of the energy released is captured in ATP synthesis. In turn, the thermodynamically unfavorable reactions of anabolism are driven by energy released upon ATP hydrolysis.

27.2a The Three Types of Stoichiometries in Cells

The metabolic significance of ATP coupling is revealed by considering the three kinds of stoichiometry in cellular processes. The first two are fixed by the laws of chemistry, but the third is unique to living systems and reveals a fundamental difference between the inanimate world of chemistry and physics and the world of biological function, as shaped by evolution—that is, the world of living organisms. The fundamental difference is the stoichiometry of ATP coupling.

1. Reaction Stoichiometry This is simple chemical stoichiometry—the number of each kind of atom in any chemical reaction remains the same, and thus equal numbers must be present on both sides of the equation. This requirement holds even for a process as complex as cellular respiration:

The six carbons in glucose appear as six CO_2 , the 12 H of glucose appear as the 12 H in six molecules of water, and the 18 oxygens are distributed between CO_2 and H_2O .

2. Obligate Coupling Stoichiometry Cellular respiration is an oxidation–reduction process, and the oxidation of glucose is coupled to the reduction of NAD^+ and [FAD]. (Brackets here denote that the relevant FAD is covalently linked to succinate dehydrogenase; see Chapter 20.) The NADH and [FADH₂] thus formed are oxidized in the electron-transport pathway:

Sequence (a) accounts for the oxidation of glucose via glycolysis and the citric acid cycle. Sequence (b) is the overall equation for electron transport per glucose. The stoichiometry of coupling by the biological e^- carriers, NAD^+ and FAD, is fixed by the chemistry of electron transfer; each of the coenzymes serves as an e^- pair acceptor. Reduction of each O atom takes an e^- pair. Metabolism must obey these facts of chemistry: Biological oxidation of glucose releases 12 e^- pairs, creating a requirement for 12 equivalents of e^- pair acceptors, which transfer the electrons to 12 O atoms. By evolutionary chance, NAD^+/NADH and FAD/FADH_2 carry these electrons, but the stoichiometry is fixed by the chemistry.

3. Evolved Coupling Stoichiometries The participation of ATP is fundamentally different from the role played by pyridine nucleotides and flavins. The stoichiometry of adenine nucleotides in metabolic sequences is not fixed by chemical necessity. Instead, the stoichiometries we observe are the consequences of evolutionary design. The overall equation for cellular respiration, including the coupled formation of ATP by oxidative phosphorylation, is

The stoichiometry of ATP formation, $38 \text{ADP} + 38 \text{P}_i \longrightarrow 38 \text{ATP} + 38 \text{H}_2\text{O}$, cannot be predicted from any chemical considerations. The value of 38 ATP is an end result of biological adaptation. It is a trait that evolved through interactions between chemistry, heredity, and the environment over the course of evolution. Like any evolved character, ATP stoichiometry is the result of compromise. The final trait is one particularly suited to the fitness of the organism.

The number 38 is not magical. The value of 38 was established a long time ago in evolution, when the prevailing atmospheric conditions and the competitive situation were undoubtedly very different from those today. The significance of this number is that it provides a high yield of ATP for each glucose molecule, yet the yield is still low enough that essentially all of the glucose is metabolized.

This ATP yield of 38 for cellular respiration is for the reaction within an uncompartimentalized (prokaryotic) cell. In eukaryotes, where much of the cellular respiration is compartmentalized within mitochondria, mitochondrial ADP/ATP exchange imposes a metabolic cost on the proton gradient of one H^+ per ATP, so the overall yield of ATP per glucose is 32–34, not 38 (see Chapter 20).

27.2b ATP Coupling Stoichiometry Determines the K_{eq} for Metabolic Sequences

The fundamental biological purpose of ATP as an energy-coupling agent is to drive thermodynamically unfavorable reactions. In effect, the energy release accompanying ATP hydrolysis is transmitted to the unfavorable reaction so that the overall free energy change for the coupled process is negative (that is, favorable). The involvement of ATP serves to alter the free energy change for a reaction; or to put it another way, the role of ATP is to change the equilibrium ratio of [reactants] to [products] for a reaction. (See the A Deeper Look box at the end of Section 3.7: “ATP Changes the K_{eq} by a Factor of 10^8 .”)

Another way of viewing these relationships is to note that, at equilibrium, the concentrations of ADP and P_i will be vastly greater than that of ATP because ΔG° for ATP hydrolysis is a large negative number.

Since $\Delta G^\circ = -30.5 \text{ kJ/mol}$, $\ln K_{\text{eq}} = 12.3$. So $K_{\text{eq}} = 2.2 \times 10^5$. Choosing starting conditions of $[\text{ATP}] = 8 \text{ mM}$, $[\text{ADP}] = 8 \text{ mM}$, and $[\text{P}_i] = 1 \text{ mM}$, we can assume that, at equilibrium, $[\text{ATP}]$ has fallen to some insignificant value x , $[\text{ADP}] = \text{approximately } 16 \text{ mM}$, and $[\text{P}_i] = \text{approximately } 9 \text{ mM}$. The concentration of ATP at equilibrium, x , then calculates to be about 1 nM .

However, the cell where this reaction is at equilibrium is a dead cell. Living cells break down energy-yielding nutrient molecules to generate ATP. It is significant to note that the catabolism of glucose by glycolysis requires the investment of two ATP per glucose before any energy yields are realized. Further, fatty acid oxidation depends on fatty acid activation by acyl-CoA synthetase, a reaction that consumes two ATP equivalents. Thus, a cell deficient in ATP is doomed. Nevertheless, catabolism of energy-yielding nutrients proceeds with an overall decrease in free energy, and much of this energy is captured in ATP synthesis. Kinetic controls over the rates of the catabolic pathways are designed to ensure that the $[\text{ATP}]/([\text{ADP}][\text{P}_i])$ ratio is maintained very high. The cell, by employing kinetic controls over the rates of metabolic pathways, maintains a very high $[\text{ATP}]/([\text{ADP}][\text{P}_i])$ ratio so that ATP hydrolysis can serve as the driving force for virtually all biochemical events.

27.2c ATP Has Two Metabolic Roles

The role of ATP in metabolism is two-fold:

1. It serves in a stoichiometric role to establish large equilibrium constants for metabolic conversions and to render metabolic sequences thermodynamically favorable. This is the role referred to when we call ATP the *energy currency* of the cell.
2. ATP also serves as an important allosteric effector in the kinetic regulation of metabolism. Its concentration (relative to those of ADP and AMP) is an index of the energy status of the cell and determines the rates of regulatory enzymes situated at key points in metabolism, such as PFK in glycolysis and FBPase in gluconeogenesis.

27.3 | Is There a Good Index of Cellular Energy Status?

Energy transduction and energy storage in the *adenylate system*—ATP, ADP, and AMP—lie at the very heart of metabolism. The amount of ATP a cell uses per minute is roughly equivalent to the steady-state amount of ATP it contains. Thus, the metabolic lifetime of an ATP molecule is brief. ATP, ADP, and AMP are all important effectors in exerting kinetic control on regulatory enzymes situated at key points in metabolism, so uncontrolled changes in their concentrations could have drastic consequences. The regulation of metabolism by adenylates in turn requires close control of the relative concentrations of ATP, ADP, and AMP. Some ATP-consuming reactions produce ADP; PFK and hexokinase are examples. Others lead to the formation of AMP, as in fatty acid activation by acyl-CoA synthetases:

27.3a Adenylate Kinase Interconverts ATP, ADP, and AMP

Adenylate kinase catalyzes the reversible phosphorylation of AMP by ATP (see Chapter 18), linking all three members of the adenylate pool—AMP, ADP, and ATP:

The free energy of hydrolysis of a phosphoanhydride bond is essentially the same in ADP and ATP (see Chapter 3), and the standard free energy change for this reaction is close to zero.

27.3b Energy Charge Relates the ATP Levels to the Total Adenine Nucleotide Pool

The role of the adenylate system is to provide phosphoryl groups at high group-transfer potential to drive thermodynamically unfavorable reactions. The capacity of the adenylate system to fulfill this role depends on how fully charged it is with phosphoric anhydrides. Energy charge is an index of this capacity:

$$\text{Energy charge} = \frac{1}{2} \left(\frac{2[\text{ATP}] + [\text{ADP}]}{[\text{ATP}] + [\text{ADP}] + [\text{AMP}]} \right)$$

The denominator represents the total adenylate pool ($[\text{ATP}] + [\text{ADP}] + [\text{AMP}]$); the numerator is the number of phosphoric anhydride bonds in the pool, two for each ATP and one for each ADP. The factor $\frac{1}{2}$ normalizes the equation so that energy charge, or E.C., has the range 0 to 1.0. If all the adenylate is in the form of ATP, E.C. = 1.0, and the potential for phosphoryl transfer is maximal. At the other extreme, if AMP is the only adenylate form present, E.C. = 0. It is reasonable to assume that the adenylate kinase reaction is never far from equilibrium in the cell. Then, the relative amounts of the three adenine nucleotides are fixed by the energy charge. Figure 27.2 shows the relative changes in the concentrations of the adenylates as energy charge varies from 0 to 1.0.

Figure 27.2 Relative concentrations of AMP, ADP, and ATP as a function of energy charge. (This graph was constructed assuming that the adenylate kinase reaction is at equilibrium and that ΔG° for the reaction is -473 J/mol ; $K_{\text{eq}} = 1.2$.)

27.3c Key Enzymes Are Regulated by Energy Charge

Regulatory enzymes typically respond in reciprocal fashion to adenine nucleotides. For example, PFK is stimulated by AMP and inhibited by ATP. If the activities of various regulatory enzymes are examined *in vitro* as a function of energy charge, an interesting relationship appears. Regulatory enzymes in energy-producing catabolic pathways show greater activity at low energy charge, but the activity falls off abruptly as E.C. approaches 1.0. In contrast, regulatory enzymes of anabolic sequences are not very active at low energy charge, but their activities increase exponentially as E.C. nears 1.0. These contrasting responses are termed **R**, for ATP-regenerating, and **U**, for ATP-utilizing (Figure 27.3). Regulatory enzymes such as PFK and pyruvate kinase in glycolysis follow the **R** response curve as E.C. is varied. Note that PFK itself is an ATP-utilizing enzyme, using ATP to phosphorylate fructose-6-phosphate to yield fructose-1,6-bisphosphate. Nevertheless, because PFK acts physiologically as the valve controlling the flux of carbohydrate down the catabolic pathways of cellular respiration that lead to ATP regeneration, it responds as an **R** enzyme to energy charge. Regulatory enzymes in anabolic pathways, such as acetyl-CoA carboxylase, which initiates fatty acid biosynthesis, respond as **U** enzymes.

The overall purposes of the **R** and **U** pathways are diametrically opposite in terms of ATP involvement. Note in Figure 27.3 that the **R** and **U** curves intersect at a rather high E.C. value. As E.C. increases past this point, **R** activities decline precipitously and **U** activities rise. That is, when E.C. is very high, biosynthesis is accelerated, whereas catabolism diminishes. The consequence of these effects is that ATP is used up faster than it is regenerated, and so E.C. begins to fall. As E.C. drops below the point of intersection, **R** processes are favored over **U**. Then, ATP is generated faster than it is consumed, and E.C. rises again. The net result is that the value of energy charge oscillates about a point of **steady state** (Figure 27.3). The experimental results obtained from careful measurement of the relative amounts of AMP, ADP, and ATP in living cells reveals that normal cells have an energy charge in the neighborhood of 0.85 to 0.88. Maintenance of this steady-state value is one criterion of cell health and normalcy. ATP levels are always substantially greater than ADP or AMP levels. Further, ATP levels in cells are virtually constant. The consequence of these considerations is that changes in the amounts of ADP and AMP are far more important regulatory signals than [ATP].

Figure 27.3 Responses of regulatory enzymes to variation in energy charge.

27.3d Phosphorylation Potential Is a Measure of Relative ATP Levels

Because energy charge is maintained at a relatively constant value in normal cells, it is not an informative index of cellular capacity to carry out phosphorylation reactions. The relative concentrations of ATP, ADP, and P_i do provide such information, and a function called **phosphorylation potential** has been defined in terms of these concentrations:

Phosphorylation potential, Γ , is equal to $[\text{ATP}]/([\text{ADP}][P_i])$.

Note that this expression includes a term for the concentration of inorganic phosphate. $[P_i]$ has substantial influence on the thermodynamics of ATP hydrolysis. In contrast with energy charge, phosphorylation potential varies over a significant range as the actual proportions of ATP, ADP, and P_i in cells vary in response to metabolic state. Γ ranges from 200 to 800 M^{-1} , or more, with higher levels signifying more ATP and correspondingly greater phosphorylation potential. Since Γ varies as [ATP], [ADP], and $[P_i]$ vary, it is a better index of cellular energy status than energy charge.

27.4 | How Is Overall Energy Balance Regulated in Cells?

AMP-activated protein kinase (AMPK) is the cellular energy sensor. Metabolic inputs to this sensor determine whether its output, protein kinase activity, takes place. When cellular energy levels are high, as signaled by high ATP concentrations, AMPK is

inactive. When cellular energy levels are depleted, as signaled by high [AMP], AMPK is allosterically activated and phosphorylates many targets controlling cellular energy production and consumption. Recall that, due to the nature of the adenylate kinase equilibrium (see Section 18.3), AMP levels increase exponentially as ATP levels decrease. AMP is an allosteric activator of AMPK, whereas ATP at high levels acts as an allosteric inhibitor by displacing AMP from the allosteric site. Thus, competition between AMP and ATP for binding to the AMPK allosteric sites determines the activity of AMPK. Activation of AMPK (1) sets in motion catabolic pathways leading to ATP synthesis and (2) shuts down pathways that consume ATP energy, such as biosynthesis and cell growth. In effect, AMPK acts like a metabolic fuel gauge.

27.4a The Structure and Regulation of AMPK

AMPK is an $\alpha\beta\gamma$ -heterotrimer (Figure 27.4). The α -subunit is the catalytic subunit; it has an N-terminal Ser/Thr protein kinase domain and a C-terminal $\beta\gamma$ -binding domain. The β -subunit has at its C terminus an $\alpha\gamma$ -binding domain. The γ -subunit is the regulatory subunit; it has a pair of allosteric sites where adenine nucleotides bind. These sites are located toward its C terminus within four CBS domains (so named for their homology to *cystathionine- β -synthase*). These CBS domains act in pairs to form structures known as Bateman modules. Bateman modules CBS1 and CBS3 reversibly bind AMP, ADP, or ATP; module CBS2 is never occupied; and CBS4 is always occupied by AMP. AMP binding to the CBS1 and CBS3 sites is highly cooperative, such that binding of AMP to one module markedly enhances AMP binding at the other. This cooperativity renders AMPK exquisitely sensitive to changes in AMP concentration.

AMP binding to AMPK increases its protein kinase activity by more than 1000-fold. The underlying mechanism involves a **pseudosubstrate sequence** (see Section 15.4b) within CBS domain 2 that fits into the α -subunit catalytic site. When AMP binds to the Bateman modules, conformational changes in the γ -subunit displace the pseudosubstrate sequence from the kinase catalytic site, freeing it to act. The structural relationships between the AMPK subunits can be seen in the core structure of the mammalian $\alpha\beta\gamma$ complex (Figure 27.5).

AMP activates AMPK in two ways: First, it is an allosteric activator; second, AMP (or ADP) binding favors phosphorylation of Thr¹⁷² within the α -subunit kinase domain. Phosphorylation of Thr¹⁷² is necessary for α -subunit protein kinase activity and is achieved by several upstream protein kinases (such as LKB1 and CamKK β), which are themselves constitutively active (that is, always active). Whether AMPK remains phosphorylated depends on the activity of phosphoprotein phosphatases, and AMP (or ADP) exerts its favorable effects on Thr¹⁷² phosphorylation by inhibiting its dephosphorylation by these phosphatases. Thr¹⁷² lies within the **activation loop** of the kinase; activation

Figure 27.5 Core structure of the mammalian AMPK heterotrimer. The α -subunit is green, the β -subunit is yellow, and the γ -subunit is white. The γ -subunit has three AMP-binding sites; the three molecules of bound AMP are shown, one in red, one in pink. ATP and ADP can compete with AMP for binding at the AMP sites shown as occupied by red and pink AMP molecules. The molecule of AMP shown in blue cannot be exchanged for ATP or ADP (PDB id = 2V8Q).

Figure 27.4 Domain structure of the AMP-activated protein kinase subunits. (Adapted from Figure 1 in Hardie, D. G., Hawley, S. A., and Scott, J. W., 2006. AMP-activated protein kinase: Development of the energy sensor concept. *Journal of Physiology* 574:7–15.)

loops are common features of protein kinases whose activation requires phosphorylation by other protein kinases. Both of these favorable actions are reversed if ATP displaces AMP or ADP from the CBS1 and CBS3 allosteric sites.

In actuality, AMPK is acting as an energy charge sensor, because the two exchangeable adenine nucleotide-binding sites on the γ -subunit can bind either AMP, ADP, or ATP. AMP and ATP exert allosteric effects, but ADP does not. However, ADP occupation of these sites prevents dephosphorylation of Thr¹⁷², whereas ATP favors Thr¹⁷² dephosphorylation. Thus, ADP binding to the γ -subunit protects AMPK from dephosphorylation, which would inactivate it. In its ADP-bound, Thr¹⁷²-phosphorylated state, AMPK is poised to undergo allosteric activation during energy stress, when AMP levels rise to a level where AMP displaces ADP from the allosteric sites. Since the intracellular concentrations of ADP normally exceed those of AMP, competition between ADP and ATP for binding to the γ -subunit is the likely determinant of the state of Thr¹⁷² phosphorylation.

27.4b AMPK Targets Key Enzymes in Energy Production and Consumption

Activation of AMPK leads to phosphorylation of many key enzymes in energy metabolism. Those involved in energy production that are activated upon phosphorylation by AMPK include phosphofructokinase-2 (PFK-2; see Chapter 22). In contrast to protein kinase A phosphorylation of PFK-2, AMPK phosphorylation of liver PFK-2 enhances fructose-2,6-bisphosphate synthesis, which in turn stimulates glycolysis. Enzymes involved in energy consumption that are down-regulated upon phosphorylation by AMPK include glycogen synthase (see Chapter 22), acetyl-CoA carboxylase (which catalyzes the committed step in fatty acid biosynthesis; see Chapter 24), and 3-hydroxy-3-methylglutaryl-CoA reductase, which carries out the key regulatory reaction in cholesterol biosynthesis (see Chapter 24). Further, AMPK phosphorylation of various transcription factors leads to diminished expression of genes encoding biosynthetic enzymes and elevated expression of catabolic genes. Activation of AMPK also enhances energy production by promoting mitochondrial biogenesis.

27.4c AMPK Controls Whole-Body Energy Homeostasis

Beyond these cellular effects, AMPK plays a central role in energy balance in multicellular organisms (Figure 27.6). AMPK in skeletal muscle is activated by hormones such as adiponectin and leptin, adipocyte-derived hormones that govern eating behavior and energy homeostasis (see section 27.6). Physical activity (exercise) also activates muscle AMPK. In turn, skeletal muscle AMPK activates glucose uptake, fatty acid oxidation, and mitochondrial biogenesis through its phosphorylation of metabolic enzymes and transcription factors that control expression of genes involved in energy production and consumption. AMPK's actions in the liver lead to lowered ATP (energy) consumption through down-regulation of fatty acid synthesis, cholesterol synthesis, and gluconeogenesis. **Metformin**, a widely used drug for the treatment of type 2 diabetes (see the Human Biochemistry box “Metformin—a Diabetes Drug with Multiple Actions” in Section 22.1), lowers blood glucose levels through inhibition of liver gluconeogenesis; metformin achieves this result through activation of AMPK. AMPK blocks insulin secretion by pancreatic β -cells; insulin is a hormone that favors energy storage (glycogen and fat synthesis). AMPK is also a master regulator of eating behavior through its activity in the hypothalamus, the key center for regulation of food intake. These effects of AMPK are described in Section 27.6.

27.4d AMPK Inhibits mTORC1, the Master Growth Regulator of Eukaryotic Cells

mTOR (mechanistic Target of Rapamycin) is a master coordinator of metabolism in multicellular organisms. mTOR is a Ser/Thr protein kinase of the phosphoinositide-3-kinase (PIKK) family. Its unusual name stems from its inhibition by rapamycin, a

Figure 27.6 AMPK regulation of energy production and consumption in mammals. (Adapted from Figure 1 in Kahn, B. B., Alquier, T., Carling, D., and Hardie, D. G., 2005. AMP-activated protein kinase: Ancient energy gauge provides clues to modern understanding of metabolism. *Cell Metabolism* 1:15–25.)

compound produced by bacteria discovered in a soil sample from Easter Island (Rapa Nui is the Polynesian name for Easter Island). Rapamycin inhibits the proliferation of eukaryotic cells. The physiological role of mTOR is to respond to environmental and hormonal signals and decide whether cells should grow and divide. mTOR is the catalytic subunit in two multisubunit complexes, mTORC1 and mTORC2. The human mTORC1 complex (958 kDa) consists of six subunits organized as two trimers (Figure 27.7). Each trimer contains an mTOR protein kinase (1349 residues) subunit and one each of the non-catalytic polypeptides Raptor (regulatory-associated protein of mTOR, 1343 residues) and mLST8 (326 residues). As the central regulator of cell function through its control over anabolism and catabolism, the mTORC1 complex is responsive to nutrient levels. If nutrient levels are high, mTORC1 phosphorylates proteins controlling transcription and translation of genes encoding the enzymes of anabolic pathways necessary for growth, such as lipid and pyrimidine biosynthesis and ribosomal biogenesis. (mTORC2 regulates cell proliferation in a similar matter.)

Localization to the Lysosomal Membrane Is Essential for mTORC1 Activation The response of mTORC1 to nutrients is complex and indirect. Both glucose and amino acids induce localization of mTORC1 to the lysosome, the organelle whose array of digestive enzymes is involved in nutrient recycling. Localization of mTORC1 to the cytosolic surface of lysosomes is an essential step in mTORC1 activation and the promotion of cell growth in response to abundant nutrient levels. Recruitment of mTORC1 to the lysosome is carried out by the lysosomal membrane-associated **Rag proteins**. These proteins are members of the Ras-related GTP-binding protein (Rag) family of GTPases, consisting of four proteins in higher eukaryotes—RagA (313 residues), RagB (374 residues), RagC (399 residues), and Rag D (400 residues).

Figure 27.7 The structure of the mTORC1 complex. (a) The mTORC1 complex is organized as a dimer of trimers composed of mTOR (blue), Raptor (yellow), and mLST8 (gray; PDB id = 6BCX). The mTOR kinase active sites are indicated by the arrows. See Yang, H., et al., 2017. Structural mechanisms of mTORC1 activation by RHEB and inhibition by PRAS40. *Nature* 552:368–373.

Rag GTPases function as heterodimers in which one monomer of either RagA or RagB partners with one monomer of RagC or RagD. When amino acids are abundant, RagA is loaded with GTP. If RagC has GDP bound, the RagA:GTP/RagC:GDP complex recruits mTORC1 to the lysosomal membrane. The reciprocal arrangement—RagA:GDP/RagC:GTP—cannot recruit mTORC1 to the lysosome.

The Response of mTORC1 to Amino Acid Availability Amino acid signaling to mTORC1 is dependent on the lysosome-based **GATOR** (GTPase-Activating Protein towards Rags) complexes, which respond to multiple amino acids, including arginine, leucine, and S-adenosylmethionine. When these amino acids are abundant, the GATOR1 complex inhibits the intrinsic GTPase activity of RagA, so GTP is the favored nucleotide, and mTORC1 is recruited and activated. GATOR2 is an upstream regulator of GATOR1 that restores the GTPase-activating function of GATOR1, leading to hydrolysis of RagA-bound GTP, thereby shutting down RagA activation of mTORC1.

Activation of mTORC1 Depends on Lysosomal Rheb Once mTORC1 becomes associated with the lysosome, the protein kinase activity of mTORC1 is allosterically activated through association with Rheb. Rheb (“Ras homologue enriched in brain”) is another small G protein (184 amino acid residues). Rheb is anchored to the lysosomal membrane by a C-terminal farnesyl group (see Figure 9.23c). Activation of the mTORC1 protein kinase leads to protein phosphorylations that stimulate the anabolic pathways driving cellular growth.

The Response of mTORC1 to Glucose When glucose levels are low, the cell’s energy status declines. Such conditions trigger activation of AMPK. AMPK disrupts the action of mTORC1 through phosphorylation of the heterodimeric protein **TSC1/TSC2**. TSC proteins are tumor suppressor gene products. The TSC heterodimer is a GTPase-activating protein for Rheb, converting its bound GTP to GDP, thereby suppressing Rheb’s ability to allosterically activate mTORC1. This inhibition of mTORC1 by AMPK conserves energy by turning off anabolic pathways. Nutrient availability is vital to cells, and nutrient signaling to mTORC1 is complex and redundant. A diverse range of sensors and signaling complexes in addition to AMPK mediate mTORC1 responses to glucose levels.

27.5 How Is Metabolism Integrated in a Multicellular Organism?

In complex multicellular organisms, organ systems have arisen to carry out specific physiological functions. Each organ relies on a repertoire of metabolic pathways that is consistent with its physiological purpose. Such specialization depends on coordination of metabolic responsibilities among organs so that the organism as a whole may thrive. Essentially all cells in animals have the set of enzymes common to the central pathways of intermediary metabolism, especially the enzymes involved in the formation of ATP and the synthesis of glycogen and lipid reserves. Nevertheless, organs differ in the metabolic fuels they prefer as substrates for energy production. Important differences also occur in the ways ATP is used to fulfill the organs' specialized metabolic functions. To illustrate these relationships, we will consider the metabolic interactions among the major organ systems found in humans: brain, skeletal muscle, heart, adipose tissue, and liver. In particular, the focus will be on energy metabolism in these organs (Figure 27.8). The major fuel depots in animals are *glycogen* in liver and muscle; *triacylglycerols* (fats) stored in adipose tissue; and *protein*, most of which is in skeletal muscle. In general, the order of preference for the use of

Red arrows indicate preferred routes in the well-fed state

Figure 27.8 Metabolic relationships among the major human organs.

Table 27.1 Energy Metabolism in Major Vertebrate Organs

Organ	Energy Reservoir	Preferred Substrate	Energy Sources Exported
Brain	None	Glucose (ketone bodies during starvation)	None
Skeletal muscle (resting)	Glycogen	Fatty acids	None
Skeletal muscle (strenuous exertion)	None	Glucose from glycogen	Lactate
Heart muscle	Glycogen	Fatty acids	None
Adipose tissue	Triacylglycerol	Fatty acids	Fatty acids, glycerol
Liver	Glycogen, triacylglycerol	Amino acids, glucose, fatty acids	Fatty acids, glucose, ketone bodies

these fuels is the order given: glycogen > triacylglycerol > protein. Nevertheless, the tissues of the body work together to maintain **energy homeostasis (caloric homeostasis)**, defined as *a constant availability of fuels in the blood*.

Humans have a total of 11 organ systems, but only the five earlier mentioned play a major role in energy metabolism: the brain, muscles, heart (a specialized muscle), fat (adipose tissue), and liver. Table 27.1 summarizes the metabolism of these major human organs. Each has a specialized metabolic role.

27.5a The Brain Accounts for 20% of the Body's Oxygen Consumption

The brain has two remarkable metabolic features. First, it has a very high respiratory metabolism. In resting adult humans, 20% of the oxygen consumed is used by the brain, even though it constitutes only 2% or so of body mass. Interestingly, this level of oxygen consumption is independent of mental activity, continuing even during sleep. Second, the brain is an organ with no significant fuel reserves—no glycogen, expendable protein, or fat. Normally, the brain uses only glucose as a fuel and is totally dependent on the blood for a continuous, incoming supply. Interruption of glucose supply for even brief periods (as in a stroke) can lead to irreversible losses in brain function. The brain uses glucose to carry out ATP synthesis via cellular respiration. High rates of ATP production are necessary to power the plasma membrane Na^+ , K^+ -ATPase so that the membrane potential essential for transmission of nerve impulses is maintained.

During prolonged fasting or starvation, the body's glycogen reserves are depleted. Under such conditions, the brain adapts to use β -hydroxybutyrate (Figure 27.9) as a source of fuel, converting it to acetyl-CoA for energy production via the citric acid cycle. β -Hydroxybutyrate (see Chapter 23) is formed from fatty acids in the liver. Although the brain cannot use free fatty acids or lipids directly from the blood as fuel, the conversion of these substances to β -hydroxybutyrate in the liver allows the brain to use body fat as a source of energy. The brain's other potential source of fuel during starvation is glucose obtained from gluconeogenesis in the liver (see Chapter 22), using the carbon skeletons of amino acids derived from muscle protein breakdown. The adaptation of the brain to use β -hydroxybutyrate from fat spares protein from degradation until lipid reserves are exhausted.

27.5b Muscle Metabolism Is Fueled by Glucose and Free Fatty Acids

Skeletal muscle is responsible for about 30% of the O_2 consumed by the human body at rest. During periods of maximal exertion, skeletal muscle can account for more than 90% of the total metabolism. Muscle metabolism is primarily dedicated to the production of ATP as the source of energy for contraction and relaxation. Muscle contraction occurs when a motor nerve impulse causes Ca^{2+} release from specialized endomembrane compartments (the transverse tubules and sarcoplasmic reticulum). Ca^{2+} floods the *sarcoplasm* (the cytosolic compartment of muscle cells), where it binds

Figure 27.9 Ketone bodies such as β -hydroxybutyrate provide the brain with a source of acetyl-CoA when glucose is unavailable.

to **troponin C**, a regulatory protein, initiating a series of events that culminate in the sliding of myosin thick filaments along actin thin filaments. This mechanical movement is driven by energy released upon hydrolysis of ATP (see Chapter 16). The net result is that the muscle shortens. Relaxation occurs when the Ca^{2+} ions are pumped back into the sarcoplasmic reticulum by the action of a Ca^{2+} -transporting membrane ATPase. Two Ca^{2+} ions are translocated per ATP hydrolyzed. The amount of ATP used during relaxation is almost as much as that consumed during contraction.

Because muscle contraction is an intermittent process that occurs upon demand, muscle metabolism is designed to generate energy upon demand. Muscle at rest uses free fatty acids, glucose, or ketone bodies as fuel and produces ATP via oxidative phosphorylation. Resting muscle also contains about 2% glycogen and about 0.08% phosphocreatine by weight (Figure 27.10). When ATP is used to drive muscle contraction, the ADP formed can be reconverted to ATP by *creatine kinase* at the expense of phosphocreatine. Muscle phosphocreatine can generate enough ATP to power about 4 seconds of exertion. During strenuous exertion, such as a 100 meter sprint, once the phosphocreatine is depleted, muscle relies solely on its glycogen reserves, making the ATP for contraction via glycolysis. In contrast with the citric acid cycle and oxidative phosphorylation pathways, glycolysis is capable of explosive bursts of activity, and the flux of glucose-6-phosphate through this pathway can increase 2000-fold almost instantaneously. The triggers for this activation are Ca^{2+} and the fight-or-flight hormone *epinephrine* (see Chapters 22 and 32). Little interorgan cooperation occurs during strenuous (anaerobic) exercise.

Muscle fatigue is the inability of a muscle to maintain power output. During maximum exertion, the onset of fatigue takes only 20 seconds or so. Fatigue is not the result of exhaustion of the glycogen reserves, nor is it a consequence of lactate accumulation in the muscle. Instead, it is caused by a decline in intramuscular pH as protons are generated during glycolysis. (The overall conversion of glucose to two lactate in glycolysis is accompanied by the release of two H^+ .) The pH may fall as low

Figure 27.10 Phosphocreatine serves as a reservoir of ATP-synthesizing potential.

as 6.4. Lower pH directly affects the ability of muscle to contract. Further, the decline in PFK activity at low pH leads to a lowered flux of hexose through glycolysis and inadequate ATP levels. One benefit of PFK inhibition is that the ATP remaining is not consumed in the PFK reaction, thereby sparing the cell from the more serious consequences of losing all of its ATP.

During fasting or excessive activity, skeletal muscle protein is degraded to amino acids so that their carbon skeletons can be used as fuel. Many of the skeletons are converted to pyruvate, which can be transaminated back into alanine for export via the circulation (Figure 27.11). Alanine is carried to the liver, which in turn deaminates it

Figure 27.11 The transamination of pyruvate to alanine by glutamate-alanine aminotransferase.

Human Biochemistry

Athletic Performance Enhancement with Creatine Supplements?

The creatine pool in a 70-kg (154-pound) human body is about 120 grams. This pool includes dietary creatine (from meat) and creatine synthesized by the human body from its precursors (arginine,

glycine, and methionine). Of this creatine, 95% is stored in the skeletal and smooth muscles, about 70% of which is in the form of phosphocreatine. Supplementing the diet with 20 to 30 grams of creatine per day for 4 to 21 days can increase the muscle creatine pool by as much as 50% in someone with a previously low creatine level. Thereafter, supplements of 2 grams per day will maintain elevated creatine stores. Studies indicate that creatine supplementation gives some improvement in athletic performance during high-intensity, short-duration events (such as weight lifting), but no benefit in endurance events (such as distance running). The distinction makes sense in light of phosphocreatine's role as the substrate that creatine kinase uses to regenerate ATP from ADP. Intense muscular activity quickly (less than 2 seconds) exhausts ATP supplies; [phosphocreatine]_{muscle} is sufficient to restore ATP levels for a few extra seconds, but no more. The U.S. Food and Drug Administration advises consumers to consult with their doctors before using creatine as a dietary supplement.

AP Images/Michael Probst

AP Images/Kirsty Wigglesworth

back into pyruvate so that it can serve as a substrate for gluconeogenesis. Although muscle protein can be mobilized as an energy source, it is not efficient for an organism to consume its muscle and lower its overall fitness for survival. Muscle protein represents a fuel of last resort.

27.5c The Heart Prefers Fatty Acids as Fuel

In contrast with the intermittent work of skeletal muscle, the activity of heart muscle is constant and rhythmic. The range of activity in heart is also much less than that in muscle. Consequently, the heart functions as a completely aerobic organ and, as such, is very rich in mitochondria. Roughly half the cytoplasmic volume of heart muscle cells is occupied by mitochondria. Under normal working conditions, the heart prefers fatty acids as fuel, oxidizing acetyl-CoA units via the citric acid cycle and producing ATP for contraction via oxidative phosphorylation. Heart tissue has minimal energy reserves: a small amount of phosphocreatine and limited quantities of glycogen. As a result, the heart must be continually nourished with oxygen and free fatty acids, glucose, or ketone bodies as fuel.

27.5d Adipose Tissue Is Hormonally Active

Adipose tissue is an amorphous tissue that is widely distributed throughout the body—around blood vessels, in the abdominal cavity and mammary glands, and most prevalently, as deposits under the skin. Long considered merely a storage depot for fat, adipose tissue is now appreciated as an endocrine organ responsible for secretion of a variety of hormones that govern eating behavior and caloric homeostasis. It consists principally of cells known as adipocytes that no longer replicate. However, adipocytes can increase in number as adipocyte precursor cells divide, and obese individuals tend to have more of them. As much as 65% of the weight of adipose tissue is triacylglycerol that is stored in adipocytes, essentially as oil droplets. The average 70-kg man has enough caloric reserve stored as fat to sustain a 6000 kJ/day rate of energy production for 3 months, which is adequate for survival, assuming no serious metabolic aberrations (such as nitrogen, mineral, or vitamin deficiencies). Despite their role as energy storage depots, adipocytes have a high rate of metabolic activity, synthesizing and breaking down triacylglycerol so that the average turnover time for a triacylglycerol molecule is just a few days. Adipocytes actively carry out cellular respiration, transforming glucose to energy via glycolysis, the citric acid cycle, and oxidative phosphorylation. If glucose levels in the diet are high, glucose is converted to acetyl-CoA for fatty acid synthesis. However, under most conditions, free fatty acids for triacylglycerol synthesis are obtained from the liver. Because adipocytes lack glycerol kinase, they cannot recycle the glycerol of triacylglycerol but rather depend on glycolytic conversion of glucose to dihydroxyacetone-3-phosphate (DHAP)

Human Biochemistry

Fat-Free Mice—A Model for Diabetes

Scientists at the U.S. National Institutes of Health have created transgenic mice that lack white adipose tissue throughout their lifetimes. These mice were created by blocking the normal differentiation of stem cells into adipocytes so that essentially no white adipose tissue can be formed in these animals. These fat-free mice have double the food intake and five times the water intake of normal mice. Fat-free mice also show decreased physical activity and must be kept warm on little heating pads to survive, because they lack insulating fat. They are also diabetic, with three times the normal blood glucose and triacylglycerol levels and only 5% of normal leptin levels; they die prematurely. Like type 2 dia-

betic patients, fat-free mice have markedly elevated insulin levels (50 to 400 times normal) but are unresponsive to insulin. These mice serve as an excellent model for the disease *lipotrophic diabetes*, an inherited disease characterized by the absence of adipose tissue and severe diabetic symptoms. Indeed, transplantation of adipose tissue into these fat-free mice cured their diabetes. As the major organ for triacylglycerol storage, white adipose tissue helps control energy homeostasis (food intake and energy expenditure) via the release of leptin and other hormonelike substances (see the discussion in Section 27.6). Clearly, absence of adipose tissue has widespread, harmful consequences for metabolism.

and the reduction of DHAP to glycerol-3-phosphate for triacylglycerol biosynthesis. Adipocytes also require glucose to feed the pentose phosphate pathway for NADPH production.

Glucose plays a pivotal role for adipocytes. If glucose levels are adequate, glycerol-3-phosphate is formed in glycolysis and the free fatty acids liberated in triacylglycerol breakdown are re-esterified to glycerol to re-form triacylglycerols. However, if glucose levels are low, [glycerol-3-phosphate] falls and free fatty acids are released to the bloodstream (see Chapter 23).

Brown Fat A specialized type of adipose tissue, **brown fat**, is found in newborns and hibernating animals. An abundance of mitochondria, which are rich in cytochromes, is responsible for the brown color of this fat. As usual, these mitochondria are very active in electron transport–driven proton translocation, but these particular mitochondria contain in their inner membranes a protein, **thermogenin**, also known as *uncoupling protein 1* (see Chapter 20), that creates a passive proton channel, permitting the H^+ ions to reenter the mitochondrial matrix without generating ATP. Instead, the energy of oxidation is dissipated as heat. Indeed, brown fat is specialized to oxidize fatty acids for heat production rather than ATP synthesis.

27.5e The Liver Is the Body's Metabolic Processing Center

The liver serves as the major metabolic processing center in vertebrates. Except for dietary triacylglycerols, which are metabolized principally by adipose tissue, most of the incoming nutrients that pass through the intestinal tract are routed via the portal vein to the liver for processing and distribution. Much of the liver's activity centers around conversions involving glucose-6-phosphate (Figure 27.12). Glucose-6-phosphate can be converted to glycogen, released as blood glucose, used to generate NADPH and pentoses via the pentose phosphate cycle, or catabolized to acetyl-CoA for fatty acid synthesis or for energy production via oxidative phosphorylation. Most of the liver glucose-6-phosphate arises from dietary carbohydrate, from degradation of glycogen reserves, or from muscle lactate that enters the gluconeogenic pathway.

Figure 27.12 Metabolic conversions of glucose-6-phosphate in the liver.

Human Biochemistry

The Metabolic Effects of Alcohol Consumption

Ethanol metabolism alters the NAD^+/NADH ratio. Ethanol is metabolized to acetate in the liver by alcohol dehydrogenase and aldehyde dehydrogenase:

Acetate is then converted to acetyl-CoA. Excessive conversion of available NAD^+ to NADH impairs NAD^+ -requiring reactions, such as the citric acid cycle, gluconeogenesis from lactate, and fatty acid oxidation. Accumulation of acetyl-CoA favors fatty acid synthesis, which, along with blockage of fatty acid oxidation, causes elevated triacylglycerol levels in the liver. Over

time, these triacylglycerols accumulate as fatty deposits, which ultimately contribute to cirrhosis of the liver. Impairment of gluconeogenesis leads to buildup of this pathway's substrate, lactate. Lactic acid accumulation in the blood causes acidosis. A further consequence is that acetaldehyde can form adducts with protein $-\text{NH}_2$ groups, which may inhibit protein function. Because gluconeogenesis is limited, alcohol consumption can cause *hypoglycemia* (low blood sugar) in someone who is undernourished. In turn, hypoglycemia can cause irreversible damage to the central nervous system. A high $[\text{NADH}]/[\text{NAD}^+]$ ratio also impairs SIRT1 function; SIRT1 is a key player in protecting cells against stress-induced degenerative disease (see Section 27.7).

The liver plays an important regulatory role in metabolism by buffering the level of blood glucose. Liver has two enzymes for glucose phosphorylation: hexokinase and glucokinase (type-IV hexokinase). Unlike hexokinase, glucokinase has a low affinity for glucose. Glucokinase requires 5 mM glucose to reach 0.5 V_{max} . When blood glucose levels are high, glucokinase activity augments hexokinase in phosphorylating glucose as an initial step leading to its storage in glycogen. The major metabolic hormones—epinephrine, glucagon, and insulin—all influence glucose metabolism in the liver to keep blood glucose levels relatively constant (see Chapters 22 and 32).

The liver is a major center for fatty acid turnover. When the demand for metabolic energy is high, triacylglycerols are broken down and fatty acids are degraded in the liver to acetyl-CoA to form ketone bodies, which are exported to the heart, brain, and other tissues. If energy demands are low, fatty acids are incorporated into triacylglycerols that are carried to adipose tissue for deposition as fat. Cholesterol is also synthesized in the liver from two-carbon units derived from acetyl-CoA.

In addition to these central functions in carbohydrate and fat-based energy metabolism, the liver serves other purposes. For example, the liver can use amino acids as metabolic fuels. Amino acids are first converted to their corresponding α -keto acids by aminotransferases. The amino group is excreted after incorporation into urea in the urea cycle. The carbon skeletons of glucogenic amino acids can be used for glucose synthesis, whereas those of ketogenic amino acids appear in ketone bodies (see Figure 25.41). The liver is also the principal detoxification organ in the body. The endoplasmic reticulum of liver cells is rich in enzymes that convert biologically active substances such as hormones, poisons, and drugs into less harmful byproducts.

Liver disease leads to serious metabolic derangements, particularly in amino acid metabolism. In cirrhosis, the liver becomes defective in converting NH_4^+ to urea for excretion, and blood levels of NH_4^+ rise. Ammonia is toxic to the central nervous system, and coma ensues.

27.6 | What Regulates Our Eating Behavior?

Over 70% of Americans are overweight, and more than one in three Americans is clinically obese (overweight by 20% or more). Obesity is the single most important cause of type 2 (adult-onset, insulin-independent) diabetes. Research into the regulatory controls that govern our feeding behavior has become a medical urgency with great financial incentives, given the epidemic proportions of obesity and widespread preoccupation with dieting and weight loss.

27.6a The Hormones That Control Eating Behavior Come from Many Different Tissues

Appetite and weight regulation are determined by a complex neuroendocrine system that involves hormones produced in the stomach, small intestines, pancreas, adipose tissue, and central nervous system. These hormones act in the brain, principally on neurons within the arcuate nucleus region of the hypothalamus. The arcuate nucleus is an anatomically distinct brain area that functions in homeostasis of body weight, body temperature, blood pressure, and other vital functions (Figure 27.13). The neurons respond to these signals by activating, or not, pathways involved in eating (food intake) and energy expenditure. Hormones that regulate eating behavior can be divided into short-term regulators that determine individual meals and long-term regulators that act to stabilize the levels of body fat deposits. Two subsets of neurons are involved: (1) the **NPY/AgRP**-producing neurons that release **NPY (neuropeptide Y)**, the protein that stimulates the neurons that trigger eating behavior, and (2) the **melanocortin**-producing pro-opiomelanocortin (POMC) neurons, whose products inhibit the neurons initiating eating behavior. **AgRP** is **agouti-related peptide**, a protein that blocks the activity of melanocortin-producing neurons. **Melanocortins** are a group of peptide hormones that includes **α - and β -melanocyte-stimulating hormones (α -MSH and β -MSH)**. Melanocortins act on melanocortin receptors (MCRs), which are mem-

Figure 27.13 The regulatory pathways that control eating. The pink neurons targeted by NPY/AgRP and melanocortin-producing pro-opiomelanocortin (POMC) neurons are likely neurons of the PVH (paraventricular region of the hypothalamus). In turn, neurons of the PVH make connections to the hindbrain and spinal cord regions more directly involved in regulation of food intake and energy expenditure. It's complicated. (Adapted from Figure 1 in Schwartz, M. W., and Morton, G. J., 2002. Obesity: Keeping hunger at bay. *Nature* **418**:595–597.)

bers of the 7-TMS G-protein–coupled receptor (GPCR) family of membrane receptors; MCRs trigger cellular responses through adenylyl cyclase activation.

27.6b Ghrelin and Cholecystokinin Are Short-Term Regulators of Eating Behavior

Short-term regulators of eating include **ghrelin** and **cholecystokinin**. Ghrelin is an appetite-stimulating peptide hormone produced in the stomach. Production of ghrelin is maximal when the stomach is empty, but ghrelin levels fall quickly once food is consumed. Cholecystokinin is a peptide hormone released from the gastrointestinal tract during eating. In contrast to ghrelin, cholecystokinin signals satiety (the sense of fullness) and tends to curtail further eating. Together, ghrelin and cholecystokinin constitute a meal-to-meal control system that regulates the onset and end of eating behavior. The activity of this control system is also modulated by the long-term regulators.

27.6c Insulin and Leptin Are Long-Term Regulators of Eating Behavior

Long-term regulators of eating behavior include **insulin** and **leptin**, both of which inhibit eating and promote energy expenditure. Insulin is the key hormone produced in response to food excess and the well-fed state. It signals caloric abundance. Insulin is produced in the β -cells of the pancreas when blood glucose levels rise. A major role of insulin is to stimulate glucose uptake from the blood into muscle, fat, and other tissues. Blood insulin levels correlate with body fat amounts. Insulin also stimulates fat cells to make leptin. Leptin (from the Greek word *lepto*, meaning “thin”) is a 16-kDa, 146-amino acid residue protein produced principally in adipocytes (fat cells). Leptin has a four-helix bundle tertiary structure similar to that of cytokines (protein hormones involved in cell–cell communication; see Figure 27.14). Normally, as fat deposits accumulate in adipocytes, more and more leptin is produced in these cells and released into the bloodstream. Leptin levels in the blood communicate the status of triacylglycerol levels in the adipocytes to the central nervous system so that appropriate changes in appetite take place. If leptin levels are low (starvation), appetite increases; if leptin levels are high (overfeeding), appetite is suppressed. Leptin also regulates fat metabolism in adipocytes, inhibiting fatty acid biosynthesis and stimulating fat metabolism. In the latter case, leptin induces synthesis of the enzymes in the fatty acid oxidation pathway and increases expression of *uncoupling protein 2* (UCP2), a mitochondrial protein that uncouples oxidation from phosphorylation so that the energy of oxidation is lost as heat (thermogenesis). Leptin binding to leptin receptors in the hypothalamus inhibits release of NPY. Because NPY is a potent *orexigenic* (appetite-stimulating) peptide hormone, leptin is therefore an *anorexic* (appetite-suppressing)

Figure 27.14 Structures of human leptin (PDB id = 1AX8), neuropeptide Y (PDB id = 1RON), and PPY₃₋₃₆ (PDB id = 2DEZ). (The leptin structure shown here is for leptin E100 [a W100E mutant]. Leptin E100 is a fully functional form of leptin.)

agent. Functional leptin receptors are also essential for pituitary function, growth hormone secretion, and normal puberty. When body fat stores decline, the circulating levels of leptin and insulin also decline. Hypothalamic neurons sense this decline and act to increase appetite to restore body fat levels.

Intermediate regulation of eating behavior is accomplished by the gut hormone **PYY₃₋₃₆**. PYY₃₋₃₆ is produced in endocrine cells found in distal regions of the small intestine, areas that receive ingested food some time after a meal is eaten. PYY₃₋₃₆ inhibits eating for many hours after a meal by acting on the NPY/AgRP-producing neurons in the arcuate nucleus. Clearly, the regulatory controls that govern eating are complex and layered. Some believe that defects in these controls are common and biased in favor of overeating, an advantageous evolutionary strategy that may have unforeseen consequences in these bountiful times.

To this point, our focus has been on hormonal controls influencing energy homeostasis and food intake. Superimposed on these regulatory mechanisms are neural controls originating in those cognitive centers of the brain involved in learning, memory, socialization, and decision-making processes. For example, hedonistic (pleasure-seeking) mechanisms triggered by seeing, smelling, tasting, or even imagining food can override the normal hormonal regulation of eating behavior that is driven by nutrient levels in the blood. Eating or not is determined by a very complex interplay between energy status and the emotional and/or rational disposition of the brain. Our lack of understanding of these phenomena hinders our treatment of the obesity epidemic.

27.6d AMPK Mediates Many of the Hypothalamic Responses to These Hormones

The actions of leptin, ghrelin, and NPY converge at AMPK. Leptin inhibits AMPK activity in the arcuate nucleus, and this inhibition underlies the anorexic effects of leptin. Leptin action on AMPK depends on a particular melanocortin receptor type known as the **melanocortin-4 receptor (MC4R)**. On the other hand, ghrelin and NPY activate hypothalamic AMPK, which stimulates food intake and leads, over time, to increased body weight. The effects of AMPK in the hypothalamus that lead to alterations in eating behavior may be mediated through changes in malonyl-CoA levels. Malonyl-CoA is believed to be a key indicator of energy levels in hypothalamic neurons. Low [malonyl-CoA] in hypothalamic neurons is associated with increased food intake, and elevated malonyl-CoA levels are associated with suppression of eating. The inhibition of acetyl-CoA carboxylase (and thus, malonyl-CoA synthesis) as a result of phosphorylation by AMPK plays an important part in the regulation of our eating behavior. Dysregulation of the malonyl-CoA and AMPK circuit is implicated in the development of metabolic syndrome, a suite of metabolic aberrations associated with obesity, including insulin resistance, high levels of insulin in the blood, abnormal blood lipid profiles, inflammation, and the likelihood to develop type 2 diabetes.

27.7 | Can You Really Live Longer by Eating Less?

Nutritional studies published in 1935 showed that rats fed a low-calorie, but balanced and nutritious diet, lived nearly twice as long as rats with unlimited access to food (2.4 years versus 1.3 years). Subsequent research over the ensuing 85 years has shown that the relationship between diet and longevity is a general one for organisms from yeast to mammals.

27.7a Caloric Restriction Leads to Longevity

To achieve this effect of **caloric restriction (CR)** on longevity, animals are given a level of food that amounts to 60% to 70% of what they would eat if they were allowed free access to food. In animals, CR results in lower blood glucose levels, declines in glycogen and fat stores, enhanced responsiveness to insulin, lower body temperature, and diminished reproductive capacity. The extended life span given by CR offers a definite

evolutionary advantage: Any animal that could slow the aging process and postpone reproduction in times of food scarcity and then resume reproduction when food became available would out-compete animals without such ability.

Another remarkable feature of CR is that it diminishes the likelihood for development of many age-related diseases, such as cancer, diabetes, and atherosclerosis. Is this benefit simply the result of lowered caloric intake, or does CR lead to significant regulatory changes that affect many aspects of an organism's physiology? The answer to this and other questions is emerging from vigorous research efforts toward understanding CR.

In this regard, experiments show that mTOR plays a role in the aging process. Either genetic disruption of mTOR signaling or rapamycin inhibition of mTOR activity extends lifespan in experimental animals (nematodes, flies, and mice). Beyond its effects on aging, rapamycin delays the onset of diseases associated with aging, such as Alzheimer's and cancer.

27.7b Mutations in the *SIR2* Gene Decrease Life Span

Many important clues about the mechanism of CR came from genetic investigations. Deletion of a gene termed *SIR2* (for silent information regulator 2) abolished the ability of CR to lengthen life span in yeast and roundworms, implicating the *SIR2* gene product in longevity. *SIR2* originally was discovered through its ability to silence the transcription of genes that encode rRNA. *SIR2*-related genes are found in some prokaryotes and virtually all eukaryotes, including yeast, nematodes, fruit flies, and humans. Humans have seven such genes, designated *SIRT1* through *SIRT7*, SIRT being an abbreviation of **sirtuin**, the generic name for proteins encoded by *SIR2* genes. SIRTs differ in their cellular localization, with SIRT1 cycling between the cytosol and nucleus, and SIRTs 3, 4, and 5 confined to the mitochondria. SIRT1 is the best studied of the human sirtuins. Sirtuins are NAD^+ -dependent protein deacetylases (Figure 27.15). Cleavage of acetyl groups from acetylated lysine side chains in proteins is an exergonic reaction, as is cleavage of the *N*-glycosidic bond in NAD^+ ($\Delta G^\circ = -34$ kJ/mol). Thus, involvement of NAD^+ in the reaction is not a thermodynamic necessity. However, NAD^+ involvement does couple the reaction to an important signal of metabolic status, namely, the availability of NAD^+ . So oxidative metabolism, which drives conversion of NADH to NAD^+ , enhances sirtuin activity. One adaptive response found with CR is increased mitochondrial biogenesis in liver, fat, and muscle, which is a response that would raise the NAD^+ concentration.

Sirtuin-catalyzed removal of acetyl groups from lysine residues of histones, the core proteins of nucleosomes, would allow the nucleosomes to interact more strongly with DNA, making transcription more difficult. Perhaps more significantly, SIRT-catalyzed removal of acetyl groups from K residues in transcription factors and metabolic enzymes is an effective mechanism for transcriptional and metabolic regulation in response to changes in the NAD^+/NADH ratio. Almost all the enzymes of energy metabolism are acetylated and thus potentially regulated by SIRT deacetylation. Thus, sirtuins are energy sensors that integrate metabolism and the regulation of gene expression.

Figure 27.15 The NAD^+ -dependent protein deacetylase reaction of sirtuins. The enzymes catalyzing this reaction are classified as lysine (K) deacetylases (KDACs). Acetylated peptides include *N*-acetyl lysine side chains of histone H3 and H4 and acetylated p53 (p53 is the protein product of the *p53* tumor suppressor gene).

Recent research suggests that sirtuins might function as general protein deacylases, capable of removing any acyl group from a protein and targeting a wide range of acylated proteins. In addition, suggesting that SIRT1 acts to promote longevity may be misleading. Instead, it seems more likely that the actions of SIRT1 are directed toward mobilizing pathways that protect against stress. Given that chronic diseases and aging are a direct result of the ravaging effects of stress, this hypothesis proposes that sirtuins promote health maintenance, not longevity, and that longevity is a secondary effect.

27.7c SIRT1 Is a Key Regulator in Caloric Restriction

As a key regulator in CR, the human sirtuin protein SIRT1 connects nutrient availability to the expression of metabolic genes. A striking feature of CR is the loss of fat stores and reduction in **white adipose tissue (WAT)**. SIRT1 participates in the transcriptional regulation of adipogenesis through interaction with **PPAR γ** (peroxisome proliferator-activator receptor- γ), a nuclear hormone receptor that activates transcription of genes involved in adipogenesis and fat storage. SIRT1 binding to two PPAR γ corepressors, NCoR and SMRT, prevents transcription of genes controlled by PPAR γ , leading to loss of fat stores. Because adipose tissue functions as an endocrine organ, this loss of fat has significant hormonal consequences for energy metabolism (Figure 27.15).

In liver, SIRT1 interacts with and deacetylates **PGC-1 α** (peroxisome proliferator-activator receptor- γ coactivator-1), a transcriptional regulator of genes involved in energy metabolism and mitochondrial biogenesis. Thus, CR leads to increased transcription of the genes encoding the enzymes of gluconeogenesis and repression of genes encoding glycolytic enzymes. Acting in these roles, SIRT1 connects nutrient availability to the regulation of major pathways of energy storage (glycogen and fat) and fuel utilization.

27.7d SIRT1, mTORC1, AMPK, CR, and Metabolic Syndrome

SIRT1 is also regulated through reversible phosphorylation. Phosphorylation of SIRT1 Ser⁴⁷ by the master regulator mTORC1 inhibits SIRT1. Recall that mTORC1 is active when nutrient levels are high. In contrast, when cAMP-dependent PKA phosphorylates Ser⁴³⁴ within the SIRT1 catalytic domain, SIRT1 is activated. Thus, activation of SIRT1 is a response to β -adrenergic hormones like epinephrine. Adrenergic hormones are released as a response to cold stress, and when they activate SIRT1, it promotes fatty acid oxidation and thermogenesis in brown fat. Further, when glucose levels are depleted, as in CR, AMPK activates SIRT1 through phosphorylation of T⁵³⁰.

Certain generalizations are clear. AMPK is a key regulator of metabolism through its role as the sensor of energy status. The NAD⁺-dependent deacetylase SIRT1 becomes activated when nutrients are limiting, as in CR. So, both AMPK and SIRT1 respond to nutrient limitation. AMPK responds by down-regulating anabolic processes and activating ATP-producing catabolic processes. AMPK accomplishes these ends through phosphorylation of metabolic enzymes and transcription factors. The effects of SIRT1 are achieved through its deacetylation of metabolic enzymes and transcription factors, and depending on the transcription factor, gene expression may be enhanced or diminished. AMPK and SIRT1 functions are coordinated to ensure that the cellular responses to changing conditions of nutrient availability are appropriate.

As mentioned in Section 27.6, metabolic syndrome is a suite of symptoms that precede the development of type 2 diabetes; the symptoms of metabolic syndrome are the exact opposite of the benefits of caloric restriction. The symptoms include high blood pressure, elevated blood triglyceride levels, low blood HDL-cholesterol levels, high blood glucose levels, and central obesity (accumulation of body fat around the waist). The relationships between the altered metabolism seen in metabolic syndrome and the effects of CR are intriguing. Caloric restriction reverses all the symptoms of metabolic syndrome. A deeper understanding of the relationships between nutrient intake and changes in metabolic regulation is key to health and wellbeing.

Foundational Biochemistry Things You Should Know after Reading Chapter 27.

- Systems analysis can simplify the complexity of metabolism.
- The metabolism of a heterotrophic cell can be portrayed as three interconnected functional blocks: catabolism, anabolism, and macromolecular synthesis/growth.
- Only a few intermediates connect the systems of catabolism and anabolism: four sugar- P s, three α -keto acids, two coenzyme A derivatives, and PEP.
- ATP and NADPH couple catabolism and anabolism.
- Phototrophs have a fourth functional block consisting of photosynthesis and CO_2 fixation.
- In phototrophs, ATP and NADPH are produced by photosynthesis.
- Virtually every metabolic pathway either produces or consumes ATP.
- The overall thermodynamic efficiency of any metabolic sequence is determined by its ATP stoichiometry.
- Catabolic pathways release energy that is captured as ATP.
- The thermodynamically unfavorable reactions of anabolism are driven by ATP hydrolysis.
- Obligate coupling stoichiometry: Chemical considerations fix the stoichiometry of electron-pair carriers such as NADH and $[\text{FADH}_2]$ in metabolic pathways.
- The stoichiometry of ATP coupling is not fixed by chemistry; instead, it is an evolved characteristic of living systems.
- ATP coupling stoichiometry determines the K_{eq} for a metabolic sequence.
- ATP has two metabolic roles: (1) ATP serves a stoichiometric role that renders metabolic pathways emphatically favorable, and (2) ATP has an allosteric role in the kinetic regulation of metabolism.
- Energy charge is a concept used to quantify cellular energy status.
- Energy charge is based on the ratio of the sum of the phosphoric anhydride bonds in ADP and ATP divided by the total adenine nucleotide pool.
- The adenylate kinase reaction connects the three principal adenine nucleotides: AMP, ADP, and ATP.
- Because of the reciprocal relationship between adenine nucleotide regulation of catabolic and anabolic pathways, the energy charge of cells is tightly regulated to remain fairly constant at high energy charge.
- Phosphorylation potential (the ratio of $[\text{ATP}]/[\text{ADP}][\text{P}_i]$) changes as ATP levels change.
- AMP-activated protein kinase (AMPK) is the cellular energy sensor.
- ATP is an allosteric inhibitor of AMPK; AMP is an allosteric activator of AMPK.
- When cellular energy status is high ($[\text{ATP}]$ is high), AMPK is inactive.
- When cellular energy status is low ($[\text{AMP}]$ is high), AMPK is activated.
- AMPK targets key enzymes in energy-producing and energy-consuming pathways, turning on those that lead to ATP synthesis and turning off those that consume ATP.
- mTOR (mechanistic target of rapamycin) is a master coordinator of metabolism in multicellular organisms.
- AMPK disrupts the action of mTORC1 through phosphorylation of a heterodimeric protein called TSC1/2.
- When nutrient levels are high, the mTORC1 complex phosphorylates proteins controlling transcription and translation of genes that encode anabolic pathways.
- Metabolism is integrated in multicellular organisms.
- The tissues of the body work together to maintain energy homeostasis.
- The organ systems of multicellular organisms have specialized metabolic roles.
- The brain has very high respiratory metabolism, accounting for 20% of the total oxygen consumption by the body.
- The brain has no stored fuel, so it depends on the bloodstream for a constant supply of glucose.
- Under conditions of starvation, the brain can use ketone bodies instead of glucose for fuel.
- Muscle is responsible for about 30% of O_2 consumption at rest, and more than 90% during strenuous exercise.
- Almost as much ATP is used to pump Ca^{2+} ions back into the sarcoplasmic reticulum as was used in muscle contraction.
- Creatine kinase allows muscle to use phosphocreatine to restore ATP levels that have been depleted.
- During fasting or starvation, muscle protein is degraded to form α -keto acids that can be used as energy sources or to fuel gluconeogenesis.
- Heart muscle prefers fatty acids as fuel.
- Adipose tissue is not merely a repository for triglycerides; it is also an important endocrine organ, secreting hormones such as leptin that regulate eating behavior and caloric homeostasis.
- Brown fat is adipose tissue rich in mitochondria.
- Thermogenesis is the metabolic role of brown fat: The mitochondria in brown fat have uncoupling proteins that dissipate the proton gradient as heat.
- The liver is the major metabolic processing center in animals.
- The liver is responsible for glucose homeostasis through maintenance of constant blood [glucose].
- The liver is the principal site of fatty acid turnover.
- The liver can use amino acids as metabolic fuel, for gluconeogenesis, or for ketone body synthesis.
- The hormones that control eating behavior come from many different organs—fat, stomach, pancreas, intestines, and the central nervous system.
- Two subsets of neurons located in the arcuate nucleus of the hypothalamus regulate eating behavior: the NPY/AgRP-producing neurons that release NPY, a hormone that triggers eating, and the melanocortin-producing POMC neurons whose products inhibit eating behavior.
- Ghrelin and cholecystokinin are short-term regulators of eating behavior.
- Leptin and insulin are long-term regulators of eating behavior.
- The gut hormone PPY₃₋₃₆ is an intermediate regulator of eating behavior.
- AMPK mediates many of the hypothalamic responses to these hormones.
- Superimposed on these biochemical mechanisms are neuronal controls arising from cognitive centers in the brain that can override metabolic regulation.

- Caloric restriction (CR) leads to longevity.
- The *SIRT* gene products, referred to as SIRT, are sirtuins: NAD⁺-dependent protein deacetylases (NAD⁺-dependent KDACS).
- Almost all metabolic enzymes are acetylated and thus potentially regulated by the sirtuins.
- SIRT1 deacetylates metabolic enzymes, histones, and certain transcription factors.
- The metabolic role of SIRT1 is to integrate metabolism and gene expression with the availability of calories.
- SIRT1 is a key regulator in caloric restriction.
- Thus, both AMPK and SIRT1 respond to nutrient limitation.
- AMPK accomplishes these ends through phosphorylation of metabolic enzymes and transcription factors.
- SIRT1 activity is dependent on the availability of NAD⁺ and, thus, oxidative metabolism.
- The effects of SIRT1 are achieved through its deacetylation of metabolic enzymes and transcription factors.
- AMPK and SIRT1 functions are coordinated so that cellular responses to changing nutrient availability are appropriate.
- mTORC1 phosphorylation of SIRT1 Ser⁴⁷ inhibits its deacetylase activity.
- PKA phosphorylation of Ser⁴³⁴ within the SIRT1 catalytic domain activates SIRT1.
- AMPK and SIRT1 act to ensure that cellular responses to changes in of nutrient availability are appropriate.
- Sirtuins promote health maintenance by mobilizing pathways that protect against physiological stress.
- Caloric restriction reverses the symptoms of metabolic syndrome.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. The Energetics of Opposing Metabolic Sequences** (Integrates with Chapters 3, 18, and 22.) The conversion of PEP to pyruvate by pyruvate kinase (glycolysis) and the reverse reaction to form PEP from pyruvate by pyruvate carboxylase and PEP carboxykinase (gluconeogenesis) represent a substrate cycle. The direction of net conversion is determined by the relative concentrations of allosteric regulators that exert kinetic control over pyruvate kinase, pyruvate carboxylase, and PEP carboxykinase. Recall that the last step in glycolysis is catalyzed by pyruvate kinase:

The standard free energy change is -31.7 kJ/mol .

- Calculate the equilibrium constant for this reaction.
- If $[\text{ATP}] = [\text{ADP}]$, by what factor must $[\text{pyruvate}]$ exceed $[\text{PEP}]$ for this reaction to proceed in the reverse direction?

The reversal of this reaction in eukaryotic cells is essential to gluconeogenesis and proceeds in two steps, each requiring an equivalent of nucleoside triphosphate energy:

Pyruvate carboxylase

PEP carboxykinase

- The ΔG° for the overall reaction is $+0.8 \text{ kJ/mol}$. What is the value of K_{eq} ?
 - Assuming $[\text{ATP}] = [\text{ADP}]$, $[\text{GTP}] = [\text{GDP}]$, and $[\text{P}_i] = 1 \text{ mM}$ when this reaction reaches equilibrium, what is the ratio of $[\text{PEP}]/[\text{pyruvate}]$?
 - Are both directions in the substrate cycle likely to be strongly favored under physiological conditions?
- 2. Calculating Energy Charge and Phosphorylation Potential** (Integrates with Chapter 3.) Assume the following intracellular concentrations in muscle tissue: $[\text{ATP}] = 8 \text{ mM}$, $[\text{ADP}] = 0.9 \text{ mM}$, $[\text{AMP}] = 0.04 \text{ mM}$, $[\text{P}_i] = 8 \text{ mM}$. What is the *energy charge* in muscle? What is the *phosphorylation potential*?

- 3. Evolved Stoichiometry in ATP Production** (Integrates with Chapter 20) Section 27.2 highlights the evolved nature of ATP coupling coefficients in metabolic pathways. Revisit the electron transport/oxidative phosphorylation process in Chapter 20 and describe at least three aspects of this process that could affect the stoichiometry of ATP production.
- 4. How Long Do ATP and Phosphocreatine Supplies Last During Muscle Contraction?** Strenuous muscle exertion (as in the 100 meter dash) rapidly depletes ATP levels. How long will 8 mM ATP last if 1 gram of muscle consumes $300 \mu\text{mol}$ of ATP per minute? (Assume muscle is 70% water.) Muscle contains phosphocreatine as a reserve of phosphorylation potential. Assuming $[\text{phosphocreatine}] = 40 \text{ mM}$, $[\text{creatine}] = 4 \text{ mM}$, and ΔG° ($\text{phosphocreatine} + \text{H}_2\text{O} \rightleftharpoons \text{creatine} + \text{P}_i$) = -43.3 kJ/mol , how low must $[\text{ATP}]$ become before it can be replenished by the reaction: $\text{phosphocreatine} + \text{ADP} \rightleftharpoons \text{ATP} + \text{creatine}$? [Remember, ΔG° (ATP hydrolysis) = -30.5 kJ/mol .]
- 5. What Is the Metabolic Value of NADPH in ATP Equivalents?** (Integrates with Chapter 20.) The standard reduction potentials for the $(\text{NAD}^+/\text{NADH})$ and $(\text{NADP}^+/\text{NADPH})$ couples are identical, namely, -320 mV . Assuming the in vivo concentration ratios $\text{NAD}^+/\text{NADH} = 20$ and $\text{NADP}^+/\text{NADPH} = 0.1$, what is ΔG for the following reaction?

Assuming standard state conditions for the reaction, $\text{ADP} + \text{P}_i \longrightarrow \text{ATP} + \text{H}_2\text{O}$, calculate how many ATP equivalents can be formed from $\text{ADP} + \text{P}_i$ by the energy released in this reaction.

- 6. NAD⁺/NADH in Catabolism or Anabolism** NAD^+/NADH is largely used in the catabolic block of metabolism. Name an anabolic pathway that uses NAD^+/NADH .
- 7. Adenylate Kinase Is an Amplifier** (Integrates with Chapter 3.) Assume the total intracellular pool of adenylates ($\text{ATP} + \text{ADP} + \text{AMP}$) = 8 mM , 90% of which is ATP. What are $[\text{ADP}]$ and $[\text{AMP}]$ if the adenylate kinase reaction is at equilibrium? Suppose $[\text{ATP}]$ drops suddenly by 10% . What are the concentrations now for ADP and AMP, assuming that the adenylate kinase reaction is at equilibrium? By what factor has the AMP concentration changed?
- 8. Regulating the Flux Through Metabolic Pathways** (Integrates with Chapters 18 and 22.) The reactions catalyzed by PFK and FBPase constitute another substrate cycle. PFK is AMP activated; FBPase

is AMP inhibited. In muscle, the maximal activity of PFK (mmol of substrate transformed per minute) is ten times greater than FBPase activity. If the increase in [AMP] described in problem 5 raised PFK activity from 10% to 90% of its maximal value but lowered FBPase activity from 90% to 10% of its maximal value, by what factor is the flux of fructose-6-P through the glycolytic pathway changed? (*Hint*: Let PFK maximal activity = 10, FBPase maximal activity = 1; calculate the relative activities of the two enzymes at low [AMP] and at high [AMP]; let J , the flux of F-6-P through the substrate cycle under any condition, equal the velocity of the PFK reaction *minus* the velocity of the FBPase reaction.)

9. **The Effects of Leptin on Fat Metabolism** (Integrates with Chapters 23 and 24.) Leptin induces synthesis of fatty acid oxidation enzymes and uncoupling protein 2 in adipocytes as well as causes inhibition of acetyl-CoA carboxylase, resulting in a decline in fatty acid biosynthesis. This effect on acetyl-CoA carboxylase, as an additional consequence, enhances fatty acid oxidation. Explain how leptin-induced inhibition of acetyl-CoA carboxylase might promote fatty acid oxidation.
10. **Ethanol as a Source of Metabolic Energy** (Integrates with Chapters 19 and 20.) Acetate produced in ethanol metabolism can be transformed into acetyl-CoA by the acetyl thiokinase reaction:

Acetyl-CoA then can enter the citric acid cycle and undergo oxidation to two CO_2 . How many ATP equivalents can be generated in a liver cell from the oxidation of one molecule of ethanol to two CO_2 by this route, assuming oxidative phosphorylation is part of the process? (Assume all reactions prior to acetyl-CoA entering the citric acid cycle occur outside the mitochondrion.) Per carbon atom, which is a better metabolic fuel, ethanol or glucose? That is, how many ATP equivalents per carbon atom are generated by combustion of glucose versus ethanol to CO_2 ?

11. **ATP Coupling Coefficients and the Thermodynamics of Opposing Metabolic Sequences I** (Integrates with Chapter 23.) Assuming each NADH is worth three ATP, each FADH_2 is worth two ATP, and each NADPH is worth four ATP: How many ATP equivalents are produced when one molecule of palmitoyl-CoA is oxidized to eight molecules of acetyl-CoA by the fatty acid β -oxidation pathway? How many ATP equivalents are consumed when eight molecules of acetyl-CoA are transformed into one molecule of palmitoyl-CoA by the fatty acid biosynthetic pathway? Can both of these metabolic sequences be metabolically favorable at the same time if ΔG for ATP synthesis is +50 kJ/mol?
12. **ATP Coupling Coefficients and the Thermodynamics of Opposing Metabolic Sequences II** (Integrates with Chapters 18–21.) If each NADH is worth three ATP, each FADH_2 is worth two ATP, and each NADPH is worth four ATP, calculate the equilibrium constant for cellular respiration, assuming synthesis of each ATP costs 50 kJ/mol of energy. Calculate the equilibrium constant for CO_2 fixation under the same conditions, except here ATP will be hydrolyzed to $\text{ADP} + \text{P}_i$ with the release of 50 kJ/mol. Comment on whether these reactions are thermodynamically favorable under such conditions.
13. **ATP as Regulator** (Integrates with Chapter 15) Discuss at least three ways in which ATP acts, directly or indirectly, as a potent regulator of enzymes or proteins.
14. **Acetylation of Lysine and DNA/Histone Interactions** Sirtuin catalyzes the removal of acetyl groups from lysine residues of histone proteins in the nucleosomes. This allows the nucleosomes to interact more strongly with DNA, limiting transcription. Explain how the deacetylation of lysine residues on histone proteins leads to stronger interactions between the histones and DNA.
15. **Metabolic Inhibitors as a Diabetes Treatment Strategy** (Integrates with Chapter 22.) In type 2 diabetics, glucose production in the liver is not

appropriately regulated, so glucose is overproduced. One strategy to treat this disease focuses on the development of drugs targeted against regulated steps in glycogenolysis and gluconeogenesis, the pathways by which liver produces glucose for release into the blood. Which enzymes would you select for as potential targets for such drugs?

16. **Treatment of Diabetes** Diabetes is characterized by chronic elevated blood levels of glucose due to lack of insulin (for type 1 diabetes) or unresponsiveness to insulin (for type 2 diabetes). Independent of the type of diabetes, lifestyle factors like diet control and regular exercise can help patients to manage the condition. Explain how regular exercise can help a patient manage blood glucose levels. (*Hint*: See section 27.4b.)
17. **Drug Targets to Regulate Eating Behavior** As chief scientist for drug development at PhatPharmaceuticals, Inc., you want to create a series of new weight-loss drugs. You have a grand plan to design drugs that might limit production of some hormones or promote the production of others. Which hormones are on your “limit production” list and which are on your “raise levels” list?
18. **Leptin Injections as an Obesity Therapy** The existence of leptin was revealed when the *ob/ob* genetically obese strain of mice was discovered. These mice have a defective leptin gene. Predict the effects of daily leptin injections into *ob/ob* mice on food intake, fatty acid oxidation, and body weight. Similar clinical trials have been conducted on humans, with limited success. Suggest a reason why this therapy might not be a miracle cure for overweight individuals.
19. **Hormones That Regulate Eating Behavior** Would it be appropriate to call neuropeptide Y (NPY) the obesity-promoting hormone? What would be the phenotype of a mouse whose melanocortin-producing neurons failed to produce melanocortin? What would be the phenotype of a mouse lacking a functional MC3R gene? What would be the phenotype of a mouse lacking a functional leptin receptor gene?
20. **Consequences of Alcohol Consumption on the NAD^+/NADH Ratio** The Human Biochemistry box, “The Metabolic Effects of Alcohol Consumption,” points out that ethanol is metabolized to acetate in the liver by alcohol dehydrogenase and aldehyde dehydrogenase:

These reactions alter the NAD^+/NADH ratio in liver cells. From your knowledge of glycolysis, gluconeogenesis, and fatty acid oxidation, what might be the effect of an altered NAD^+/NADH ratio on these pathways? What is the basis of this effect?

21. **The Phenotype of a T172D Mutation in AMPK** A T172D mutant of AMPK is locked in a permanently active state. Explain.
22. **Malonyl-CoA as a Key Indicator of Nutrient Availability**
- Some scientists support the malonyl-CoA hypothesis, which suggests that malonyl-CoA is a key indicator of nutrient availability and the brain uses its abundance to assess whole-body energy homeostasis. Others have pointed out that malonyl-CoA is a significant inhibitor of carnitine acyltransferase-1 (see Figure 24.16). Thus, malonyl-CoA may be influencing the levels of another metabolite whose concentration is more important as a signal of energy status. What metabolite might that be?
 - Another test of the malonyl-CoA hypothesis was conducted through the creation of a transgenic strain of mice that lacked functional hypothalamic fatty acid synthase (see Chapter 24). Predict the effect of this genetic modification on cellular malonyl-CoA levels in the hypothalamus, the eating behavior of these transgenic mice, their body fat content, and their physical activity levels. Defend your predictions.

23. Confirming the Function of Leptin

- a. Leptin is an anorexic (appetite-suppressing) protein. A congenitally obese strain of mice (*ob/ob* mice) lacks both copies of the gene encoding leptin. Propose an experiment to confirm the function of leptin.
- b. A second strain of obese mice (*db/db* mice) produces leptin in abundance but fails to respond to it. Assuming the *db* mutation leads to loss of function in a protein, what protein is likely to be nonfunctional or absent? How might you test your idea?

24. Preferred Metabolic Fuels Consult Figure 27.6, and answer the following questions: Which organs use both fatty acids and glucose as a fuel in the well-fed state, which rely mostly on glucose, which rely mostly on fatty acids, which one never uses fatty acids, and which one produces lactate.

25. R versus U Enzymes in Response to Energy Charge Figure 27.3 illustrates the response of R (ATP-regenerating) and U (ATP-using) enzymes to energy charge.

- a. Would hexokinase be an R enzyme or a U enzyme? Would glutamine-PRPP amidotransferase, the second enzyme in purine biosynthesis, be an R enzyme or a U enzyme?

- b. If energy charge = 0.5: Is the activity of hexokinase high or low? Is ribose-5-P pyrophosphokinase activity high or low?
- c. If energy charge = 0.95: Is the activity of hexokinase high or low? Is ribose-5-P pyrophosphokinase activity high or low?

PSAFE Problem

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

Examine the PSAFE for resistin, and describe the formation of the resistin hexamer.

Think-Pair-Share Question

Consider the regulation of energy metabolism in the organs shown in Figure 27.8.

Predict which arrows in this figure would be activated or inhibited by: insulin, glucagon, leptin, AMPK, or epinephrine. Are there any differences in regulation between the organs shown? Refer to any previous chapter to justify your answer.

DNA Metabolism: Replication, Recombination, and Repair

Heredity

*I am the family face;
Flesh perishes, I live on,
Projecting trait and trace
Through time to times anon,
And leaping from place to place
Over oblivion.*

*The years-heired feature that can
In curve and voice and eye
Despise the human span
Of durance—that is I;
The eternal thing in man,
That heeds no call to die.*

Thomas Hardy
(in *Moments of Vision and
Miscellaneous Verses*, 1917)

◀ An illustration of DNA, the substance of heredity.

Essential Questions

DNA is the physical repository of genetic information and the material of heredity that is passed on to progeny. **How is this genetic information in the form of DNA replicated, how does rearrangement of this information occur, and how is its integrity maintained in the face of damage?**

Heredity, which we can define generally as the tendency of an organism to possess the characteristics of its parent(s), is clearly evident throughout nature and since the dawn of history has served to justify the classification of organisms according to shared similarities. The basis of heredity, however, was a mystery. Early in the twentieth century, geneticists demonstrated that **genes**, the elements or units carrying and transferring inherited characteristics from parent to offspring, are contained within the nuclei of cells in association with the chromosomes. Yet the chemical identity of genes remained unknown, and genetics was an abstract science. Even the realization that chromosomes are composed of nucleic acids and proteins did little to define the molecular nature of the gene because, at the time, no one understood either of these substances.

The material of heredity must have certain properties. It must be very stable so that genetic information can be stored in it and transmitted countless times to subsequent generations. It must be capable of precise copying or replication so that its information is not lost or altered. And, although stable, it must also be subject to change to account, in the short term, for the appearance of mutant forms and, in the long term, for evolution. DNA is the material of heredity.

DNA Metabolism

The chapters that precede this one have reviewed the major pathways of intermediary metabolism, pointing out the synthesis and breakdown of the major classes of cellular molecules. When we consider DNA from the perspective of metabolism, its role as the hereditary substance focuses our inquiry. While DNA catabolism contributes little to energy metabolism in most cells, DNA synthesis is a central aspect of cellular existence. New DNA molecules are synthesized by copying existing DNA in a manner that

Key Questions

- 28.8 Can DNA Be Repaired?
- 28.9 What Is the Molecular Basis of Mutation?
- 28.10 Can Genetic Recombination Create Protein Diversity?

A template is something whose edge is shaped in a particular way so that it can serve as a guide in making a similar object with a corresponding contour. In DNA replication, each of the original strands acts as a template by specifying the order of nucleotides in the newly synthesized strand according to the base-pairing rules of Watson and Crick.

reproduces its information content through a process called **DNA replication**. As the genetic material, DNA persists over the lifetime of the cell and appears essentially unaltered in subsequent generations. Occasionally, its information is shuffled as regions of DNA are exchanged between chromosomes, a process known as **recombination**. Recombination creates genetic variation upon which evolution can act. As a chemical, DNA is susceptible to reactions that modify its bases or disrupt its sugar–phosphate backbone. Because its effective lifetime exceeds the lifetime of cells, **DNA repair** is necessary to preserve the fidelity of its genetic information. This chapter addresses these dominant features of DNA metabolism: replication, recombination, and repair.

28.1 | How Is DNA Replicated?

Transfer of genetic information from generation to generation requires the faithful reproduction of the parental DNA. DNA reproduction produces two identical copies of the original DNA double helix through DNA replication. The mechanism for DNA replication is strand separation followed by the copying of each strand. In the process, each separated strand acts as a **template** for the synthesis of a new complementary strand whose nucleotide sequence is fixed by the base-pairing rules proposed by Watson and Crick (see Chapter 10). Strand separation is achieved by unwinding the double helix (Figure 28.1). Base pairing then dictates the proper sequence of nucleotide addition to achieve an accurate replication of each original strand. Thus, each original strand ends up paired with a new complementary partner, and two identical double-stranded DNA molecules are formed from one. This mode of DNA replication is referred to as **semiconservative** because one of the two original strands is conserved in each of the two progeny molecules.

28.1a DNA Replication Is Bidirectional

Replication of DNA molecules begins at one or more specific regions called the **origin(s) of replication** and, excepting certain bacteriophage chromosomes and plasmids, proceeds in both directions from this origin (Figure 28.2). For example, replication of *E. coli* DNA begins at *oriC*, a unique 245-bp chromosomal site that contains 11 GATC tetranucleotide sequences along its length. From *oriC*, replication advances in both directions around the circular chromosome. That is, bidirectional replication involves two **replication forks** that move in opposite directions. Bidirectional replication predicts that, if radioactively labeled nucleotides are provided as substrates for new DNA synthesis, both replication forks will become radioactively labeled. The experiment illustrated in Figure 28.2(b) confirms this prediction.

28.1b Replication Requires Unwinding of the DNA Helix

Semiconservative replication depends on unwinding the DNA double helix to expose single-stranded templates to polymerase action. For a double helix to unwind, it must either rotate about its axis (while the ends of its strands are held fixed), or positive supercoils must be introduced, one for each turn of the helix unwound (see Chapter 11). If the chromosome is circular, as in *E. coli*, only the latter alternative is possible. Because DNA replication in *E. coli* proceeds at a rate approaching 1000 nucleotides per second and there are about 10 bp per helical turn, the chromosome would accumulate 100 positive supercoils per second! In effect, the DNA would become too tightly supercoiled to allow unwinding of the strands.

DNA gyrase, a type II topoisomerase, acts to overcome the torsional stress imposed upon unwinding; DNA gyrase introduces negative supercoils at the expense of ATP hydrolysis. The unwinding reaction is driven by **helicases** (see Section 16.4), a class of proteins that catalyze the ATP-dependent unwinding of DNA double helices. Unlike topoisomerases that alter the linking number of dsDNA through phosphodiester bond breakage and reunion (see Chapter 11), helicases simply disrupt the base-pairing interactions that hold the two strands of duplex DNA together. A helicase molecule requires a single-stranded region for binding. It then moves along the single strand, unwinding the double-stranded DNA in an ATP-dependent process. **SSB (single-stranded DNA-binding protein)** binds to the unwound strands, preventing their re-annealing. At least 10 distinct DNA helicases

Figure 28.1 DNA replication: Strand separation followed by the copying of each strand.

Figure 28.2 Bidirectional replication.

(a) Comparison of labeling during unidirectional versus bidirectional replication. **(b)** An autoradiogram of *E. coli* chromosome replication in the presence of radioactive thymidine confirms bidirectional replication. The replicating DNA was obtained from detergent-treated cells, spread out on a microscope slide and dried. See Prescott, D. M., and Kuempel, P. L., 1972. Bidirectional Replication of the Chromosome in *Escherichia coli*. *Proceedings of the National Academy of Sciences, USA* **69**:2842–2845.

Chemistry in History

Slayton A. Evans Jr

Dr. Slayton Evans Jr (1943–2001) was a distinguished professor of chemistry at the University of North Carolina at Chapel Hill (UNC-CH). He rose from modest beginnings to become the Kenan Professor of Chemistry at UNC-CH and an internationally known expert in organophosphorus chemistry.

Dr. Evans was born in Chicago, but was raised in a segregated housing project in Meridian, Mississippi. He was fascinated by plants and insects at an early age and kept a notebook that recorded the characteristics of insects in his collection. He paid for his tuition in a segregated Roman Catholic grade school by mowing lawns and (in 8th grade) working as a janitor at the school. He won both academic and athletic scholarships to Tougaloo College, where he excelled at chemistry. He did graduate work at the Illinois Institute of Technology

and received the Ph.D. in Chemistry from Case Western Reserve University.

Following postdoctoral work at the University of Texas at Arlington and the University of Notre Dame, he took a position as the first African-American assistant professor of chemistry at UNC-CH. Within 10 years, he had risen to the rank of Professor of Chemistry and had established a research laboratory of graduate and undergraduate students and postdocs from around the world. He championed the recruitment of minority students to UNC-CH and served on and chaired committees for the American Chemistry Society, the National Institutes of Health and the National Science Foundation. Following his death from cancer in 2001, a lectureship and a research award were established in his name.

involved in different aspects of DNA and RNA metabolism have been found in *E. coli* alone. **DnaB** is the DNA helicase acting in *E. coli* DNA replication. DnaB helicase assembles as a hexameric (α_6) doughnut-shaped protein ring, with DNA passing through its hole.

28.1c DNA Replication Is Semidiscontinuous

As shown in Figure 28.2, both parental DNA strands are replicated at each advancing replication fork. The enzyme that carries out DNA replication is **DNA polymerase**. This enzyme uses single-stranded DNA (ssDNA) as a template and makes a complementary strand by polymerizing deoxynucleotides in the order specified by their pairing with bases in the template. DNA polymerases synthesize DNA only in a 5'→3' direction, reading the antiparallel template strand in a 3'→5' sense. A dilemma arises: How does DNA polymerase copy the parent strand that runs in the 5'→3' direction at the replication fork? It turns out that *replication is semidiscontinuous* (Figure 28.3).

Figure 28.3 The semidiscontinuous model for DNA replication. Newly synthesized DNA is shown as red. **(a)** Leading- and lagging-strand synthesis. Note that the leading strand is synthesized continuously in the 5'→3' direction as the DNA polymerase reads along the 3'→5' parental template for the leading strand in the 3'→5' direction. Since DNA polymerases can only move along any template in a 3'→5' direction, the other parental strand, the one labeled "5'→3'" is copied, by necessity, in a discontinuous fashion to form short, 5'→3' fragments (lagging strand synthesis). **(b)** Synthesis of both strands carried out by a dimeric DNA polymerase situated at the replication fork. Because DNA polymerase must read the template strand in the 3'→5' direction, the 5'→3' parental strand must wrap around in trombone fashion. **(c)** Bidirectional replication, showing how half of each new strand is replicated by leading-strand synthesis and half by lagging-strand synthesis.

As the DNA helix is unwound during its replication, the 3'→5' strand (as defined by the direction that the replication fork is moving) can be copied continuously by DNA polymerase synthesizing in the 5'→3' direction behind the replication fork. The other parental strand is copied only when a sufficient stretch of its sequence has been exposed for DNA polymerase to read it in the 3'→5' sense. Thus, one parental strand is copied continuously to give a newly synthesized copy, called the **leading strand**, at each replication fork. The other parental strand is copied in an intermittent, or discontinuous, mode to yield a set of fragments 1000 to 2000 nucleotides in length, called the **Okazaki fragments** (Figure 28.3a). These fragments are then joined to form an intact **lagging strand**. Because both strands are synthesized in concert by a dimeric DNA polymerase situated at the replication fork, the 5'→3' parental strand must wrap around in *trombone fashion* so that the unit of dimeric DNA polymerase replicating it can move along it in the 3'→5' direction (Figure 28.3b). Because DNA replication is bidirectional, each of the two DNA duplexes produced in DNA replication contains one old and one new DNA strand, and half of the new strand was formed by leading strand synthesis and the other half by lagging strand synthesis.

28.1d The Biochemical Evidence for Semidiscontinuous DNA Replication

In 1968, Tsuneko and Reiji Okazaki provided biochemical verification of the semidiscontinuous pattern of DNA replication just described. The Okazakis exposed a rapidly dividing *E. coli* culture to ^3H -labeled thymidine for 30 seconds, quickly collected the cells, and found that half of the label incorporated into nucleic acid appeared in short ssDNA chains just 1000 to 2000 nucleotides in length. (The other half of the radioactivity was recovered in very large DNA molecules.) Subsequent experiments demonstrated that with time, the newly synthesized short ssDNA **Okazaki fragments** covalently joined to form longer polynucleotide chains, in accord with a semidiscontinuous mode of replication. The generality of this mode of replication has been corroborated with electron micrographs of DNA undergoing replication in eukaryotic cells.

28.1e Initiation of DNA Replication

The initiation of DNA replication must be timed to serve the cell's metabolic state—that is, it must take place when, and only when, the cell is ready to divide. When that time comes, the DNA double helix must be melted at origin-of-replication (*ori*) sites and the protein complexes that catalyze DNA replication must be recruited there and assembled into a functional replication complex, called a **replicon**. The proteins that bind to *ori* sites and recruit helicases to unwind the DNA double helix are AAA+ ATPases, an evolutionarily ancient family of proteins involved in a variety of energy-dependent unfolding and remodeling of proteins and nucleic acids (see Section 16.4). In *E. coli*, the *oriC* DNA sequence is composed of conserved repeats that are recognized by **DnaA**, an AAA+ ATPase **replication initiator**. In addition, *oriC* has an easily melted AT-rich region known as the **DUE** (DNA unwinding element) where the double helix is unwound to form the single-stranded **replication bubble**. The hexameric helicase **DnaB** is recruited to the replication bubble by DnaA with the assistance of DnaC, another AAA+ ATPase, and loaded onto the DNA single strand that will become the lagging strand during DNA replication. This process of AAA+ ATPase proteins binding at origins of replication, DNA melting, and recruitment of helicases is fundamental in all cells, whether prokaryotic or eukaryotic. However, the specific mechanisms and the proteins that drive them vary across bacteria, archaea, and eukaryotes.

28.2 | What Are the Functions of DNA Polymerases?

The enzymes that replicate DNA are called DNA polymerases. All DNA polymerases, whether from prokaryotic or eukaryotic sources, share the same fundamental catalytic mechanism:

1. The incoming base is selected within the DNA polymerase active site, as determined by Watson–Crick geometric interactions with the corresponding base in the template strand.
2. Chain growth is in the 5'→3' direction and is antiparallel to the template strand.
3. DNA polymerases cannot initiate DNA synthesis de novo—all require a primer oligonucleotide with a free 3'-OH to build upon.

The material discussed in this section applies to all DNA polymerases, prokaryotic and eukaryotic.

28.2a Biochemical Characterization of DNA Polymerases

DNA polymerases can catalyze the synthesis of DNA if provided with all four deoxynucleoside-5'-triphosphates (dATP, dTTP, dCTP, dGTP), a template DNA strand to copy, and a **primer**. A primer is essential because DNA polymerases can elongate only preexisting polynucleotide chains; they cannot join two deoxyribonucleoside-5'-phosphates together to make the initial phosphodiester bond. The primer base pairs with the template DNA, forming a short, double-stranded region. This primer must possess a free 3'-OH end to which an incoming deoxynucleoside monophosphate is added. In vivo, a short RNA strand is invariably the primer; it is synthesized by a DNA-dependent RNA polymerase activity known as **primase**. Like other RNA polymerases, primase can synthesize oligonucleotide chains de novo. Unlike DNA polymerases, it does not require an oligonucleotide precursor.

DNA replication begins when DNA polymerase binds at the 3'-end of the primer. The appropriate one of the four dNTPs is selected as substrate, pyrophosphate (PP_i) is released, and the dNMP is linked to the 3'-OH of the primer chain through formation of a phosphoester bond (Figure 28.4). The deoxynucleotide selected as substrate is chosen through its geometric fit with the template base to form a Watson–Crick base pair. As DNA polymerase catalyzes the successive addition of deoxynucleotide units to the 3'-end of the primer, the chain is elongated in the 5'→3' direction, forming a polynucleotide sequence that is antiparallel and complementary to the template. Cells contain a variety of different DNA polymerases (see Table 28.1) and they differ in how many rounds of deoxynucleotide addition they can catalyze before dissociating from the

Figure 28.4 The chain elongation reaction catalyzed by DNA polymerase. The 3'-OH of the terminal nucleotide in the primer strand carries out a nucleophilic attack on the α -phosphoryl group of the incoming dNTP to form a phosphoester bond, and PP_i is released. The subsequent hydrolysis of PP_i by inorganic pyrophosphatase renders the reaction effectively irreversible.

template strand. The degree to which a particular DNA polymerase remains associated with the template is referred to as its **processivity**. Some DNA polymerases, such as those whose primary function is DNA repair rather than DNA replication, are only modestly processive, synthesizing a DNA strand only 3 to 200 bases long before falling off. On the other hand, replicative DNA polymerases are extraordinarily processive. The *E. coli* replicative DNA polymerase, known as DNA polymerase III holoenzyme, can replicate an entire strand of the *E. coli* chromosome (4.6 megabases) without falling off!

28.2b *E. coli* Cells Have Several Different DNA Polymerases

Table 28.1 compares the properties of the principal DNA polymerases in *E. coli*. These enzymes are nicknamed **pol** and numbered **I** through **V** in order of their discovery. DNA polymerases I, II, and V function principally in DNA repair; **DNA polymerase III** is the chief DNA-replicating enzyme of *E. coli*. Only 40 or so copies of this enzyme are present per cell.

28.2c *E. coli* DNA Polymerase III Holoenzyme Replicates the *E. coli* Chromosome

In its holoenzyme form, DNA polymerase III is the enzyme responsible for replication of the *E. coli* chromosome. The simplest form of DNA polymerase III showing any DNA-synthesizing activity in vitro, core DNA polymerase III, is 165 kDa in size and consists of three polypeptides: α (130 kDa), ϵ (27.5 kDa), and θ (8.6 kDa). In vivo, core DNA polymerase III functions as part of a multisubunit complex, the **DNA polymerase III holoenzyme**, which is composed of 10 different kinds of subunits (Table 28.2). The various

Table 28.2 Subunits of *E. coli* DNA Polymerase III Holoenzyme

Subunit	Mass (kDa)	Function
α	130	Polymerase
ϵ	27.5	3'-Exonuclease
θ	8.6	ϵ -Subunit stabilization
τ	71	DNA template binding; core enzyme dimerization
β	41	Sliding clamp, processivity
γ	47.5	Part of the γ -complex*
δ	39	Part of the γ -complex*
δ'	37	Part of the γ -complex*
χ	17	Interaction with SSB and the γ -complex
ψ	15	Interaction with χ and the γ -complex

*Subunits τ , γ , δ , δ' , χ , and ψ form the so-called γ -complex responsible for adding β -subunits (the sliding clamp) to DNA and anchoring the sliding clamp to the two core DNA polymerase III structures. The γ -complex is referred to as the clamp loader.

auxiliary subunits increase both the polymerase activity of the core enzyme and its processivity. DNA polymerase III holoenzyme synthesizes DNA strands at a speed of nearly 1 kb/sec. DNA polymerase III holoenzyme is organized in the following way: Two core ($\alpha\epsilon\theta$) DNA polymerase III units and one **γ -complex** are attached to DnaB helicase via two τ -subunits to form a structure known as **DNA polymerase III***. (A γ -complex consists of one copy each of the γ -subunit, the δ -subunit, and the δ' -subunit.) In turn, each core polymerase within DNA polymerase III* binds to a β -subunit dimer to create DNA polymerase III holoenzyme, a 17-subunit ($(\alpha\epsilon\theta)_2 2\beta_2 \tau_2 \gamma \delta \delta' \chi \psi$) complex (Figure 28.5). The 17-subunit DNA polymerase III holoenzyme structure is sometimes referred to as a **replisome**. The γ -complex is responsible for assembly of the DNA polymerase III holoenzyme complex onto DNA. The γ -complex of the holoenzyme acts as a **clamp loader** by catalyzing

Figure 28.5 DNA polymerase III holoenzyme is a dimeric polymerase. One unit of polymerase synthesizes the leading strand, and the other synthesizes the lagging strand. Because DNA synthesis always proceeds in the 5'→3' direction as the template strand is read in the 3'→5' direction, lagging-strand synthesis must take place on a looped-out template. This single-stranded loop is more than 1000 bases long. Lagging-strand synthesis requires repeated priming. Primase bound to the DnaB helicase carries out this function, periodically forming new RNA primers on the lagging strand. All single-stranded regions of DNA are coated with SSB (not shown).

Figure 28.6 Structure of the *E. coli* β_2 -sliding clamp. (a) Ribbon diagram of the β -subunit dimer of the DNA polymerase III holoenzyme on B-DNA, viewed down the axis of the DNA. One monomer of the β -subunit dimer is colored blue and the other yellow. The centrally located DNA is multicolored. (b) Space-filling model of the β -subunit dimer on B-DNA. The hole formed by the β -subunits (diameter ≈ 3.5 nm) is large enough to easily accommodate the product of DNA polymerase III holoenzyme action, double-stranded DNA (diameter ≈ 2.5 nm) with no steric repulsion (PDB id = 2POL). The rest of polymerase III holoenzyme (core polymerase + γ -complex) associates with this sliding clamp to form the replicative polymerase (not shown).

the ATP-dependent transfer of a pair of β -subunits to each strand of the DNA template. Each β -subunit dimer forms a closed ring around a DNA strand and acts as a tight clamp that can slide along the DNA (Figure 28.6). Each **β_2 -sliding clamp** tethers a core polymerase to the template, accounting for the great processivity of the DNA polymerase holoenzyme. This complex can replicate an entire strand of the *E. coli* genome (more than 4.6 megabases) without dissociating. Compare this to the processivity of DNA polymerase I, which is only 20 bases!

The core polymerase synthesizing the lagging strand must release from the DNA template when synthesis of an Okazaki fragment is completed and rejoin the template at the next RNA primer to begin synthesis of the next Okazaki fragment. The τ -subunit serves as a “processivity switch” that accomplishes this purpose. The τ -subunit is usually “off” and is turned “on” only on the lagging strand *and* only when synthesis of an Okazaki fragment is completed. When activated, τ ejects the β_2 -sliding clamp bound to the lagging strand core polymerase. Almost immediately, the lagging strand core polymerase is reloaded onto a new β_2 -sliding clamp at the 3'-end of next RNA primer, and synthesis of the next Okazaki fragment commences.

DnaB bound to ssDNA

28.2d A DNA Polymerase III Holoenzyme Sits at Each Replication Fork

Figure 28.7 and Table 28.3 present a snapshot of the enzymatic apparatus assembled at a replication fork. DNA gyrase (topoisomerase) and DnaB helicase unwind the

Figure 28.7 General features of a replication fork. The DNA duplex is unwound by the action of DNA gyrase and helicase, and the single strands are coated with SSB (ssDNA-binding protein). Primase periodically primes synthesis on the lagging strand. Each half of the dimeric replicative polymerase is a core polymerase bound to its template strand by a β -subunit sliding clamp. DNA polymerase I and DNA ligase act downstream on the lagging strand to remove RNA primers, replace them with DNA, and ligate the Okazaki fragments.

Table 28.3 Proteins Involved in DNA Replication in *E. coli*

Protein	Function
DNA gyrase	Unwinding DNA
SSB	Single-stranded DNA binding
DnaA	Initiation factor; origin-binding protein
DnaB	5'→3' helicase (DNA unwinding)
DnaC	DnaB chaperone; loading DnaB on DNA
Primase (DnaG)	Synthesis of RNA primer
DNA polymerase III holoenzyme	Elongation (DNA synthesis)
DNA polymerase I	Excises RNA primer, fills in with DNA
DNA ligase	Covalently links Okazaki fragments
Tus	Termination

DNA double helix, and the unwound, single-stranded regions of DNA are maintained through interaction with SSB. SSB removes any secondary structure from ssDNA and prevents endonucleolytic cleavage of the DNA. **Primase (DnaG)** synthesizes an RNA primer on the lagging strand; the leading strand, which needs priming only once, was primed when replication was initiated. The lagging strand template is looped around, and each replicative DNA polymerase moves 5'→3' relative to its strand, copying template and synthesizing a new DNA strand. Each replicative polymerase is tethered to the DNA by its β -subunit sliding clamp. The DNA polymerase III γ -complex periodically unclamps and then reclamps β -subunits on the lagging strand as the primer for each new Okazaki fragment is encountered. Downstream on the lagging strand, DNA polymerase I excises the RNA primer and replaces it with DNA, and DNA ligase seals the remaining nick.

28.2e DNA Polymerase I Removes the RNA Primers and Fills in the Gaps

E. coli DNA polymerase I, the first DNA polymerase discovered (in 1957 by Arthur Kornberg), acts to remove the RNA primers and replace them with DNA. DNA polymerase I also acts in DNA repair. It fulfills these roles because, in addition to its 5'→3' polymerase activity, *E. coli* DNA polymerase I has two other catalytic functions: a 3'→5' *exonuclease* (3'-*exonuclease*) activity and a 5'→3' *exonuclease* (5'-*exonuclease*) activity. The three distinct catalytic activities of DNA polymerase I reside in separate active sites in the enzyme. The 5'-*exonuclease* activity is not a commonly found property of DNA polymerases. This 5'-*exonuclease* activity is the mechanism for removal of the RNA primers.

28.2f DNA Polymerase I Also Plays a Role in DNA Double-Strand Break Repair

DNA polymerase I can bind to double-stranded DNA where there is a break or gap in one of the strands. It then uses its 5'-*exonuclease* activity to remove mononucleotides and oligonucleotides, degrading the broken strand from its exposed 5'-end as it moves in a 5'→3 direction. One function of the 5'-*exonuclease* is to remove distorted (mispaired) segments lying in the path of an advancing polymerase. Indeed, the biological roles of DNA polymerase I depend on its ability to bind at nicks (single-stranded breaks) in dsDNA and move in the 5'→3' direction, removing successive nucleotides with its 5'-*exonucleolytic* activity. (This overall process is known as **nick translation** because the nick is translated [that is, moved] down the DNA.) This 5'-*exonuclease* activity plays an important role in primer removal during DNA replication, as we've noted. The second *E. coli* DNA polymerase, **DNA polymerase II**, is a DNA repair enzyme expressed in response to DNA damage.

Figure 28.8 The 3'→5' exonuclease activity of DNA polymerase I removes nucleotides from the 3'-end of the growing DNA chain. The newly synthesized strand is shown as a purple ribbon.

28.2g DNA Ligase Seals the Nicks Between Okazaki Fragments

DNA ligase seals nicks in double-stranded DNA where a 3'-OH and a 5'-phosphate are juxtaposed (see Chapter 12). This enzyme is responsible for joining Okazaki fragments together to make the lagging strand a covalently contiguous polynucleotide chain.

28.2h DNA Polymerase Is Its Own Proofreader

DNA polymerases possess a 3'-exonuclease activity, a function that enhances the accuracy of DNA replication. This 3'-exonuclease, a property of the ϵ -subunit, removes nucleotides from the 3'-end of the growing chain (Figure 28.8). By this means, the 3'-exonuclease negates the action of the polymerase. Its purpose, however, is to remove incorrect (mismatched) bases. Although the 3'-exonuclease works slowly compared to the polymerase, the polymerase cannot elongate an improperly base-paired primer terminus. Thus, the relatively slow 3'-exonuclease has time to act and remove the mispaired nucleotide. Therefore, the polymerase active site is a proofreader, and the 3'-exonuclease activity is an editor. This check on the accuracy of base pairing enhances the overall precision of the process.

28.2i DNA Replication Terminates at the *Ter* Region

Located diametrically opposite from *oriC* on the *E. coli* circular chromosome is a terminus region, the *Ter*, or *t*, locus. The oppositely moving replication forks meet here, and replication is terminated. The *Ter* region contains a number of short DNA sequences, with a consensus core element 5'-GTGTGTTGT. These *Ter* sequences act as terminators; clusters of three or four *Ter* sequences are organized into two sets inversely oriented with respect to one another. One set blocks the clockwise-moving replication fork, and its inverted counterpart blocks the counterclockwise-moving replication fork. Termination requires binding of a specific replication termination protein, **Tus protein**, to *Ter*. Tus protein is a **conrahelicase**. That is, Tus protein prevents the DNA duplex from unwinding by blocking progression of the replication fork and inhibiting the ATP-dependent DnaB helicase activity. Final synthesis of both duplexes is completed.

A Deeper Look

A Mechanism for All Polymerases

Thomas A. Steitz suggested that biosynthesis of nucleic acids proceeds by an enzymatic mechanism that is universal among all DNA and RNA polymerases. His suggestion is based on structural studies indicating that DNA polymerases use a two-metal-ion mechanism to catalyze nucleotide addition during elongation of a growing polynucleotide chain (see accompanying figure). The incoming nucleotide has two Mg^{2+} ions (shown here as Me^{2+} , a generic representation for divalent cations) coordinated to its phosphate groups. These metal ions interact with two aspartate residues that are highly conserved in DNA (and RNA) polymerases. These residues in phage T7 DNA polymerase are D705 and D882. One metal ion, designated A, interacts with the O atom of the free 3'-OH group on the polynucleotide chain, lowering its affinity for its hydrogen. A water molecule in the active site (not shown) likely assists in this deprotonation. This interaction promotes nucleophilic attack of the 3'-O on the phosphorus atom in the α -phosphate of the incoming nucleotide. The second metal ion (B in the figure) assists departure of the product pyrophosphate group from the incoming nucleotide. Together, the two metal ions stabilize the pentacoordinate transition state on the α -phosphorus atom.

28.2j DNA Polymerases Are Immobilized in Replication Factories

Chromosomal DNA replication begins when two replisomes are assembled at *ori* sequences to form two replication forks (one replisome per fork). One replisome is depicted in Figure 28.7. The traditional description of what takes place next is a process whereby the replication forks diverge in opposite directions as DNA replication proceeds. In this view, the replicative DNA polymerases are pictured as locomotives moving in opposite directions along DNA railroad tracks (as might be imagined for Figure 28.2). In actuality, in vivo studies reveal that the two replication forks remain linked together. Such co-joined replisomes (one for each replication fork) represent a structure aptly described as a **replication factory** (Figure 28.9). The DNA is fed through the DNA polymerases within the replication factory, much like tape is fed past the heads of a tape player, with all four newly replicated strands of DNA looping out from this fixed structure (Figure 28.9). Note that each newly replicated strand is paired with a strand of parental DNA. Replication factories, also called **replicons**, are thought to be a feature of chromosomal DNA replication across all domains of life.

28.3 | Why Are There So Many DNA Polymerases?

Table 28.1 listed the many DNA polymerases found in *E. coli* cells. Their existence raises the question: Why do cells have multiple DNA polymerases?

28.3a Cells Have Different Versions of DNA Polymerase, Each for a Particular Purpose

A host of different DNA polymerases have been discovered, and even simple bacteria such as *E. coli* have seven distinct DNA polymerases. Yeast (*Saccharomyces cerevisiae*) has 9, and 16 have been identified in humans. Based on sequence homology, polymerases can be grouped into seven different families. The families differ in terms of the biological function served by family members. For example, family A includes DNA polymerases principally involved in DNA repair (*E. coli* DNA polymerase I, mammalian DNA-repair DNA polymerase θ , and mitochondrial DNA polymerase γ , which carries out mitochondrial DNA replication as well as repair). Family B polymerases include the eukaryotic DNA polymerases predominantly involved in replication of chromosomal DNA (the mammalian replicative DNA polymerases α , δ , and ϵ , as well as the eukaryotic DNA-repair DNA polymerase ζ and *E. coli* DNA polymerase II). Family C has the bacterial DNA-replicating enzymes (including *E. coli* DNA polymerase III). Members of families X and Y act in DNA repair pathways. Family X members include the eukaryotic DNA polymerases β , σ , λ , and μ , and others. Family Y comprises the translesion DNA polymerases, low-fidelity enzymes that allow the replication fork to bypass chemically damaged regions of DNA and continue on. Family Y includes eukaryotic DNA polymerases ι , κ , and η (η is also known as RevI). Family RT designates the DNA polymerases of retroviruses (such as HIV) and the telomerases that renew the ends of eukaryotic chromosomes. RT polymerases are novel in that they use RNA as the template (see Section 28.6).

28.3b The Common Architecture of DNA Polymerases

Despite sequence variation, the various DNA polymerase structures more or less follow a common architectural pattern that is reminiscent of a right hand, with distinct structural domains referred to as fingers, palm, and thumb (Figure 28.10). The active site of the polymerase, where deoxynucleotide addition to the growing chain is catalyzed, is located in the crevice within the palm domain that lies between the fingers and thumb domains. The fingers domain acts in deoxynucleotide recognition and binding, and the thumb is responsible for DNA binding, in the following manner: When the DNA polymerase binds to template-primer duplex DNA, its thumb domain closes around the DNA so that the DNA is bound in a groove formed by the thumb and palm. A dNTP substrate is then selected by the polymerase, and dNTP binding induces a conformational change in the fingers, which now rotate toward the polymerase active site in the palm.

Figure 28.9 Model of the replication factory. The replication factory (or replicon) is composed of two replisomes that extrude loops of newly synthesized DNA as the parental DNA duplex is fed in. The replication factory is indicated by the purple-shaded region. The replisomes (orange) define the replication fork and the movement of parental and newly synthesized dsDNA is indicated by arrows. The green bands represent double-stranded DNA, where one strand is parental and the other newly synthesized. The double-stranded DNA represented by the green band looping out above the replication factory is one of the two progeny dsDNA molecules produced by the replication factory from the parental DNA. The green band looping out below the replication factory is the other progeny dsDNA molecule. Adapted from Figure 1 in Li, H., Yao, N. Y., and O'Donnell, M. E., 2020. Anatomy of a DNA replication factory. *Biochemical Society Transactions* 48:2769–2778.

Figure 28.10 A structural paradigm for DNA polymerases, bacteriophage RB69 DNA polymerase. Ternary complex formed between the RB69 DNA polymerase, DNA, and dNTP. The N-terminal domain of the protein (residues 1–108 and 340–382) is in yellow, the exonuclease domain (residues 109–339) is in red, the palm (residues 383–468 and 573–729) is in magenta, the fingers (residues 469–572) are blue, and the thumb (residues 730–903) is green. The DNA is given in stick representation, with the primer in gold and the template in blue-purple. A dNTP substrate (red) is shown at the active site, as are the two Ca^{2+} ions (light blue spheres that are necessary for the two-metal-ion DNA polymerase catalytic mechanism). Note also the calcium ion (blue sphere) at the exonuclease active site. (PDB id = 1IG9. Adapted from Figure 1 in Franklin, M. C., Wang, J., and Steitz, T. A., 2001. Structure of the replicating complex of a Pol α family DNA polymerase. *Cell* 105:657–667.)

The enzymatic reaction of phosphodiester bond formation now takes place as a dNMP is added to the 3'-end of the growing primer strand. Pyrophosphate is released, and the polymerase translocates one base farther along the template strand. In essence, all DNA polymerases are molecular motors that synthesize DNA, using dNTP substrates to add dNMP units to the primer strand, as they move along the template strand, reading its base sequence.

Figure 28.11 The eukaryotic cell cycle. The stages of mitosis and cell division define the M phase (*M* for mitosis). G_1 (*G* for gap, not growth) is typically the longest part of the cell cycle; G_1 is characterized by rapid growth and metabolic activity. Cells that are quiescent, that is, not growing and dividing (such as neurons), are said to be in G_0 . The S phase is the time of DNA synthesis. S is followed by G_2 , a relatively short period of growth when the cell prepares for cell division. Cell cycle times vary from less than 24 hours (rapidly dividing cells such as the epithelial cells lining the mouth and gut) to hundreds of days.

28.4 | How Is DNA Replicated in Eukaryotic Cells?

DNA replication in eukaryotic cells shows strong parallels with prokaryotic DNA replication, but it is vastly more complex. First, eukaryotic DNA is organized into chromosomes that are compartmentalized within the nucleus. Furthermore, these chromosomes must be duplicated with high fidelity once (and only once!) each time the cell divides. For example, in a dividing human cell, a carefully choreographed replication of 6 billion bp of DNA distributed among 46 chromosomes occurs. The events associated with cell growth and division in eukaryotic cells fall into a general sequence called the **cell cycle**. The cell cycle has four distinct phases: M, G_1 , S, and G_2 (Figure 28.11). (Fully differentiated cells in multicellular organisms typically enter a quiescent, nondividing state after G_1 that is called G_0 . Such cells may remain in G_0 indefinitely.) Eukaryotic cells have solved the problem of replicating their enormous genomes in the few hours allotted to the S phase by initiating DNA replication at multiple origins of replication distributed along each chromosome. Eukaryotic origins of replication seem to be defined more by peculiarities in the local structure of chromatin and DNA than by any sequence context. Depending on the organism and cell type, replication origins are DNA regions 0.5 to 2 kbp in size that occur every 3 to 300 kbp (for example, an average human chromosome has several hundred replication origins). Since eukaryotic DNA replication proceeds concomitantly throughout the genome, each eukaryotic chromosome must contain many replicons.

28.4a The Cell Cycle Controls the Timing of DNA Replication

Progression through the cell cycle is regulated through a series of **checkpoints** that control whether the cell continues into the next phase. These checkpoints are situated to ensure that *all* the necessary steps in each phase of the cycle have been satisfactorily completed before the next phase is entered. If conditions for advancement to the next phase are not met, the cycle is arrested until they are.

Checkpoints, Cyclins, and CDKs Checkpoints depend on **cyclins** and **cyclin-dependent protein kinases (CDKs)**. *Cyclin* is the name given to a class of proteins synthesized at one phase of the cell cycle and degraded at another. Thus, cyclins appear and then disappear at specific times during the cell cycle. Cyclins are larger than the small CDK protein kinase subunits to which they bind. The various CDKs are inactive unless complexed with their specific cyclin partners. In turn, these CDKs control events at each phase of the cycle by targeting specific proteins for phosphorylation. Destruction of the phase-specific cyclin at the end of the phase inactivates the CDK.

Initiation of Replication DNA replication is the defining characteristic of the S phase of the cell cycle. The switch from G1 to S is triggered by phosphorylation events carried out by two protein kinases: the Dbf4-dependent kinase **DDK** (consisting of the Cdc7 protein kinase and its regulatory subunit Dbf4) and the S-phase cyclin-dependent protein kinase **S-CDK**. Eukaryotic cells initiate DNA replication at multiple origins, and two replication forks are established at each origin. Initiation of replication depends on the **origin recognition complex**, or **ORC**, a protein complex that binds to replication origins. Indeed, eukaryotic replication origins are defined as nucleotide sequences that bind ORC. Stable maintenance of the eukaryotic genome demands that DNA replication occurs only once per cell cycle. This demand is met by dividing initiation of DNA replication into two steps: (1) the **licensing of replication origins** during late M or early G1, and (2) the **activation of replication** at the origins during S phase through the action of DDK and S-CDK.

Licensing of Replication Licensing involves the highly regulated assembly of **prereplication complexes (pre-RCs)** on origins of replication. Early in G1 (just after M), the ORC (a heterohexameric complex of Orc1-6) serves as a landing pad for proteins essential to replication control. Binding of these proteins to ORC establishes a pre-RC, but only within this window of opportunity during G1. The crescent-shaped ORC complex binds DNA along its concave face, bending and unwinding the DNA in an ATP-dependent process. ORC then recruits Cdc6 (in its phosphorylated form, Cdc6p), and the MCM proteins. Cdc6p and Cdt1 are **replication activation proteins**.

The MCM proteins are a family of six related proteins. MCM proteins are also known as **replication licensing factors** because they license, or permit, DNA replication to occur. The MCM proteins assemble as hexameric helicases that render the chromosomes competent for replication. Two MCM complexes are active within each origin, one for each replication fork. The pre-RC therefore consists of ORC, Cdc6, Cdt1, the MCM complexes, and other proteins.

Assembly of the DNA Replication Factory Construction of the eukaryotic DNA replication apparatus begins when S-CDK and DDK phosphorylate initiation factors Sld2 and Sld3. In effect, the phosphorylations catalyzed by S-CDK and DDK trigger the passage of the cell from G1 to S and the activation of replication initiation. The initiation factor Dpb11 interacts with Sld2p and Sld3p to form a ternary complex (the Sld2p/Sld3p/Dpb11 complex) which then associates with the origin of replication and recruits proteins Cdc45 and the GINS complex. While the Sld2p/Sld3p/Dpb11 complex is essential for the initiation of DNA replication, it is not retained once replication has begun. In addition, Cdc6 is degraded following replication initiation, thereby precluding the possibility for errant replication initiation events until after mitosis, when Cdc6 accumulates again.

Cdc45 and GINS bind MCM2-7, completing formation of the **CMG (Cdc45-MCM-GINS) helicase**, the active helicase that unwinds the DNA duplex so that DNA replication can proceed. The CMG helicase and the Sld2p/Sld3p/Dpb11 complex also establish contact with the DNA polymerases that replicate the DNA: DNA polymerase δ is the lagging-strand DNA polymerase and DNA polymerase ϵ is the leading-strand polymerase (see Table 28.4). The Cdc45 protein is a key factor in converting the pre-RC into a functional initiation complex; the GINS protein complex binds single-stranded DNA and aids in recruiting the polymerase that synthesizes the lagging-strand RNA primers (primase).

Table 28.4 Biochemical Properties of the Principal Human DNA Polymerases		
Polymerase Localization and Function	Subunits (mass in kDa)	Subunit Function
<i>DNA polymerase α</i>

It is important to stress that two replisomes are assembled at each origin of replication and together they constitute the replicon. Establishment of the replicon begins when two CMG helicases form a dimer in the presence of Ctf4 (Chromosome transmission fidelity protein 4), itself a homotrimer. Each Ctf4 trimer acts as the hub of its replisome (Figure 28.12). It also serves as the platform for the primase (DNA polymerase α). Thus, Ctf4 trimers serve to organize replicons containing two CMG helicases and one centrally located primase (Figure 28.12).

Figure 28.12 The eukaryotic replicon. In this view, the two replisomes of the replicon are bound together by Ctf4 (pink). Each is extruding newly synthesized DNA below as parental DNA duplex is fed in from the top. The CMG helicase (blue) consists of Cdc45, Mcm2–7 hexamer, and GINS complex. Each CMG helicase creates a replication fork as it unwinds the parental DNA entering it. As the helicase separates the double-stranded parental DNA to expose the single strands as templates, DNA polymerases carry out leading and lagging strand synthesis. Note that the two replisomes share the single primase (green), labeled Pol α-primase here. As indicated by the black arrows above and below it, this single primase alternately serves each replication fork by synthesizing primers on each of the lagging strands. The eukaryotic sliding clamps (red) are trimeric proteins called PCNA. Eukaryotic DNA polymerase δ (yellow) is the lagging-strand DNA polymerase; eukaryotic DNA polymerase ε is the leading-strand DNA polymerase (orange). Adapted from Figure 4 in Li, H., Yao, N. Y., and O'Donnell, M. E., 2020. Anatomy of a DNA replication factory. *Biochemical Society Transactions* 48:2769–2778.

The CMG helicases use the energy of ATP hydrolysis to unwind the duplex DNA and separate the strands. As each CMG helicase opens the DNA duplex, two replication forks are created, one for each CMG helicase. DNA replication commences at each replication fork (Figure 28.12). The DNA strand that runs through each CMG helicase is the template for leading-strand synthesis by DNA polymerase ϵ . The strand not running through the CMG helicase is the lagging strand. It is primed by the Pol α -primase and copied by DNA polymerase δ (Figure 28.12).

28.4b Proteins of the Prereplication Complex Are AAA+ ATPase Family Members

Cdc6, the Orc proteins, and MCM proteins are members of the **AAA+ ATPase family**, a group of proteins characterized by sequence and structural homology, ATPase activity, and a general function as molecular chaperones. The binding of both ORC and Cdc6 to chromatin in the process of pre-RC assembly is ATP-dependent. ORC with ATP bound can bind to origins of replication and recruit Cdc6 and Cdt1 to form a pre-RC in which both ORC and Cdc6 have bound ATP. Cdc6 is required for the recruitment of the MCM proteins, specifically, a complex of MCM2–7 with ATP-dependent helicase activity. To establish the pre-RC, MCM2–7 must be stably associated with the origin, and this stability is achieved following ATP hydrolysis, first by Cdc6 and then by ORC.

28.4c Geminin Provides Another Control Over Replication Initiation

Geminin is a protein that provides another level of regulatory control over DNA replication. Geminin inhibits DNA replication by preventing the incorporation of MCM complexes into the pre-RC. Geminin is active during S, G₂, and M phases, but its destruction during mitosis permits replication initiation in G₁. Geminin binds to Cdt1, preventing it from recruiting MCM proteins to the pre-RC. Geminin exists as a parallel coiled-coil homodimer. It interacts with Cdt1 in two ways: It has an array of glutamate residues on its surface that interact with positive charges on Cdt1, and an adjacent region on geminin interacts independently with the N-terminal region of Cdt1.

28.4d Eukaryotic Cells Also Contain a Number of Different DNA Polymerases

At least 19 different DNA polymerases have been described in eukaryotic cells thus far. These various polymerases have been assigned Greek letters in the order of their discovery (Table 28.4 lists the principal ones). Multiple DNA polymerases participate in leading- and lagging-strand synthesis, but three— α , δ , and ϵ —share the major burden. **DNA polymerase α** has an associated primase subunit and functions in the initiation of nuclear DNA replication. Given a template, it not only synthesizes an RNA primer of about 10 nucleotides, but it then adds 20 to 30 deoxynucleotides to extend the chain in the 5'→3' direction. **DNA polymerase δ** , a heterotetrameric enzyme, is the lagging-strand DNA polymerase in eukaryotic DNA replication. It interacts with PCNA protein (PCNA stands for proliferating cell nuclear antigen). Through its association with PCNA, DNA polymerase δ carries out highly processive DNA synthesis. PCNA is the eukaryotic counterpart of the *E. coli* β_2 -sliding clamp; it clamps DNA polymerase δ to the DNA. Like β_2 , PCNA encircles the double helix, but in contrast to the prokaryotic β_2 -sliding clamp, PCNA is a homotrimer, not a homodimer (Figure 28.13; see also Figure 28.7). DNA polymerase ϵ has an acidic C-terminal extension lacking in other DNA polymerases, and evidence suggests that this domain is a sensor for DNA damage checkpoint control, halting DNA replication until the damage is repaired. **DNA polymerase β** is the DNA-replicating enzyme of mitochondria; **DNA polymerase β** functions in DNA repair. The more recently discovered eukaryotic DNA polymerases (including ζ , η , ι , κ , and Rev1) are more error-prone, resulting in lower fidelity of DNA replication. Nevertheless, they have the important ability to function in DNA replication and repair when damaged regions of DNA are encountered.

Figure 28.13 Structure of the human PCNA homotrimer. **(a)** Ribbon representation of the PCNA trimer (PDB id = 1AXC) with an axial view of a B-form DNA duplex in its center. The molecular mass of each PCNA monomer is 37 kDa. **(b)** Molecular surface of the PCNA trimer-DNA complex.

Other proteins involved in eukaryotic DNA replication include **replication protein A (RPA)**, an ssDNA-binding protein that is the eukaryotic counterpart of SSB, and **replication factor C (RFC)**. RFC loads the PCNA sliding clamp onto replicating DNA, thus acting as the eukaryotic counterpart of the prokaryotic γ -complex.

28.5 | How Are the Ends of Chromosomes Replicated?

Eukaryotic chromosomes are linear. The ends of chromosomes have specialized structures known as **telomeres**. The telomeres of virtually all eukaryotic chromosomes consist of short (5–8 bp), tandemly repeated, GC-rich nucleotide sequences that form protective caps 1 to 12 kbp long at the ends of chromosomal DNA. For example, the telomeres of human germline cells (sperm and eggs) contain between 1000 and 1700 copies of the hexameric repeat TTAGGG (Figure 28.14a). Telomeres aid in chromosome maintenance and stability by protecting against DNA degradation or rearrangement. DNA polymerases cannot replicate the extreme 5'-ends of chromosomes because these enzymes require a template and a primer and replicate only in the 5'→3' direction. Thus, lagging strand synthesis at the 3'-ends of chromosomes is primed by RNA primase to form Okazaki fragments, but these RNA primers are subsequently removed, resulting in gaps in the progeny 5'-terminal strands at each end of the chromosome after each round of replication (primer gap; see Figure 28.14).

Telomeres are added to the ends of chromosomal DNA by an RNA-dependent DNA polymerase known as **telomerase**. It maintains chromosome length by restoring telomeres at the 3'-ends of chromosomes. Telomerase is a specialized reverse transcriptase containing a catalytic subunit, referred to as **TERT**, for **TElomerase Reverse Transcriptase**, and an RNA component that serves as the template for telomere synthesis, referred to variously as **RT**, for **RNA Template**, or **TER**, for **TEmplate-containing telomerase RNA**. In human telomerase, the RNA part is 451 nucleotides long. Its template sequence is CUAACCCUAAC (base-pairs with TTAGGG). During the S-phase of the cell cycle, telomerase uses the 3'-end of the DNA as a primer and adds successive TTAGGG repeats to it, employing its RNA as template over and over again (Figure 28.14). The G-rich ends of telomeres can arrange into four-stranded G-quadruplex structures (see Figure 11.20).

The single-stranded 3'-overhangs at the telomeric ends of chromosomes are a hazard because they resemble damaged DNA. Such damage has the potential to recruit DNA repair enzymes whose action at telomeres would do more harm than good. **Shelterin**, a protein complex with six distinct subunits, is the telomere end-protection protein. It binds to telomeres and folds the DNA strands so that no single-stranded ends are exposed to DNA repair systems. In addition, several of the shelterin subunits act to recruit telomerase when it's time for the telomeres to be replicated.

28.6 | How Are RNA Genomes Replicated?

Many viruses have genomes composed of RNA, not DNA. How then is the information in these RNA genomes replicated? In 1964, Howard Temin noted that inhibitors of DNA synthesis prevented infection of cells in culture by RNA tumor viruses such as avian sarcoma virus. On the basis of this observation, Temin proposed that DNA is an intermediate in the replication of such viruses; that is, an RNA tumor virus can use viral RNA as the template for DNA synthesis.

RNA viral chromosome → DNA intermediate → RNA viral chromosome

In 1970, Temin and David Baltimore independently discovered a viral enzyme capable of mediating such a process, namely, an **RNA-directed DNA polymerase** or, as it is

Figure 28.14 Telomere replication. **(a)** Telomeres on human chromosomes. TTAGGG tandem repeats are found at the 3'-ends of the DNA strands, paired with the complementary sequence 3'-AATCCC-5' on the other DNA strand. Thus, a G-rich region is created at the 3'-end of each DNA strand, and a C-rich region is created at the 5'-end of each DNA strand. Typically, at each end of the chromosome, the G-rich strand protrudes 12 to 16 nucleotides beyond its complementary C-rich strand. **(b)** The ribonucleic acid of human telomerase serves as the template for the DNA polymerase activity of telomerase. Nucleotides 46 to 56 of this RNA are CUAACCCUAAC and provide the template function for the telomerase-catalyzed addition of TTAGGG units to the 3'-end of a DNA strand. **(c)** In replication of the lagging strand, short RNA primers are added (pink) and extended by DNA polymerase. When the RNA primer at the 5'-end of each strand is removed, there is no nucleotide sequence to read in the next round of DNA replication. The result is a gap (primer gap) at the 5'-end of each strand (only one end of a chromosome is shown in this figure). **(d)** Asterisks indicate sequences at the 3'-end that cannot be copied by conventional DNA replication. Synthesis of telomeric DNA by telomerase extends the 5'-ends of DNA strands, allowing the strands to be copied by normal DNA replication.

A Deeper Look

RNA as Genetic Material

The genetic material of cells is dsDNA but virtually all plant viruses, several bacteriophages, and many animal viruses have genomes consisting of RNA. Viruses with RNA genomes can evolve more quickly to changing circumstances because viral RNA polymerases are more error-prone. (They lack the proofreading mechanisms that DNA polymerases have.) As a consequence, RNA viruses are better equipped to evade ever-evolving host defense mechanisms. In most cases, this RNA is single stranded. Viruses with single-stranded genomes use the single strand as a

template for synthesis of a complementary strand, which can then serve as template in replicating the original strand. **Retroviruses** are an interesting group of eukaryotic viruses with single-stranded RNA genomes that replicate through a dsDNA intermediate. Furthermore, the life cycle of retroviruses includes an obligatory step in which the dsDNA is inserted into the host cell genome in a transposition event (see Section 28.7). Retroviruses are responsible for many diseases, including tumors and other disorders. **HIV-1**, the **human immunodeficiency virus** that causes **AIDS**, is a retrovirus.

usually called, **reverse transcriptase**. All RNA tumor viruses contain such an enzyme within their virions (viral particles). RNA viruses that replicate their RNA genomes via a DNA intermediate are classified as **retroviruses**.

Like other DNA and RNA polymerases, reverse transcriptase synthesizes polynucleotides in the 5'→3' direction, and like all DNA polymerases, reverse transcriptase requires a primer. Interestingly, the primer is a specific tRNA molecule captured by the virion from the host cell in which it was produced. The 3'-end of the tRNA is base-paired with the viral RNA template at the site where DNA synthesis initiates, and its free 3'-OH accepts the initial deoxynucleotide once transcription commences. Reverse transcriptase then transcribes the RNA template into a complementary DNA (cDNA) strand to form a double-stranded DNA:RNA hybrid.

28.6a The Enzymatic Activities of Reverse Transcriptases

Reverse transcriptases possess three enzymatic activities, all of which are essential to viral replication:

1. **RNA-directed DNA polymerase activity**, for which the enzyme is named (see Figure 12.11). This enzymatic activity creates a single-stranded DNA copy of the RNA genome of the virus.
2. **RNase H activity**. Recall that RNase H is a nuclease that specifically degrades RNA chains in DNA:RNA hybrids (see Figure 12.11). The RNase H function of reverse transcriptase is an exonuclease activity that degrades the template genomic RNA and also removes the priming tRNA after DNA synthesis is completed.
3. **DNA-directed DNA polymerase activity**. This activity replicates the ssDNA remaining after RNase H degradation of the viral genome, yielding a DNA duplex. This DNA duplex directs the remainder of the viral infection process or becomes integrated into the host chromosome, where it can lie dormant for many years as a **provirus**. Activation of the provirus restores the infectious state.

HIV reverse transcriptase is of great clinical interest because it is the enzyme for replication of the AIDS virus. DNA synthesis by HIV reverse transcriptase is blocked by dideoxynucleoside analogs such as AZT and 3TC (Figure 28.15). HIV reverse transcriptase incorporates these analogs into growing DNA chains in place of dTMP (in the case of AZT) or dCMP (in the case of 3TC). Once incorporated, these analogs block further chain elongation because they lack a 3'-OH where the next incoming dNTP can be added. HIV reverse transcriptase is error-prone: It incorporates the wrong base at a frequency of 1 per 2000 to 4000 nucleotides polymerized. This high error rate during replication of the HIV genome means that the virus is ever changing, a feature that makes it difficult to devise an effective vaccine.

(a)

(b)

Figure 28.15 The structures of AZT (3'-azido-2',3'-dideoxythymidine) and 3TC (2',3'-dideoxy-3'-thiacytidine). These 3'-substituted dideoxynucleosides are phosphorylated *in vivo* to form dideoxynucleoside-5'-triphosphate substrate analogs for HIV reverse transcriptase. AZT is a drug known as Zidovudine or Retrovir, and 3TC is known as Lamivudine or Epivir.

28.7 | How Is the Genetic Information Rearranged by Genetic Recombination?

Genetic recombination is the natural process by which genetic information is rearranged to form new associations. For example, compared to their parents, progeny may have new combinations of traits because of genetic recombination. At the molecular level, genetic recombination is the exchange (or incorporation) of one DNA sequence with (or into) another. When recombination involves reaction between very similar sequences (homologous sequences) of DNA, the process is called **homologous recombination**. When very different nucleotide sequences recombine, it's **nonhomologous recombination**. **Transposition**—the enzymatic insertion of a *transposon* (a mobile segment of DNA, see Figure 28.24) into a new location in the genome—and nonhomologous recombination (incorporation of a DNA segment whose sequence differs greatly from the DNA at the point of insertion) are two types of recombination that play a significant evolutionary role. Nonhomologous recombination occurs at a low frequency in all cells and serves as a powerful genetic force that reshapes the genomes of all organisms. Homologous recombination involves an exchange of DNA sequences between homologous chromosomes, resulting in the arrangement of genes into new combinations. Homologous recombination is generally used to fix the DNA so that information is not lost. For example, large lesions in DNA are repaired via recombination of the damaged chromosome with a homologous chromosome.

The process underlying homologous recombination is termed **general recombination** because the enzymatic machinery that mediates the exchange can use essentially any pair of homologous DNA sequences as substrates. Homologous recombination occurs in all organisms and is particularly prevalent during the production of gametes (meiosis) in diploid organisms. In higher animals—that is, those with immune systems—recombination also occurs in the DNA of somatic cells responsible for expressing proteins of the immune response, such as the immunoglobulins. This **somatic recombination** rearranges the immunoglobulin genes, dramatically increasing the potential diversity of immunoglobulins available from a fixed amount of genetic information. Homologous recombination can also occur in bacteria. Indeed, even viral chromosomes undergo recombination. For example, if two mutant viral particles simultaneously infect a host cell, a recombination event between the two viral genomes can lead to the formation of a virus chromosome that is wild-type.

28.7a General Recombination Requires Breakage and Reunion of DNA Strands

Recombination occurs by the breakage and reunion of DNA strands so that a physical exchange of parts takes place. Matthew Meselson and Jean-Jacques Weigle demonstrated this in 1961 by coinfecting *E. coli* with two genetically distinct bacteriophage λ strains, one of which had been density-labeled by growth in ^{13}C - and ^{15}N -containing media (Figure 28.16). The phage progeny were recovered and separated by CsCl density gradient centrifugation. Phage particles that displayed recombinant genotypes were distributed throughout the gradient while parental (nonrecombinant) genotypes were found within discrete heavy and light bands in the density gradient. The results showed that recombinant phage contained

Figure 28.16 Meselson and Weigle's experiment. Density-labeled, heavy phage, symbolized as ABC phage, was used to coinfect bacteria along with light, unlabeled phage, the abc phage. The progeny from the infection were collected and subjected to CsCl density gradient centrifugation. Parental-type ABC and abc phage were well separated in the gradient, but recombinant phage (Abc, aBc, abC, and so on) were distributed diffusely between the two parental bands because they contained chromosomes constituted from fragments of both heavy and light DNA.

DNA derived in varying proportions from both parents. The obvious explanation is that these recombinant DNAs arose via the breakage and rejoining of DNA molecules.

28.7b Homologous Recombination Proceeds According to the Holliday Model

In 1964, Robin Holliday proposed a model for homologous recombination in fungi that has been proven to be a generally valid depiction of homologous recombination in bacteriophages, viruses, prokaryotes, and eukaryotes (Figure 28.17). The two homologous DNA duplexes are first juxtaposed so that their sequences are aligned. This process of **chromosome pairing** is called **synapsis** (Figure 28.17a). Holliday suggested that recombination begins with the introduction of single-stranded nicks in the DNA at homologous sites on the two paired chromosomes (Figure 28.17b). The two duplexes partially unwind, and the free, single-stranded end of one duplex begins to base-pair with its nearly complementary, single-stranded region along the intact strand in the other duplex, and vice versa (Figure 28.17c). This **strand invasion** is followed by ligation of the free ends from different duplexes to create a cross-stranded intermediate known as a **Holliday junction** (Figure 28.17d). The cross-stranded junction can now migrate in either direction (**branch migration**) by unwinding and rewinding of the two duplexes (Figure 28.17e). Branch migration results in **strand exchange**; heteroduplex regions of varying length are possible. For the joint molecule formed by strand exchange to be resolved into two DNA duplex molecules, another pair of nicks must be introduced. Resolution can be represented best if the duplexes are drawn with the chromosome arms bent up or down to give a planar representation (Figure 28.17f). Nicks then take place, either at E and W, that is, in the $-$ strands that were originally nicked (see Figure 28.17b), or at N and S, that is, in the $+$ strands (the strands not previously nicked). Duplex resolution is most easily kept straight by remembering that $+$ strands are complementary to $-$ strands and any resultant duplex must have one of each. Nicks made in the strands originally nicked lead to DNA duplexes in which one strand of each remains intact. Although these duplexes contain heteroduplex regions, they are not recombinant for the markers (AZ, az) that flank the heteroduplex region; such heteroduplexes are called **patch recombinants** (Figure 28.17g). Nicks introduced into the two strands not previously nicked yield DNA molecules that are both heteroduplex and recombinant for the markers A/a and Z/z; these heteroduplexes are termed **splice recombinants** (Figure 28.17h). Although this Holliday model explains the outcome of recombination, it provides no mechanistic explanation for the strand exchange reactions and other molecular details of the process.

28.7c The Enzymes of General Recombination Include RecA, RecBCD, RuvA, RuvB, and RuvC

To illustrate recombination mechanisms, we focus on general recombination as it occurs in *E. coli*. The principal players in the process are the **RecBCD** enzyme complex, which initiates recombination; the **RecA** protein, which binds single-stranded DNA, forming a nucleoprotein filament capable of strand invasion and homologous pairing; and the **RuvA**, **RuvB**, and **RuvC** proteins, which drive branch migration and process the Holliday junction into recombinant products. Eukaryotic homologs of these prokaryotic recombination proteins have been identified, indicating that the fundamental process of general recombination is conserved across all organisms.

Figure 28.17 The Holliday model for homologous recombination. **Above:** Molecular graphic showing the structure of a Holliday junction. Each of the four DNA strands is colored differently (PDB id = 1DCW). **Right:** The + and - signs label strands of like polarity. For example, assume that the two strands running 5'→3' as read left to right are labeled +; and the two strands running 3'→5' as read left to right are labeled -. Only strands of like polarity exchange DNA during recombination. (See text for detailed description.)

28.7d The RecBCD Enzyme Complex Unwinds dsDNA and Cleaves Its Single Strands

The RecBCD complex is composed of the proteins **RecB** (140 kDa; 1180 amino acids), **RecC** (130 kDa; 1122 amino acids), and **RecD** (67 kDa; 608 amino acids). This multifunctional enzyme complex has both helicase and nuclease activity and initiates recombination by attaching to the end of a DNA duplex (or at a double-stranded break in the DNA) and using its ATP-dependent helicase function to unwind the dsDNA (Figure 28.18a). RecB and RecD are helicases powered by ATP hydrolysis; each consumes an ATP per base pair of DNA traversed. The RecD motor is faster than the RecB motor and leads the way. The greater speed of RecD causes the DNA to loop out between RecD and RecB. The RecB subunit also contains a nuclease domain, which is tethered to the RecB helicase domain by a 30-residue-long linker. As RecBCD progresses along unwinding the duplex, the RecB nuclease activity cleaves both of the newly formed single strands (although the strand that provided the 3'-end at the RecBCD entry site is cut more frequently than the 5'-terminal strand [Figure 28.18b]). SSB (and some RecA protein) readily binds to the emerging single strands. Sooner or later, RecBCD encounters a particular nucleotide sequence, a so-called **Chi** (crossover hotspot instigator, symbolized by χ) **site**, characterized by the sequence **5'-GCTGGTGG-3'**. These χ sites are recombinational hot spots; 1009 χ sites have been identified in the *E. coli* genome (on average, about one every 4.5 kbp of DNA). When a RecBCD complex approaches a χ sequence from its 3' side (the...G-3'side), RecBCD cleaves the χ -bearing DNA strand four to six bases to the 3' side of χ (Figure 28.18c). RecBCD flips so that the RecB motor leads the way, and the RecBCD complex no longer expresses nuclease activity against the 3'-terminal strand, but nuclease activity against the 5'-terminal strand increases (Figure 28.18d).

Resuming its helicase function, RecBCD unwinds the dsDNA, and collectively these processes generate an ssDNA tail bearing a χ site at its 3'-terminal end. This ssDNA may reach several kilobases in length. RecA protein now binds to the 3'-terminal strand to form a **nucleoprotein filament** (Figure 28.18e). This filament is active in pairing and strand invasion with a homologous region in another dsDNA molecule. A molecular graphic of RecBCD bound to DNA is shown in Figure 28.19.

RecBCD also plays a vital role in DNA repair (see Section 28.8). Because DNA damage is potentially lethal, RecBCD can readily displace other tightly bound DNA-binding proteins (such as RNA polymerase), which allows RecBCD function to supercede any other aspect of DNA metabolism. Consistent with its importance, a cell contains 10 to 50 RecBCD molecules, so multiple DNA breaks per cell can be readily repaired.

28.7e The RecA Protein Can Bind ssDNA and Then Interact with Duplex DNA

The **RecA** protein, or **recombinase**, is a multifunctional protein that acts in general recombination (Figure 28.20a). RecA mediates the ATP-dependent **DNA strand exchange reaction** leading to formation of a Holliday junction (Figure 28.17b–f). In the presence of ATP and ssDNA, RecA forms a right-handed helical filament having six monomers per turn, with each monomer spanning about three nucleotides of DNA. The RecA nucleoprotein filament serves as a scaffold upon which the events of recombination take place. This filament has a deep spiral groove large enough to encompass three strands of DNA. Although RecA-bound ssDNA is relatively stretched and underwound, with about 18.5 nucleotides per turn, its local

Figure 28.18 Model of RecBCD-dependent initiation of recombination. **(a)** RecBCD binds to a duplex DNA end, and its helicase activity begins to unwind the DNA double helix. Rabbit ears of ssDNA loop out from RecBCD because the rate of DNA unwinding exceeds the rate of ssDNA release by RecBCD. **(b)** As it unwinds the DNA, SSB (and some RecA) bind to the single-stranded regions; the RecBCD endonuclease activity randomly cleaves the ssDNA, showing a greater tendency to cut the 3'-terminal strand rather than the 5'-terminal strand. **(c)** When RecBCD encounters a properly oriented χ site, the 3'-terminal strand is cleaved just below the 3'-end of χ . **(d)** RecBCD now directs the binding of RecA to the 3'-terminal strand, as RecBCD endonuclease activity now acts more often on the 5'-terminal strand. **(e)** A nucleoprotein filament consisting of RecA-coated 3'-strand ssDNA is formed. This nucleoprotein filament is capable of homologous pairing with a dsDNA and strand invasion.

Figure 28.19 Molecular graphic of RecBCD bound to DNA (PDB id = 1W36).

Figure 28.20 The structure of RecA, the ATP-dependent protein that mediates DNA strand exchange in general recombination. **(a)** RecA, a 352-residue, 38-kDa protein, with dATP in the ATP-binding site (PDB id = 2ODN). **(b)** Structure of a fused RecA hexamer with bound ssDNA (as poly(dT)₁₈, magenta). Each of the six RecA units is a different color, and each has a bound ADP molecule (marine blue). The adenine nucleotide-binding sites lie at the interfaces between RecA units (PDB id = 3CMU).

conformation resembles B-DNA (Figure 28.20b). Thus, when dsDNA adds to the complex, the ssDNA is poised to search for the sequence homology that leads to strand exchange. When the ssDNA encounters a region of homology that is 8 to 20 base pairs in length, DNA strand exchange begins.

Procession of strand separation of dsDNA and the re-pairing into hybrid strands along the DNA duplex initiates **strand invasion** (Figure 28.21b). Strand invasion drives the displacement of the homologous DNA strand from the DNA duplex and its replacement with the ssDNA strand, a process known as **single-strand assimilation** (or **single-strand uptake**). Strand assimilation does not occur if there is no sequence homology between the ssDNA and the invaded DNA duplex. The DNA strand displaced by the invading 3'-terminal ssDNA is free to anneal with the 5'-terminal strand in the original DNA, a step that is also mediated by RecA protein and SSB (Figure 28.21c). The result is a Holliday junction, the classic intermediate in genetic recombination.

Figure 28.21 Model for homologous recombination as promoted by RecA enzyme. **(a)** RecA protein (and SSB) aid strand invasion of the 3'-ssDNA into a homologous DNA duplex, **(b)** forming a D-loop. **(c)** The D-loop strand that has been displaced by strand invasion pairs with its complementary strand in the original duplex to form a Holliday junction as strand invasion continues.

28.7f RuvA, RuvB, and RuvC Proteins Resolve the Holliday Junction to Form the Recombination Products

The Holliday junction is processed into recombination products by **RuvA** (203 amino acids), **RuvB** (336 amino acids), and **RuvC** (173 amino acids). Specifically, RuvA and RuvB work together as a Holliday junction–specific helicase complex that dissociates the RecA filament and catalyzes branch migration. An RuvA tetramer (Figure 28.22a) fits precisely within the junction point (Figure 28.22b), which has a square-planar geometry, and this RuvA tetramer mediates the assembly of RuvB around opposite arms of the DNA junction. The RuvB protein binds to form two oppositely oriented, hexameric [(RuvB)₆] ring structures encircling the dsDNAs, one on each side of the Holliday junction. Rotation of the dsDNAs by the RuvB hexameric rings pulls the dsDNAs through (RuvB)₆ and unwinds the DNA strands across the “spool” of RuvA, which threads the separated single strands into newly forming hybrid (recombinant) duplexes (Figure 28.22b). The RuvA tetramer is a disclike structure, one face of which (Figure 28.22c) has four negatively charged central pins, each contributed by a pair of residues (Glu⁵⁵ and Asp⁵⁶) from each RuvA monomer. These four pins fit neatly into the hole at the center of the Holliday junction. The negatively charged sugar–phosphate

Figure 28.22 Model for the resolution of a Holliday junction in *E. coli* by the RuvA, RuvB, and RuvC proteins. **(a)** Ribbon diagram of the RuvA tetramer. RuvA monomers have an overall L shape (PDB id = 1CUK). **(b)** Model for RuvA/RuvB action. *(left)* The RuvA tetramer fits snugly within the Holliday junction point. *(center)* Oppositely facing RuvB hexameric rings assemble on the heteroduplexes, with the DNA passing through their centers. These RuvB hexamers act as motors to promote branch migration by driving the passage of the DNA duplexes through themselves. *(right)* Binding of RuvC at the Holliday junction and strand scission by its nuclease activity. The locations of the RuvC active sites are indicated by the scissors. **(c)** Charge distribution on the concave surface of an RuvA tetramer. Blue indicates positive charge and red, negative charge. Note the four red (negatively charged) pins at its center. **(d)** Structural model for the interaction of $(\text{RuvA})_4$ with the hypothesized square-planar Holliday junction center (PDB id = 1C7Y). (Adapted from Figures 1, 2, and 3 in Rafferty, J. B., et al., 1996. Crystal structure of DNA recombination protein RuvA and a model for its binding to the Holliday junction. *Science* 274:415–421.)

backbones of the four DNA duplexes of the Holliday junction are threaded along grooves in the positively charged RuvA face, with the negatively charged central pins appropriately situated to transiently separate the dsDNA molecules into their component single strands through repulsive electrostatic interactions with the phosphate backbones of the DNA. The separated strands of each parental duplex are then channeled into grooves in the RuvA face, where they are led into hydrogen-bonding interactions with bases contributed by strands of the other parental DNA to form the two daughter hybrid duplexes flowing out from the RuvAB complex (Figure 28.22b). Figure 28.22d illustrates a model for the RuvA tetramer with the square-planar Holliday junction.

Depending on how the strands in the Holliday junction are cleaved and resolved, patch or splice recombinant duplexes result (Figure 28.17g and h). RuvC is an endonuclease that resolves Holliday junctions into heteroduplex recombinant products (**RuvC resolvase**). An RuvC dimer binds at the Holliday junction and cuts pairs of DNA strands of similar polarity (Figure 28.22b); whether a patch or a splice recombinant results depends on which DNA pair is cleaved.

RuvB hexamers are AAA^+ -ATPase-type, DNA-driving molecular motors; similar motors act during DNA replication to propel strand separation and initiate DNA synthesis. Thus, the RuvABC system for processing Holliday junctions may represent a general paradigm for DNA manipulation in all cells.

28.7g The Three Rs of Genomic Manipulation: Replication, Recombination, and Repair

DNA replication, recombination, and repair were once considered to be separate aspects of DNA metabolism. However, it is now clear that DNA replication is an essential component of both DNA recombination and DNA repair processes. Further, recombination mechanisms play an absolutely vital role in restarting replication forks that become halted at breaks or other lesions in the DNA strands.

A Deeper Look

Knockout Mice: A Method to Investigate the Biological Role of a Gene

The function of a particular gene is not always obvious. Targeted inactivation (knockout) of the gene followed by analysis of the cell or organism may reveal defects that identify the purpose of a gene. Such studies with mice lead to knockout mice—mice having a selectively inactivated gene. One way to inactivate a target gene is to use homologous recombination to replace a gene with a nonfunctional version of itself. For example, inactivation can be accomplished by inserting a foreign gene, such as *neo*, a gene encoding resistance to the drug *G418*, within one of the exons of a copy of the gene of interest. Homologous recombination between the *neo*-bearing transgene and DNA in wild-type mouse ES cells replaces the target

gene with the inactive transgene (see accompanying figure). ES cells in which homologous recombination has occurred will be resistant to *G418*, and such cells can be selected. These recombinant ES cells can then be injected into early-stage mouse embryos, where they have a chance of becoming the germline cells of the newborn mouse. If they do, an inactivated target gene is then present in the gametes of this mouse. Mating between male and female mice with inactive target genes yields a generation of homozygous knockout mice—mice lacking a functional copy of the targeted gene. Characterization of these knockout mice reveals the physiological functions of the gene.

Two exchange events between homologous sequences in the trans gene and host target gene, one upstream of the *neo* cassette and one below, lead to insertion of *neo* within the host gene. The *neo* gene encodes an enzyme that inactivates the antibiotic *G418*. Cells carrying the *neo* gene are resistant to *G418* and can be identified by this antibiotic resistance.

It is likely that most replication forks that begin at the *E. coli oriC* initiation sites (or analogous initiation sites in eukaryotes) are derailed by nicks or more extensive DNA damage lying downstream. However, DNA replication can be reinitiated (and genome replication can be completed) following **replication fork restart**. Recombinational repair of stalled replication forks requires the action of enzymes from every aspect of DNA metabolism: replication, recombination, and repair. The initial steps in recombination-dependent replication restart depend on the recombination proteins RecA and RecBCD and the formation of a D-loop (Figure 28.21). The ability of RecA to mediate recombinational repair of stalled replication forks is undoubtedly the reason for the presence of RecA-type proteins in virtually all organisms. Indeed, the recombination system, a feature common to all cells, evolved to carry out this essential repair purpose. (A diagram illustrating recombination-dependent restart of a stalled replication fork is shown in the section on DNA repair [Section 28.8, Figure 28.26].)

It is significant to note that the organization of DNA in a D-loop is analogous to that in a replication fork, where the leading strand has a free 3'-end, just like the invading strand in the D-loop, and the lagging strand is coated with SSB (see Figure 28.19b). Subsequent steps in recombination-dependent replication restart depend on **PriA**, a multifunctional DNA helicase with two DNA-binding domains located at its N-terminus and an SSB-binding domain at its C-terminus (Figure 28.23). PriA can also rescue a stalled replication fork. The 3'-BD DNA-binding domain of PriA binds tightly to the 3'-end of invading-strand DNA (or its counterpart in a stalled replication fork, the 3'-end of leading-strand DNA). PriA's WH DNA-binding domain recognizes the three DNA arms of a D-loop (homologous DNA duplex, invading-strand:homologous DNA duplex, and 5'-end ssDNA strand; see Figure 28.21b) or the analogous structures in a stalled replication fork (parental, leading-strand, and lagging-strand). Once bound to DNA, PriA uses its CTD (C-terminal domain) to interact with SSB in order to identify single-stranded DNA regions of the 5'-, or lagging, strand. Then, the helicase

Figure 28.23 PriA protein (PDB id = 4NL4). **(a)** Structural domains (color-coded) within PriA (its N-terminus is at the top). PriA's two DNA-binding domains (3'-BD and WH, or winged helix) are at the N-terminal end. The helicase domains dominate the structure. The C-terminal domain (CTD) is the site of the SSB-binding domain of PriA. **(b)** Two views of the tertiary structure of PriA (rotated 180° relative to each other. (Adapted from Figure 1 in Bhattacharyya, B., George, N. P., Thurmes, T. M., Zhou, R., Jani, N., Wessel, S. R., et al. 2014. Structural mechanisms of PriA-mediated DNA replication restart. *Proceedings of the National Academy of Sciences, U.S.A.* **111**:1373–1378.)

domains of PriA bind the ssDNA, displacing SSB from these regions and reloading DnaB helicase as the initial step in re-establishing a functional replication fork.

28.7h Homologous Recombination in Eukaryotes Helps to Prevent Cancer

As in prokaryotes, eukaryotic homologous recombination eliminates double-stranded breaks and other deleterious lesions from chromosomes. Since the accumulation of DNA lesions is a necessary step in the development of cancer, eukaryotic homologous recombination is crucial to the prevention of cancers in humans. As in prokaryotes, eukaryotic recombination is mediated by recombinases. The eukaryotic counterpart to RecA is **Rad51**, an ATP-dependent, single-stranded DNA-binding protein. Rad51 assembles on ssDNA in a manner similar to RecA, except Rad51 is present in solution as a heptamer, not a hexamer. The ssDNA:Rad51 nucleoprotein complex in eukaryotes is referred to as a **presynaptic filament**. Rad51 assembles on ssDNA, forming a right-handed helical nucleoprotein complex that can extend for thousands of bases. Each helical turn of the filament contains 18 or 19 bases of DNA and 6 Rad51 monomers. Thus, Rad51 holds the DNA in a highly extended conformation. Assembly of the Rad51:DNA filament is dependent on proteins that mediate the Rad51:DNA interaction, including BRCA2, the protein product of the BRCA2 gene whose mutation may lead to breast cancer. BRCA2 and other mediators, such as Rad52, are needed because **RPA**, the eukaryotic counterpart of the prokaryotic DNA replication protein **SSB**, competes with Rad51 for binding to ssDNA. Mediators such as BRCA2 displace RPA, allowing Rad51 to bind. Strand invasion and D-loop formation require other proteins, including Hop2-Mnd1. **Rad54** acts in the ATP hydrolysis-driven strand exchange reaction that leads to formation of a Holliday junction. Specific endonucleases then cleave the DNA strands to resolve the Holliday junction. BRCA2 can also mediate the binding of RAD51 to DNA regions that have become single-stranded as a result of DNA damage or DNA replication problems.

28.7i Transposons Are DNA Sequences That Can Move from Place to Place in the Genome

In 1950, Barbara McClintock reported the results of her studies on an activator gene in maize (*Zea mays*, or as it's usually called, corn) that was recognizable principally by its ability to cause mutations in other genes. Activator genes were thus an internal source of mutation. A most puzzling property was their ability to move relatively freely about the genome. Since scientists had labored to establish that genes occupied fixed locations on chromosomes, the idea of genes moving around was viewed as

Human Biochemistry

The Breast Cancer Susceptibility Genes BRCA1 and BRCA2 Are Involved in DNA Damage Control and DNA Repair

Mutations in the BRCA1 and BRCA2 genes cause increased likelihood of breast, ovarian, and other cancers. The BRCA1 protein functions in regulation of the cell cycle in response to DNA damage control. Phosphorylation of BRCA1 by DNA damage-response proteins controls the expression, phosphorylation, and cellular localization of specific cyclin-CDKs involved in the cell cycle G₂/M checkpoint and the onset of mitosis. Activation of these cyclin-CDKs leads to arrest of the cell cycle in G₂ until the damage to DNA is repaired. Furthermore, BRCA1 aids in homologous recombination repair of DSBs during S/G₂ by loading the Rad51 recombinase at the DSB. Mutations in BRCA1 that impair its function allow the cell cycle to enter mitosis and DNA damage to accumulate, raising the risk of cancer.

The BRCA2 protein participates in the pathway for DNA repair by homologous recombination. The BRCA2 protein (3418 amino acids) is a very large protein with 8 conserved sequence motifs of about 30 amino acids each, known as the *BRC repeats*. These repeats act as binding sites for RAD51, the eukaryotic analog of RecA. BRCA2 transfers

RAD51 to a ssDNA strand coated with RPA (the eukaryotic counterpart of SSB), allowing formation of the RAD51–ssDNA nucleoprotein filament that is an essential intermediate in eukaryotic homologous recombination (see Figure 28.20b). Mutations that impair BRCA2 function prevent DNA repair by homologous recombination, leading to accumulation of DNA damage and a greater likelihood of cancer.

incredible. The recognition that McClintock so richly deserved for her explanation of this novel phenomenon had to await verification by molecular biologists. In 1983, Barbara McClintock was finally awarded the Nobel Prize in Physiology or Medicine. The mobility of McClintock's activator genes, or so-called jumping genes led to their designation as **mobile elements**, **transposable elements**, or, simply, **transposons**. Transposons are found in all kingdoms of life and constitute a significant portion of genomes. In humans, 54% of the genome is transposon DNA.

Transposons are segments of DNA that are moved enzymatically from place to place in the genome (Figure 28.24). Transposons range in size from several hundred base pairs to more than 8 kbp. Transposons contain a gene encoding an enzyme called **transposase**. This is the enzyme responsible for transposon mobility. It binds to the end of a transposon, and catalyzes a cut-and-paste mechanism that inserts the transposon into a chromosome or remobilizes the transposon to a different location in the genome. These movements are termed **transposition events**. The smallest transposons are called **insertion sequences**, or **ISs**, signifying their ability to insert apparently at random in the genome. Insertion into a new site can cause a mutation if a gene or regulatory region at the site is disrupted. Because transposition events can move genes to new places or lead to the duplication of existing genes, transposition is a major force in evolution.

28.8 | Can DNA Be Repaired?

Biological macromolecules are susceptible to chemical alterations that arise from environmental damage or errors during synthesis. For RNAs, proteins, or other cellular molecules, most consequences of such damage are avoided by replacement of these molecules through normal turnover (synthesis and degradation). However, the integrity of DNA is vital to cell survival and reproduction. Its information content must be protected over the life span of the cell and preserved from generation to generation. Safeguards include (1) high-fidelity replication systems and (2) repair systems that correct DNA damage that might alter its information content. DNA is the only molecule that, if damaged, is repaired by the cell. Usually, accurate repair is possible because the information content of duplex DNA is inherently redundant; the nucleotide sequence in one strand is directly related to the sequence in the other. DNA damage may arise from endogenous processes or from exogenous agents, such as UV light, ionizing radiation, or mutagenic chemicals. The most common forms of endogenous DNA damage arise from chemical reactions (oxidation, alkylation, or deamination of bases) or loss of

Figure 28.24 The typical transposon has inverted nucleotide-sequence repeats at its termini, represented here as the 12-bp sequence ACGTACGTACGT **(a)**. It acts at a target sequence (shown here as the sequence CATGC) within host DNA by creating a staggered cut **(b)** whose protruding single-stranded ends are then ligated to the transposon **(c)**. The gaps at the target site are then filled in, and the filled-in strands are ligated **(d)**. Transposon insertion thus generates direct repeats of the target site in the host DNA, and these direct repeats flank the inserted transposon.

bases due to cleavage of *N*-glycosidic bonds. Exogenous agents can damage DNA in a variety of ways, including UV-induced free-radical generation and crosslinking of adjacent pyrimidines, breakage of the polynucleotide backbone by ionizing radiation, and base modifications through chemical reactions. Cells have extraordinarily diverse and effective systems to repair these lesions in DNA so that the genetic information is not lost or altered. The human genome has 150 or so genes associated with DNA repair. DNA repair systems include direct reversal damage repair, single-strand damage repair, double-stranded break (DSB) repair, and translesion DNA synthesis.

Chemical reactions that reverse the damage, returning the DNA to its proper state, are called **direct reversal** repair systems. Examples include methyltransferases to remove methyl groups from chemically modified bases and photolyase, which repairs thymine dimers, as discussed in Section 28.8 (see Figure 28.28). However, if the nucleotide sequence has been altered, other systems of DNA repair are required. **Single-strand damage repair** relies on the intact complementary strand to guide repair. Systems repairing this sort of DNA damage include **mismatch repair (MMR)**, **base excision repair (BER)**, and **nucleotide excision repair (NER)**. Such systems will be described further on.

28.8a Double-Strand DNA Breaks

Double-strand DNA breaks (DSBs) are the most dangerous form of DNA damage. They are a particular threat to genome stability because lost sequence information cannot be recovered from the same DNA double helix. DSBs arise in all cells, prokaryotic

or eukaryotic, but they can be repaired. The most reliable repair mechanism is to use the information in a homologous chromosome to direct the repair and restore the fidelity of the broken dsDNA. Diploid cells can always provide a homologous dsDNA, but so can haploid cells such as bacteria, if the break occurs when such cells are transiently diploid, as they are during replication. DSBs are common in eukaryotic cells; estimates suggest a frequency of 10 DSBs per cell per day. Because the threat posed by DSBs is so severe, cells have several systems to repair them. The two most prominent pathways of DSB repair are: **nonhomologous DNA end-joining (NHEJ)** and **homologous recombination (HR)**.

In NHEJ, the broken ends at the break site are rejoined. While NHEJ is the simplest way to repair a DSB, the lack of a proper DNA template means that NHEJ is error-prone (Figure 28.25). NHEJ is the dominant DSB repair pathway during most of the cell cycle and arose early in evolution as the principal DSB repair pathway. A key problem in NHEJ is to bring the ends near one another so that they can be linked together again. A heterodimeric protein, Ku70/80, composed of 70-kDa Ku70 and 83-kDa Ku80 subunits, binds to the broken DNA ends and moves onto the DNA like a nut screwing on a bolt (Figure 28.25). A Ku70/80 heterodimer at each broken end then binds the 470-kDa catalytic subunit of DNA-protein kinase (DNA-PKcs), a PI3K protein kinase family member. Assembly of Ku70/80 with DNA-PKcs completes the formation of the DNA-PK

Figure 28.25 A model for NHEJ repair of DSBs. **(a)** Double-stranded break. **(b)** Ku70/80 heterodimers (yellow) recognize the broken ends in a DSB and bind. **(c)** Ku70/80 heterodimers bind DNA-PK catalytic subunits (DNA-PKcs, blue), leading to formation of DNA-PK holoenzymes (Ku70/80:DNA-PKcs complexes) at each end. **(d)** Interactions between the C-terminal domains of the Ku80 subunits drives dimerization of the DNA-PK holoenzymes, bringing the broken ends close to one another. **(e)** Formation of the DNA-PK dimer creates a platform for recruitment of nucleases (red), DNA ligase 4 (green), and other factors essential for processing the broken ends and re-ligating them together. **(f)** Repaired DSB.

holoenzyme at each end, and the two ends come together through dimerization of the DNA-PK holoenzymes, driven by interactions between the C-terminal domains of the Ku80 subunits in each DNA-PK holoenzyme. This DNA-PK holoenzyme dimer serves as a platform for recruitment of proteins (including nucleases and DNA ligase 4) that process the damaged DNA ends and religate them. (Some proteins involved in repairing DSBs also function in immunoglobulin gene rearrangements; see Figure 28.39.)

DSBs that arise as the cell progresses from S into G₂ during the cell cycle can be repaired through homologous recombination (Figure 28.26). DSB repair via homologous recombination is much less error-prone than other alternatives. The intact sister chromatid of the damaged DNA duplex guides the process. Processing of the DSB creates single-stranded tails that become substrates for RecA-mediated nucleoprotein filament formation and homology recognition within the sister chromatid. DNA synthesis propagated from the D-loop and migration of the Holliday junction, followed by strand cleavage within the Holliday junction by resolvase, either by cleaving the crossed strands (Figure 28.26(g), left) or the noncrossed strands of the Holliday junctions (Figure 28.26(g), right).

What is effectively a DSB can arise during DNA replication if DNA damage causes the replication fork to stall (Figure 28.27). Suppose a lesion in the leading strand (circle, Figure 28.27b) causes leading-strand synthesis to stall. Continued lagging-strand synthesis results in a single-stranded region on the leading-strand template. Leading-strand invasion of the new lagging-strand duplex (mediated by RecA) creates a D-loop (Figure 28.27c), and leading-strand synthesis directed by the lagging-strand template (Figure 28.27d)

Figure 28.26 DSB repair through homologous DNA recombination. **(a)** Two homologous chromatids or DNA regions, their double-stranded DNA symbolized by a pair of lines, one chromatid orange/red, its sister chromatid black/blue. **(b)** a double-strand break in the orange/red chromatid. Homologous recombination creates a D-loop **(c)**, and sister chromatid-directed DNA replication restores the information content of the damaged duplex **(d–f)**. Depending on how the Holliday junctions are resolved, the products **(g)** are either (left) noncrossover or (right) crossover recombinants. (Adapted from Figure 1 in Hiom, K., 2010. Coping with DNA double strand breaks. *DNA Repair* 9:1256–1263.)

Figure 28.27 Restarting a stalled replication fork through homologous DNA recombination. A lesion in the DNA is symbolized by a circle; in this case, the lesion is in the leading-strand template **(a)**. Leading-strand synthesis halts because of the lesion **(b)**. Lagging-strand synthesis (red) continues, and the Okazaki fragments are ligated **(c)**. When the leading strand invades the new DNA duplex formed by lagging-strand synthesis, a D-loop is formed and strand exchange occurs. Using the lagging strand as a template, synthesis of the leading strand (black) resumes **(d)**, and the replication fork is reestablished **(e)**. (Adapted from Figure 3 in Wyman, C., and Kanaar, R., 2006. DNA double-strand break repair: All's well that ends well. *Annual Review of Genetics* 40:363–383.)

reestablishes a competent replication fork (Figure 28.27e). The site of the lesion is repaired later, usually by nucleotide excision repair (see Section 28.8c). Homologous recombination-mediated restarting of replication forks is believed to be the evolutionary driving force for the emergence of homologous recombination. Even if the NHEJ or homologous recombination repair systems fail to act, the genome may be preserved if an error-prone mode of replication allows the lesion to be bypassed. Such **translesion DNA synthesis** is more of a tolerance mechanism than a repair mechanism because it allows replication without necessarily repairing the damage. Specialized translesion DNA polymerases, such as DNA polymerase IV in *E. coli* and DNA polymerase η (η = eta) in humans, substitute for the replicative DNA polymerase in this process. Although translesion DNA polymerases tend to be error-prone, they have the advantage of allowing DNA replication to continue.

Human DNA replication has an error rate of about three base-pair mistakes during copying of the 6 billion base pairs in the diploid human genome. The low error rate is due to those DNA repair systems that review and edit the newly replicated DNA. Furthermore, about 10^4 bases (mostly purines) are lost per cell per day from spontaneous breakdown in human DNA; repair systems must replace these bases to maintain the fidelity of the encoded information.

28.8b Mismatch Repair Corrects Errors Introduced During DNA Replication

The **mismatch repair system** corrects errors introduced when DNA is replicated. It scans newly synthesized DNA for mispaired bases, excises the mismatched region, and then replaces it by DNA polymerase-mediated local replication. The key to such replacement is to know which base of the mismatched pair is correct.

The *E. coli* **methyl-directed pathway** of mismatch repair relies on methylation patterns in the DNA to determine which strand is the newly synthesized one and which one was the parental (template) strand. DNA methylation, often an identifying and characteristic feature of a prokaryote's DNA, occurs just after DNA replication. During methylation, methyl groups are added to certain bases along the new DNA strand. However, a window of opportunity exists between the end of replication and the start of methylation, when only the parental strand of a dsDNA is methylated. This window in time provides an opportunity for the mismatch repair system to review the dsDNA for mismatched bases that arose as a consequence of replication errors. By definition, the newly synthesized strand is the one containing the error, and the methylated strand is the one having the correct nucleotide sequence. When the methyl-directed mismatch repair system encounters a mismatched base pair, it searches along the DNA—through thousands of base pairs if necessary—until it finds a methylated base.

The system identifies the strand bearing the methylated base as parental, assumes its sequence is the correct one, and replaces the entire stretch of nucleotides within the new strand from this recognition point to and including the mismatched base. Mismatch repair does this by using an endonuclease to cut the new, unmethylated strand and an exonuclease to remove the mismatched bases, creating a gap in the newly synthesized strand. DNA polymerase III holoenzyme then fills in the gap, using the methylated strand as template. Finally, DNA ligase reseals the strand.

In eukaryotes, mismatch repair is similar, but it does not rely on the absence of methyl groups to identify the newly synthesized strand. Instead, strand discrimination is determined by the presence of DNA replication-associated nicks in the daughter strand.

28.8c Damage to DNA by UV Light or Chemical Modification Can Also Be Repaired

The bases in DNA are electron-rich (see Section 10.1). As such, they absorb UV light and they are susceptible to chemical modifications. Absorption of UV light can lead to formation of thymine dimers if two T residues are next to one another. These dimers disrupt the information transfer reactions implicit to transcription and translation. Bases that have been modified through unwanted chemical reaction also disrupt information transfer through improper base pairing. DNA repair mechanisms are available to reverse these modifications and maintain the integrity of the information stored in DNA.

A Deeper Look

Transgenic Animals Are Animals Carrying Foreign Genes

Experimental advances in gene transfer techniques have made it possible to introduce genes into animals by **transfection** of fertilized eggs. Transfection is defined as the uptake or injection of plasmid DNA into recipient cells. Animals that have acquired new genetic information as a consequence of the introduction of foreign genes are termed **transgenic**. Plasmids carrying the gene of interest are injected into the nucleus of an oocyte or fertilized egg, and the egg is then implanted into a receptive female. The technique has been perfected for mice (see figure, part a). In a small number of cases—10% or so—the mice that develop from the injected eggs carry the transfected gene integrated into a single chromosomal site. The gene is subsequently inherited by the progeny of the transgenic animal as if it were a normal gene. Expression of the donor gene in the transgenic animals is variable because the gene is randomly integrated into the host genome and gene expression is often influenced by chromosomal location. Nevertheless, transfection of animals has produced some startling results, as in the case of transgenic mice carrying the gene for the **rat growth hormone (rGH)**. The transgenic mice grew to nearly twice the normal size (see figure, part b). Growth hormone levels in these animals were several hundred times greater than normal. Similar results were obtained in transgenic mice transfected with the **human growth hormone (hGH)** gene. The biotechnology of transfection has been extended to farm animals,

and transgenic chickens, cows, pigs, rabbits, sheep, and even fish have been produced.

The first animal cloned from an adult cell, a sheep named Dolly, represented a milestone in cloning technology. Subsequent accomplishments include incorporation of the human gene encoding blood coagulation factor IX into sheep. Fetal sheep fibroblast cells were transfected with the human factor IX gene, nuclei from the transfected cells were transferred into sheep oocytes lacking nuclei, and these transgenic oocytes were placed in the uterus of receptive female sheep, which subsequently gave birth to transgenic lambs. The introduced factor IX transgene was specifically designed so that factor IX protein, a medically useful product for the treatment of hemophiliacs, would be expressed in the milk of the transgenic sheep. Similar successes in cows, which produce much more milk, has brought the potential for commercial production of virtually any protein into the realm of reality.

Transfection technology is one mechanism for gene therapy by replacing defective genes in animals with functional genes (see Chapter 12). Problems concerning delivery, integration and regulation of the transgene including its appropriate expression in the right cells at the proper time during development and growth of the organism, must be brought under control before gene therapy becomes commonplace in humans.

Repair of Pyrimidine Dimers Formed by UV Light UV irradiation promotes the formation of covalent bonds between adjacent thymine residues in a DNA strand, creating a cyclobutyl ring (Figure 28.28). Because the C—C bonds in this ring are shorter than the normal 0.34 nm base stacking in B-DNA, the DNA is distorted at this spot and is no longer a proper template for either replication or transcription. **Photolyase** (also called **photoreactivating enzyme**), a FAD-dependent enzyme, binds at the dimer and uses the energy of visible light to break the cyclobutyl ring, restoring the pyrimidines to their original form.

Figure 28.28 UV irradiation causes dimerization of adjacent thymine bases. A cyclobutyl ring is formed between carbons 5 and 6 of the pyrimidine rings. Normal base pairing is disrupted by the presence of such dimers.

Figure 28.29 Base excision repair. A damaged base (■) is excised from the sugar-phosphate backbone by DNA glycosylase, creating an AP site. Then, an apurinic/aprimidinic endonuclease severs the DNA strand, and an excision nuclease removes the AP site and several nucleotides. DNA polymerase I and DNA ligase then repair the gap.

Excision Repair Replacement of chemically damaged or modified bases occurs via two fundamental excision repair systems—**base excision** and **nucleotide excision**. As their names imply, these repair systems differ in whether just the base or the nucleoside at the point of damage is replaced.

Base excision repair acts on single bases that have been damaged through oxidation or other chemical modifications during normal cellular processes. The damaged base is removed by **DNA glycosylase**, which cleaves the glycosidic bond, creating an AP site where the sugar–phosphate backbone is intact but a purine (*apurinic site*) or a pyrimidine (*aprimidinic site*) is missing. An **AP endonuclease** then cleaves the backbone, an exonuclease removes the deoxyribose-P and a number of additional residues, and the gap is repaired by DNA polymerase and DNA ligase (Figure 28.29). The information of the complementary strand is used to dictate which bases are added in refilling the gap. In *E. coli*, DNA polymerase I binds at the gap and moves in the 5′→3′ direction, removing nucleotides with its 5′-exonuclease activity. The 5′→3′ DNA polymerase activity of DNA polymerase I fills in the sequence behind the 5′-exonuclease action. No net synthesis of DNA results, but this action of DNA polymerase I “edits out” sections of damaged DNA. Excision is coordinated with 5′→3′ polymerase-catalyzed replacement of the damaged nucleotides so that DNA of the right sequence is restored.

Nucleotide excision repair recognizes and repairs larger regions of damaged DNA than base excision repair. The nucleotide excision repair (NER) pathway in humans consists of more than 30 proteins engaged in DNA damage verification, excision, gap filling, and ligation. The NER pathway cuts the sugar–phosphate backbone of a DNA strand in two places, one on each side of the lesion, and removes the region. An oligonucleotide stretch 27 to 29 units long is removed. The resultant gap is then filled in using DNA polymerase (DNA polymerase I in prokaryotes or DNA polymerase δ or ϵ and PCNA plus RFC in eukaryotes), and the sugar–phosphate backbone is covalently closed by DNA ligase.

In mammalian cells, nucleotide excision repair is the main pathway for removal of carcinogenic (cancer-causing) lesions caused by sunlight or other mutagenic agents. Such lesions are recognized by **XPA** protein, named for *xeroderma pigmentosum*, an inherited human syndrome whose victims suffer serious skin lesions if exposed to sunlight. XPA, a DNA-binding dimer of 31-kDa subunits, verifies that DNA damage has occurred and serves as a platform for recruitment of the multitude of other NER factors to the damaged strand through protein–protein interactions.

28.9 | What Is the Molecular Basis of Mutation?

Genes are normally transmitted unchanged from generation to generation, owing to the great precision and fidelity with which genes are copied during chromosome duplication. However, on rare occasions, genetically heritable changes (**mutations**)

occur and result in alterations to the DNA. Most mutated genes function less effectively than the unaltered, wild-type allele, but occasionally, mutations arise that give the organism a selective advantage. When this occurs, they may be propagated for many generations. Together with recombination, mutation provides for genetic variability within species and, ultimately, the evolution of new species.

Mutations change the sequence of bases in DNA, either by the substitution of one base pair for another (so-called **point mutations**) or by the insertion or deletion of one or more base pairs (**insertions** and **deletions**).

28.9a Point Mutations Arise by Inappropriate Base-Pairing

Point mutations arise when a base pairs with an inappropriate partner. The two possible kinds of point mutations are **transitions**, in which one purine (or pyrimidine) is replaced by another, as in $A \rightarrow G$ (or $T \rightarrow C$), and **transversions**, in which a purine is substituted for a pyrimidine, or vice versa.

Point mutations arise by the pairing of bases with inappropriate partners during DNA replication, by the introduction of base analogs into DNA, or by chemical mutagens. Bases may rarely mispair (Figure 28.30), either because of their tautomeric properties (see Chapter 10) or because of other influences. Even in mispairing, the $C_1'-C_1'$ distances between bases must still be close to that of a Watson–Crick base pair (11 nm or so; see Figure 11.9) to maintain the mismatched base pair in the double helix. In tautomerization, for example, an amino group ($-\text{NH}_2$), usually an H-bond donor, can tautomerize to an imino form ($=\text{NH}$) and become an H-bond acceptor. Or a keto group ($\text{C}=\text{O}$), normally an H-bond acceptor, can tautomerize to an enol $\text{C}-\text{OH}$, an H-bond donor. Proofreading mechanisms operating during DNA replication catch most mispairings. The frequency of spontaneous mutation in prokaryotes and eukaryotes (including humans) is about 10^{-8} per base pair per generation.

(a)

Figure 28.30 Point mutations due to base mispairings. **(a)** An example based on tautomeric properties. The rare imino tautomer of adenine base pairs with cytosine rather than thymine. **(1)** The normal A-T base pair. **(2)** The A*-C base pair is possible for the adenine tautomer in which a proton has been transferred from the 6-NH₂ of adenine to N-1. **(3)** Pairing of C with the imino tautomer of A (A*) leads to a transition mutation (A-T to G-C) appearing in the next generation. **(b)** A in the syn conformation pairing with G (G is in the usual anti conformation). **(c)** T and C form a base pair by H-bonding interactions mediated by a water molecule.

Figure 28.31 5-Bromouracil usually favors the keto tautomer that mimics the base-pairing properties of thymine, but it frequently shifts to the enol form, whereupon it can base-pair with guanine, causing a T–A to C–G transition.

Figure 28.32 (a) 2-Aminopurine normally base-pairs with T but (b) may also pair with cytosine through a single hydrogen bond.

(Hypoxanthine is in its keto tautomeric form here)

Figure 28.33 Oxidative deamination of adenine in DNA yields hypoxanthine, which base-pairs with cytosine, resulting in an A–T to G–C transition.

28.9b Mutations Can Be Induced by Base Analogs

Base analogs that become incorporated into DNA can induce mutations through changes in base-pairing possibilities. Two examples are **5-bromouracil (5-BU)** and **2-aminopurine (2-AP)**. 5-Bromouracil is a thymine analog and becomes inserted into DNA at sites normally occupied by T; its 5-Br group sterically resembles thymine's 5-methyl group. However, because 5-BU frequently assumes the enol tautomeric form and pairs with G instead of A, a point mutation of the transition type may be induced (Figure 28.31). Less often, 5-BU is inserted into DNA at cytosine sites, not T sites. Then, if it base-pairs in its keto form, mimicking T, a C–G to T–A transition ensues. The adenine analog, 2-aminopurine (recall that adenine is 6-aminopurine) normally behaves like A and base-pairs with T. However, 2-AP can form a single H bond of sufficient stability with cytosine (Figure 28.32) that occasionally C replaces T in DNA replicating in the presence of 2-AP. Hypoxanthine (Figure 28.33) is an adenine analog that arises in situ in DNA through oxidative deamination of A. Hypoxanthine base-pairs with cytosine, creating an A–T to G–C transition.

28.9c Chemical Mutagens React with the Bases in DNA

Chemical mutagens are agents that chemically modify bases so that their base-pairing characteristics are altered. For instance, *nitrous acid* (HNO_2) causes the oxidative deamination of primary amine groups in adenine and cytosine. Oxidative deamination of cytosine yields uracil, which base-pairs the way T does and gives a C–G to T–A transition (Figure 28.34a). *Hydroxylamine* specifically causes C–G to T–A transitions because it reacts specifically with cytosine, converting it to a derivative that base-pairs with adenine instead of guanine (Figure 28.34c). **Alkylating agents** (Figure 28.34e) are also chemical mutagens. Alkylation of reactive sites on the bases to add methyl or ethyl groups alters their H bonding and hence base pairing. For example, methylation of O^6 on guanine (giving O^6 -methylguanine) causes this G to mispair with thymine, resulting in a G–C to A–T transition (Figure 28.34d). Alkylating agents can also induce point mutations of the transversion type. Alkylation of N^7 of guanine labilizes its *N*-glycosidic bond, which leads to elimination of the purine ring, creating a gap in the base sequence. An enzyme, AP endonuclease, then cleaves the sugar–phosphate backbone of the DNA on the 5'-side, and the gap can be repaired by enzymatic removal of the 5'-sugar–phosphate and insertion of a new nucleotide (see Figure 28.29). A transversion results if a pyrimidine nucleotide is inserted in place of the purine during enzymatic repair of this gap.

28.9d Insertions and Deletions

The addition or removal of one or more base pairs leads to *insertion* or *deletion* mutations, respectively. If the number of base pairs inserted or deleted is not divisible by three, the codon triplet reading frame will be shifted. Such shifts cause **frameshift mutations** (misincorporation of all subsequent amino acids) in the protein encoded by

Figure 28.34 Chemical mutagens. (a) HNO_2 (nitrous acid) converts cytosine to uracil and adenine to hypoxanthine. (b) Nitrosoamines, organic compounds that react to form nitrous acid, also lead to the oxidative deamination of A and C. (c) Hydroxylamine (NH_2OH) reacts with cytosine, converting it to a derivative that base-pairs with adenine instead of guanine. The result is a C-G to T-A transition. (d) Alkylation of G residues to give O^6 -methylguanine, which base-pairs with T. (e) Alkylating agents include nitrosoamines, nitrosoguanidines, nitrosoureas, alkyl sulfates, and nitrogen mustards. Note that nitrosoamines are mutagenic in two ways: They can react to yield HNO_2 , or they can act as alkylating agents. The nitrosoguanidine, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, is a very potent mutagen used in laboratories to induce mutations in experimental organisms such as *Drosophila melanogaster*. Ethylmethane sulfonate (EMS) and dimethyl sulfate are also favorite mutagens among geneticists.

the gene. Such mutations can arise if flat, aromatic molecules such as *acridine orange* insert themselves between successive bases in one or both strands of the double helix. This insertion or, more aptly, **intercalation**, doubles the distance between the bases as measured along the helix axis (see Figure 11.15). This distortion of the DNA results in inappropriate insertion or deletion of bases when the DNA is replicated. Disruptions that arise from the insertion of a transposon within a gene also fall in this category of mutation (see Figure 28.24).

28.10 | Can Genetic Recombination Create Protein Diversity?

Animals have evolved a way to exploit genetic recombination in order to generate protein diversity. This development was crucial to the evolution of the immune system. For example, the immunoglobulin genes are a highly evolved system for maximizing protein diversity from a finite amount of genetic information. This diversity is essential for gaining immunity to the great variety of infectious organisms and foreign substances that cause disease.

28.10a Cells Active in the Immune Response Are Capable of Gene Rearrangement

Only vertebrates show an immune response. If a foreign substance, called an **antigen**, gains entry to the bloodstream of a vertebrate, the animal responds via a protective system called the *immune response*. The immune response involves production of proteins capable of recognizing and destroying the antigen. This response is mounted by certain white blood cells—the **B- and T-cell lymphocytes** and the **macrophages**. B-cells are so named because they mature in the bone marrow; T-cells mature in the thymus gland. Each of these cell types is capable of gene rearrangement as a mechanism for producing proteins essential to the immune response. **Antibodies**, which can recognize and bind antigens, are immunoglobulin proteins secreted from B-cells. Because antigens can be almost anything, the immune response must have an incredible repertoire of structural recognition. Thus, vertebrates must have the potential to produce immunoglobulins of great diversity in order to recognize virtually any antigen.

28.10b Immunoglobulin G Molecules Contain Regions of Variable Amino Acid Sequence

Immunoglobulin G (IgG or γ -globulin) is the major class of antibody molecules found circulating in the bloodstream. IgG is a very abundant protein, amounting to 12 mg per mL of serum. It is a 150-kDa $\alpha_2\beta_2$ -type tetramer. The α or *H* (for *heavy*) chain is 50 kDa; the β or *L* (for *light*) chain is 25 kDa. A preparation of IgG from serum is heterogeneous in terms of the amino acid sequences represented in its L and H chains. However, the IgG L and H chains produced from any given B lymphocyte are homogeneous in amino acid sequence. L chains consist of 214 amino acid residues and are organized into two roughly equal segments: the V_L and C_L regions. The V_L designation reflects the fact that L chains isolated from serum IgG show variations in amino acid sequence over the first 108 residues, V_L symbolizing this variable region of the L polypeptide. The amino acid sequence for residues 109 to 214 of the L polypeptide is constant, as represented by its designation as the “constant light,” or C_L , region. The heavy, or H, chains consist of 446 amino acid residues. Like L chains, the amino acid sequence for the first 108 residues of H polypeptides is variable, ergo its designation as the V_H region, while residues 109 to 446 are constant in amino acid sequence. This constant heavy region consists of three quite equivalent domains of homology designated C_{H1} , C_{H2} , and C_{H3} . Each L chain has two intrachain disulfide bonds: one in the V_L region and the other in the C_L region. The C-terminal amino acid in L chains is cysteine, and

Figure 28.35 Diagram of the organization of the IgG molecule. Two identical L chains are joined with two identical H chains. Each L chain is held to an H chain via an interchain disulfide bond. The variable regions (purple) of the four polypeptides lie at the ends of the arms of the Y-shaped molecule. These regions are responsible for the antigen recognition function of the antibody molecules. The actual antigen-binding site is constituted from hypervariable residues within the V_L and V_H regions. For purposes of illustration, some features are shown on only one or the other L chain or H chain, but all features are common to both chains.

it forms an interchain disulfide bond to a neighboring H chain. Each H chain has four intrachain disulfide bonds, one in each of the four regions. Figure 28.35 presents a diagram of IgG organization. Within the variable regions of the L and H chains, certain positions are **hypervariable** with regard to amino acid composition. These hypervariable residues occur at positions 24 to 34, 50 to 55, and 89 to 96 in the L chains and at positions 31 to 35, 50 to 65, 81 to 85, and 91 to 102 in the H chains. The hypervariable regions are also called **complementarity-determining regions**, or **CDRs**, because it is these regions that form the structural site that is complementary to some part of an antigen's structure, providing the basis for antibody–antigen recognition.

The secondary structure of immunoglobulin chains is dominated by β -strands. In terms of its tertiary structure, the IgG molecule is composed of 12 discrete *collapsed β -barrel domains*. Within each domain, alternating β -strands are antiparallel to one another, a pattern known by the name *Greek key motif*. The characteristic structure of this domain is referred to as the **immunoglobulin fold** (Figure 28.36). Each of IgG's two heavy chains contributes four of these domains and each of its light chains contributes two. In the immunoglobulin genes, the arrangement of exons correlates with IgG structural organization. The four *variable-region* domains (one on each chain) are encoded by multiple exons, but the eight *constant-region* domains are each the product of a single exon. All of these *constant-region* exons are derived from a single ancestral exon encoding an immunoglobulin fold. The major *variable-region* exon probably derives from this ancestral exon also. Contemporary immunoglobulin genes are a consequence of multiple duplications of the ancestral exon.

The discovery of variability in amino acid sequence in otherwise identical polypeptide chains was surprising and almost heretical to protein chemists. For geneticists, it presented a genuine enigma. They noted that mammals, which can make millions of different antibodies, don't have millions of different antibody genes. How can the mammalian genome encode the diversity seen in L and H chains?

28.10c The Immunoglobulin Genes Undergo Gene Rearrangement

The answer to the enigma of immunoglobulin sequence diversity is found in the organization of the immunoglobulin genes. The genetic information for an immunoglobulin polypeptide chain is scattered among multiple gene segments along a chromosome

Figure 28.36 The characteristic collapsed β -barrel domain known as the *immunoglobulin fold*. The β -barrel structures for both (a) *variable* and (b) *constant regions* are shown. (c) A schematic diagram of the 12 collapsed β -barrel domains that make up an IgG molecule. CHO indicates the carbohydrate addition site; F_{ab} denotes one of the two antigen-binding fragments of IgG, and F_c , the proteolytic fragment consisting of the pairs of C_H2 and C_H3 domains.

in germline cells (sperm and eggs). During vertebrate development and the formation of B lymphocytes, these segments are brought together and assembled by **DNA rearrangement** (that is, genetic recombination) into complete genes. DNA rearrangement, or **gene reorganization**, provides a mechanism for generating a variety of protein isoforms from a limited number of genes. DNA rearrangement occurs in only a few genes, namely, those encoding the antigen-binding proteins of the immune response—the immunoglobulins and the T-cell receptors. The gene segments encoding the amino-terminal portion of the immunoglobulin polypeptides are also unusually susceptible to mutation events. The result is a population of B-cells whose antibody-encoding genes collectively show great sequence diversity even though a given cell can make only a limited set of immunoglobulin chains. Hence, at least one cell among the B-cell population likely will be capable of producing an antibody that will specifically recognize a particular antigen. Both the T-cell receptor proteins, which recognize antigens presented by the **major histocompatibility complex (MHC)** of other cells, and the genes that encode these T-cell receptor proteins are organized similarly to the IgG proteins and genes. Thus, T-cells also show great diversity in antigen recognition.

28.10d DNA Rearrangements Assemble an L-Chain Gene by Combining Three Separate Genes

The organization of various immunoglobulin gene segments in the human genome is shown in Figure 28.37. L-chain variable-region genes are assembled from two kinds of **germline genes**: V_L and J_L (J stands for *joining*). In mammals, there are two different families of **L-chain genes**: the κ , or **kappa, gene family** and the λ , or **lambda, gene family**; each family has V and J members. These families are on different chromosomes. Humans have 40 functional V genes and 5 functional J genes for the κ light chains and 31 V genes and 4 J genes for the λ light chain. The V and J genes lie upstream from the single **C_κ gene** that encodes the L-chain constant region. Each V_κ gene has its own L_κ segment for encoding the L-chain leader peptide that targets the L chain to the endoplasmic reticulum for IgG assembly and secretion. (This leader peptide is cleaved once the L chain reaches the ER lumen.) The λ family of L-chain genes is organized similarly. In different mature B-lymphocyte cells, V_κ and J_κ genes have joined in different combinations, and along with the $C-V_\kappa$ gene, form complete $L-V_\kappa$ chains with a variety of V_κ regions. However, any given B lymphocyte expresses only one V_κ - J_κ combination. Construction of the mature B-lymphocyte L-chain gene has occurred by DNA rearrangements that combine three genes ($L-V_{\kappa,\lambda}$, $J_{\kappa,\lambda}$, $C_{\kappa,\lambda}$) to make one polypeptide!

28.10e DNA Rearrangements Assemble an H-Chain Gene by Combining Four Separate Genes

The first 98 amino acids of the 108-residue, H-chain variable region are encoded by a **V_H gene**. Each V_H gene has an accompanying L_H gene that encodes its essential leader peptide. It is estimated that there are 200 to 1000 V_H genes and that they can be subdivided into eight distinct families based on nucleotide sequence homology. The members of a particular V_H family are grouped together on the chromosome, separated from one another by 10 to 20 bp. In assembling a mature H-chain gene, a V_H gene is joined to a **D gene** (D for *diversity*), which encodes amino acids 99 to 113 of the H chain. These amino acids comprise the core of the third CDR in the variable region of H chains. The V_H -D gene assemblage is linked in turn to a **J_H gene**, which encodes the remaining part of the variable region of the H chain. The V_H , D, and J_H genes are

Figure 28.37 Organization of human immunoglobulin gene segments. *Green, orange, blue, or purple* colors indicate the exons of a particular V_L or V_H gene. **(a)** L-chain gene assembly: During B-lymphocyte maturation in the bone marrow, one of the 40 V genes combines with one of the 5 J genes and is joined with a C gene. During the recombination process, the intervening DNA between the gene segments is deleted (see Figure 28.39). These rearrangements occur by a mostly random process, giving rise to many possible light-chain sequences from each gene family. **(b)** H-chain gene assembly: H chains are encoded by V, D, J, and C genes. In H-chain gene rearrangements, a D gene joins with a J gene and then one of the V genes adds to the DJ assembly. (Adapted from Figure 2b and c in Nossal, G. J. V., 2003. The double helix and immunology. *Nature* 421:440–444.)

grouped in three separate clusters on the same chromosome. The four J_H genes lie 7 kb upstream of the eight C genes, the closest of which is C_μ . Any of four **C genes** may encode the constant region of IgG H chains: $C_{\gamma 1}$, $C_{\gamma 2a}$, $C_{\gamma 2b}$, and $C_{\gamma 3}$. Each C gene is composed of multiple exons (only C_μ is shown in Figure 28.37, none of the other C genes). Ten to 20 D genes are found 1 to 80 kb farther upstream. The V_H genes lie even farther upstream. In B lymphocytes, the variable region of an H-chain gene is composed of one each of the L_H – V_H genes, a D gene, and a J_H gene joined head to tail. Because the H-chain variable region is encoded in three genes and the joinings can occur in various combinations, the H chains have a greater potential for diversity than the L-chain variable regions that are assembled from just two genes (for example, L_κ – V_κ and J_κ). In making H-chain genes, four genes have been brought together and reorganized by DNA rearrangement to produce a single polypeptide!

28.10f V–J and V–D–J Joining in Light- and Heavy-Chain Gene Assembly Is Mediated by the RAG Proteins

Specific nucleotide sequences adjacent to the various variable-region genes suggest a mechanism in which these sequences act as joining signals. All germline V and D genes are followed by a trio of segments consisting of a consensus CACAGTG heptamer, a short spacer, and a consensus ACAAAAACA nonamer. Similarly, all D and J genes are preceded by a trio of segments, in this case, a consensus GGTTTTGT nonamer, a short spacer, and a consensus CACTGTG heptamer. The spacers in V_κ , J_κ , and D genes are 12 bp long, whereas the V_λ , J_λ , and J_H spacers are 23 bp (Figure 28.38). Note that the conserved consensus elements (namely, the heptamer and nonamer sequences) downstream of a gene are complementary to those upstream from the gene with which it recombines. Indeed, it is these complementary consensus sequences that serve as **recombination signal sequences (RSSs)** and determine the site of recombination between variable-region genes. Functionally meaningful recombination happens only where one has a 12 bp spacer and the other has a 23 bp spacer, a relationship referred to as the 12/23 rule (Figure 28.39).

Lymphoid cell-specific **recombination-activating gene proteins 1 and 2 (RAG1 and RAG2)** mediate V(D)J gene recombination, functioning together as the **V(D)J recombinase**, also called the **RAG recombinase**. RAG1 (1040 residues) and RAG2 (527 residues) form RAG1/RAG2 dimers. RAG1 has a DNA-binding domain specific for the nonamer elements in RSSs, and RAG2 enhances DNA binding by RAG1 and participates in DNA cleavage (Figure 28.39). One RAG1/RAG2 dimer binds at each nonamer in an RSS (Figure 28.39b). HMGB1, an abundant nuclear protein involved in DNA organization and transcriptional regulation, plays an important role in formation of the catalytically active RAG1/RAG2 recombinase. When HMGB1 binds to DNA, it forces the DNA to bend, facilitating dimerization of the two RAG1/RAG2 dimers into the catalytically active (RAG1/RAG2)₂ heterotetramer, looping out of the 12- and 23-bp spacers

Figure 28.38 Consensus elements are given above and below germline variable-region genes that recombine to form genes encoding immunoglobulin chains. These consensus elements are complementary and are arranged in a heptamer-nonamer, 12 to 23-bp spacer pattern. (*Adapted from* Tonewaga, S., 1983. Somatic generation of antibody diversity. *Nature* **302**:575.)

Figure 28.39 A model for V(D)J recombination. Each DNA strand in the immunoglobulin gene is shown as a white bar with color-coded regions. **(a)** Diagram of RSS consensus elements between V (yellow) and J (purple) immunoglobulin gene-coding segments, with complementary RSS heptamer repeats (magenta) and nonamer repeats (green). **(b)** RAG1/RAG2 heterodimers bind to the nonamer RSSs and in the presence of HMGB1, DNA bending and formation of (RAG1/RAG2)₂ heterotetramers juxtaposes the complementary heptamer and nonamer RSSs, looping out the 12- and 23-bp spacers. **(c)** This process of synapsis brings the V and J coding regions into proximity. **(d)** The (RAG1/RAG2)₂ complex nucleases cleave the DNA at the borders of V and J protein-coding sequences and the heptamer repeats. The products of (RAG1/RAG2)₂ DNA cleavage are novel: The DNA bearing the recombination signal sequences has blunt ends, whereas the both the V- and J-coding DNA has hairpin ends. That is, the two strands of the V- and J-coding DNA segments are covalently joined. **(e)** In the next step of the recombination process, the DSB at the RSS ends (magenta) are precisely joined to make a covalently closed circular dsDNA (the signal joint), but the hairpins at the V- and J-coding ends are opened. Opening these hairpins makes a second double-stranded break (DSB). The two ends of the coding DNA at this DSB undergo further processing, with the addition or removal of nucleotides. This processing means that joining of the V- and J-coding ends will be imprecise, providing an additional means for introducing antibody diversity. **(f)** Finally, the V- and J- coding segments are joined to create a recombinant immunoglobulin-encoding gene. The processing and joining reactions require the proteins involved in NHEJ DSB repair, namely, Ku70/80, DNA-PK, DNA ligase 4, and others (see Figure 28.25).

and aligning the homologous heptamer and nonamer regions in process called **synapsis** (Figure 28.39c). Each RAG1 has a DNA cleavage catalytic site, with RAG2 contributing to active-site formation. Together they recognize and cleave the DNA at the junctions between the recombination signal sequences and the V- and J-coding regions. Specifically, $(\text{RAG1/RAG2})_2$ nuclease activity nicks one strand of V-(and J-) DNA at the RSS–coding region junction, creating a free 3'-OH that attacks the phosphodiester backbone of the complementary V- or J-strand to form the hairpin. DNA strand nicking and V- and J-hairpin formation causes formation of double-stranded breaks (DSBs) at the heptamer:V- and J-junctions (Figure 28.39d). In the next steps in the recombination process, the two RSS ends are precisely joined to make a covalently closed circular dsDNA (called the signal joint). In contrast, the hairpins at the V- and J-coding ends are opened (Figure 28.39e). Opening these hairpins is equivalent to making a double-stranded break. The two ends of the coding DNA at the DSB undergo further processing, with the addition or removal of nucleotides. This processing means that joining of the V- and J-coding ends will be imprecise, an additional mechanism for generating antibody diversity. Finally, the V- and J-coding segments are covalently joined to create a recombinant immunoglobulin-encoding gene. These processing and joining reactions are carried out by the same proteins involved in NHEJ DSB repair, namely, Ku70/80, DNA-PK, DNA ligase 4, and others (see Figure 28.25). The molecular structure of the mammalian $(\text{RAG1/RAG2})_2$ heterotetramer is shown in Figure 28.40.

Figure 28.40 Molecular graphic of the vertebrate RAG1/RAG2 heterotetramer (or more appropriately, the $(\text{RAG1/RAG2})_2$ dimer of dimers) bound to DNA. RAG1/RAG2 is a member of the DDE family of polynucleotide transferases that includes transposases and integrases. The RAG1 subunits are *orange* and *teal*; the RAG2 subunits are *red* and *blue*. The DNA, shown in *green*, consists of double-stranded oligonucleotides with sequences corresponding to 12- and 23-RSS substrates carrying consensus heptamer and nonamer repeats. Binding of $(\text{RAG1/RAG2})_2$ to the RSS nonamers drives conformational changes in RAG1 that allow the fit of only one 12-RSS and one 23-RSS, providing a molecular explanation for the 12/23 rule. Each RAG1 contains a RNase H-like motif midway along its amino acid sequence. These RAG1 RNase H domains are the $(\text{RAG1/RAG2})_2$ endonuclease sites responsible for nicking the DNA, initiating the recombinant events. (PDB id = 6DBI. Adapted from Figure 2 in Ru, H., et al., 2018. DNA melting initiates the RAG catalytic pathway. *Nature Structural and Molecular Biology* 25:732–742.)

28.10g Imprecise Joining of Immunoglobulin Genes Creates New Coding Arrangements

Joining of the ends of the immunoglobulin-coding regions during gene reorganization is somewhat imprecise, as discussed above and illustrated in Figure 28.39. This imprecision actually leads to even greater antibody diversity because new coding arrangements result. Position 96 in κ chains is typically encoded by the first triplet in the J_κ element. Most κ chains have one of four amino acids here, depending on which J_κ gene was recruited in gene assembly. However, occasionally only the second and third bases or just the third base of the codon for position 96 is contributed by the J_κ gene, with the other one or two nucleotides supplied by the V_κ segment (Figure 28.41). So, the precise point where recombination occurs during gene reorganization can vary over several nucleotides, creating even more diversity.

28.10h Antibody Diversity Is Due to Immunoglobulin Gene Rearrangements

Taking as an example the mouse with perhaps 300 V_κ genes, 4 J_κ genes, 200 V_H genes, 12 D genes, and 4 J_H genes, the number of possible combinations is given by $300 \times 4 \times 200 \times 12 \times 4$. Thus, more than 10^7 different antibody molecules can be created from roughly 500 or so different mouse variable-region genes. Including the possibility for V_κ – J_κ joinings occurring within codons adds to this diversity, as does the high rate of somatic mutation associated with the variable-region genes. (Recall that somatic mutations are mutations that arise in diploid cells and are transmitted to the progeny of these cells within the organism, but not to the offspring of the organism.) Clearly, gene rearrangement is a powerful mechanism for dramatically enhancing the protein-coding potential of genetic information.

Figure 28.41 Recombination between the V_κ and J_κ genes can vary by several nucleotides, giving rise to variations in amino acid sequence, and hence, diversity in immunoglobulin L chains.

Foundational Biochemistry Things You Should Know after Reading Chapter 28.

- DNA is the material of heredity.
- The three Rs of DNA metabolism—replication, recombination, and repair—account for the transmission, rearrangement, and stability of genetic information.
- DNA replication is semiconservative: The DNA strands are separated and then the nucleotide sequence of each strand is copied by base-pairing.
- DNA replication is bidirectional, accomplished by two replication forks moving in opposite directions.
- DNA gyrases and helicases unwind the DNA double helix so the individual strands can be copied.
- Single-stranded DNA-binding protein (SSB) prevents DNA reannealing and protects the single strands from nuclease attack.
- DNA replication is semidiscontinuous: One parental strand, the 3'→5' strand, is copied in a continuous manner to form the leading strand. The other, the 5'→3' strand, is copied in an intermittent fashion to form the lagging strand.
- The products of lagging-strand synthesis are several kilobases in length and are called Okazaki fragments.
- DNA polymerases select the proper base for replication of a strand through Watson–Crick geometric interactions.
- DNA synthesis by DNA polymerase always proceeds in the 5'→3' direction, copying the template strand in the 3'→5' direction.
- DNA polymerases require a primer strand with a free 3'-OH to build upon.
- Prokaryotes and eukaryotes have multiple DNA polymerases, each serving specific functions in DNA replication and repair.
- *E. coli* DNA polymerase III holoenzyme replicates the *E. coli* chromosome.
- *E. coli* DNA polymerase III holoenzyme consists of 10 different kinds of subunits: 2 core ($\alpha\epsilon\theta$) DNA polymerase III units, one clamp loader (γ -complex), and a β_2 -sliding clamp to tether the holoenzyme to DNA.
- Each *E. coli* DNA polymerase III holoenzyme is associated with a hexameric DnaB helicase that unwinds the DNA duplex and three primase subunits that synthesize RNA primers.
- *E. coli* DNA polymerase III holoenzyme is highly processive: It can replicate the entire *E. coli* chromosome without dissociating from the DNA.
- A DNA polymerase III holoenzyme sits at each replication fork.
- *E. coli* DNA polymerase I removes the RNA primers and fills in the gaps.
- DNA polymerase is its own proofreader.
- *E. coli* DNA polymerase I activity is important in double-strand break repair (DSB repair).
- *E. coli* DNA ligase seals the links between Okazaki fragments.
- *E. coli* DNA replication terminates at the *Ter* region.
- DNA polymerases are localized in replication factories, called replicons.
- DNA polymerases across all organisms have a common architecture and mechanism of action.
- DNA polymerases can be organized into families based on their sequence homology.
- In eukaryotic cells, the cell cycle determines the time of DNA replication through the action of checkpoints, CDKs and cyclins.
- Initiation of replication in eukaryotes depends on ORC (the origin of replication complex), the CMG helicases (replication licensing factors), Cdc6, Cdt1, and other proteins.
- The MCM proteins, the Orc proteins, and Cdc6 are AAA+ ATP family members.
- Geminin inhibits DNA replication by preventing MCM recruitment to the prereplication complex.
- The two replisomes in eukaryotic replicons are bound together by Ctf4.
- DNA polymerase δ synthesizes the lagging strand, and DNA polymerase ϵ , the leading strand.
- Telomerase, an RNA-dependent DNA polymerase, replicates telomeres, the structures at the ends of eukaryotic chromosomes.
- Telomerase consists of a DNA polymerase catalytic subunit (TERT) and an RNA subunit (RT or TER) that serves as the template for RNA-dependent synthesis of new telomeres.
- RNA genomes are replicated by reverse transcriptase, an RNA-dependent DNA polymerase.
- Reverse transcriptases possess RNA-directed DNA polymerase activity, RNase H activity, and DNA-directed DNA polymerase activity.
- Genetic information is rearranged by recombination.
- Recombination between very similar DNA sequences is called homologous recombination or general recombination.
- Recombination between dissimilar DNA sequences is called nonhomologous recombination.
- General recombination requires the breakage and reunion of DNA strands.
- Homologous recombination proceeds according to the Holliday model, with formation of a Holliday junction.
- Resolution of the Holliday junction leads to formation of patch recombinants or splice recombinants.
- The enzymes of general recombination include RecA, RecBCD, RuvA, RuvB, and RuvC.
- The RecBCD complex unwinds double-stranded DNA and cleaves its single strands.
- RecA can bind single-stranded DNA and then interact with double-stranded DNA.
- RecA mediates the ATP-dependent strand exchange reaction leading to formation of a Holliday junction.
- RecA binding to ssDNA leads to formation of a right-handed helical nucleoprotein filament in which the ssDNA is stretched and underwound.
- RuvA, RuvB, and RuvC resolve the Holliday junction to form recombination products.
- Recombination-dependent DNA replication restarts DNA replication at stalled replication forks.
- Transposons are DNA sequences that can move from place to place in the genome by recombination.
- DNA is susceptible to damage by chemical reactions, UV light, or ionizing radiation.
- DNA can be repaired by a number of different mechanisms, including mismatch repair (MMR), base excision repair (BER), and double-strand break repair (DSB repair).

- DSB repair can be carried out by either nonhomologous end-joining (NHEJ) or homologous recombination.
- NHEJ DSB repair is mediated Ku70/80, DNA-PK, DNA ligase 4, along with other proteins.
- Mismatch repair corrects errors introduced during DNA replication.
- Pyrimidine dimers formed by UV light are repaired by photolyase.
- Base excision repair involves removal of the damaged base by DNA glycosylase, cleavage of the backbone by AP endonuclease, and gap repair by DNA polymerase.
- Nucleotide excision repair recognizes and removes larger regions of damaged DNA than BER.
- Point mutations in DNA arise by inappropriate base-pairing.
- Mutations can be induced by base analogs.
- Chemical mutagens react with bases in DNA.
- Insertions or deletions lead to frameshift mutations.
- Protein diversity can be generated through genetic recombination.
- Antibody molecules such as immunoglobulins G and T-cell receptors are an excellent examples of protein diversity through genetic recombination.
- The variable regions of immunoglobulin G light and heavy chains are regions of variable amino acid sequence created by genetic recombination within the immunoglobulin genes.
- V-J and D-J joining in light- and heavy-chain gene assembly is mediated by the (RAG1/RAG2)₂ heterotetramer and the proteins of the NHEJ DSB repair pathway.
- Imprecise joining of IgG genes creates new coding arrangements.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Semiconservative or Conservative DNA Replication** ¹⁵N-labeled *E. coli* DNA has a density of 1.724 g/mL and ¹⁴N-labeled *E. coli* DNA has a density of 1.710 g/mL. *E. coli* cells grown for many generations on ¹⁴NH₄⁺ as nitrogen source are transferred to media containing ¹⁵NH₄⁺ as the sole source of nitrogen. (a) What will be the density of the DNA after one generation, assuming replication is semiconservative? (b) Suppose replication took place by a conservative mechanism in which the parental strands remained together and the two progeny strands were paired. Design an experiment that could distinguish between semiconservative and conservative modes of replication.
- The Enzymatic Activities of DNA Polymerase I** (a) What are the respective roles of the 5'-exonuclease and 3'-exonuclease activities of DNA polymerase I? (b) What might be a feature of an *E. coli* strain that lacked DNA polymerase I 3'-exonuclease activity?
- Multiple Replication Forks in *E. coli* I** (a) Assuming DNA replication proceeds at a rate of 750 base pairs per second, calculate how long it will take to replicate the entire *E. coli* genome. (b) Under optimal conditions, *E. coli* cells divide every 20 minutes. What is the minimal number of replication forks per *E. coli* chromosome to sustain such a rate of cell division?
- Multiple Replication Forks in *E. coli* II** On the basis of Figure 28.2, draw a simple diagram illustrating replication of the circular *E. coli* chromosome (a) at an early stage, (b) when one-third completed, (c) when two-thirds completed, and (d) when almost finished, assuming the initiation of replication at *oriC* has occurred only once. Then, draw a diagram showing the *E. coli* chromosome in problem 3 where the *E. coli* cell is dividing every 20 minutes.
- Molecules of DNA Polymerase III per Cell vs. Growth Rate** It is estimated that there are 40 molecules of DNA polymerase III per *E. coli* cell. Is it likely that the growth rate of *E. coli* is limited by DNA polymerase III availability?
- The Role of ATP in Replication** DNA replication is an energy-consuming process. What steps in the overall process of DNA replication require ATP hydrolysis?
- Number of Okazaki Fragments in *E. coli* and Human DNA Replication** Approximately how many Okazaki fragments are synthesized in the course of replicating an *E. coli* chromosome? How many in replicating an average human chromosome?
- The Roles of Helicases and Gyases** How do DNA gyases and helicases differ in their respective functions and modes of action?
- Gyases vs Helicases** Why might the action of gyases be considered riskier in terms of DNA integrity than the action of helicases?
- Human Genome Replication Rate** Assume DNA replication proceeds at a rate of 100 base pairs per second in human cells and origins of replication occur every 300 kbp. Assume also that human DNA polymerases are highly processive and only two molecules of DNA polymerase are needed per replication fork. How long would it take to replicate the entire diploid human genome? How many molecules of DNA polymerase does each cell need to carry out this task?
- Heteroduplex DNA Formation in Recombination** From the information in Figures 28.17 and 28.18, diagram the recombinational event leading to the formation of a heteroduplex DNA region within a bacteriophage chromosome.
- Homologous Recombination, Heteroduplex DNA, and Mismatch Repair** Homologous recombination in *E. coli* leads to the formation of regions of heteroduplex DNA. By definition, such regions contain mismatched bases. Why doesn't the mismatch repair system of *E. coli* eliminate these mismatches?
- RecA:DNA Nucleoprotein Helix/B-DNA Comparison** If RecA protein unwinds duplex DNA so that there are about 18.6 bp per turn, what is the change in $\Delta\phi$, the helical twist of DNA, compared with its value in B-DNA?
- Terminology** Determine whether the following proteins or protein complexes play a role in DNA replication (prokaryotic and eukaryotic), DNA repair (including stalled replication forks), or DNA recombination (including Ig recombination) & transposition: Rad54; Cdc45; DUE; Ku70/80; XPA protein; S-CDK; RecA; photolyase; Sld2 and Sld3; PriA; geminin; Rad51; Cdc6; DNA glycosylase; Dpb11; SSB; GINS complex; RAG1 and RAG2; RuvC; Tus; DNA ligase 4; BRCA; MCM proteins.
- Resolution of a Holliday Junction by Resolvase** Diagram a Holliday junction between two duplex DNA molecules, and show how the action of resolvase might give rise to either patch- or splice recombinant DNA molecules.
- Chemical Mutagenesis of DNA Bases** Show the nucleotide sequence changes that might arise in a dsDNA (coding strand segment GCTA) upon mutagenesis with (a) HNO₂, (b) bromouracil, and (c) 2-aminopurine.

- 17. Transitions and Transversions** Consider the original DNA sequence shown and the versions of this sequence (a–d) underneath. Indicate where a transition and/or a transversion has occurred in each version.

- 18. Transposons as Mutagens** Transposons can act as mutagenic agents. How do they do this?
- 19. Recombination in Immunoglobulin Genes** If recombination between a V_K and J_K gene formed a CCA codon at codon 95 (Figure 28.41), which amino acid would appear at this position?
- 20. IgG in ER** (Integrates with Chapter 7) Post-synthesis, IgG proteins are transported to the endoplasmic reticulum for further processing. From a review of Figure 28.36, give at least one type of processing IgG proteins undergo in the ER. Discuss potential roles for IgG processing in the ER.
- 21. Helicase Unwinding of the *E. coli* Chromosome** Hexameric helicases, such as DnaB, the MCM proteins, and papilloma virus E1 helicase (illustrated in Figures 16.22 to 16.26), unwind DNA by passing one strand of the DNA duplex through the central pore, using a mechanism based on ATP-dependent binding interactions with the bases of that strand. The genome of *E. coli* K12 consists of 4,686,137 nucleotides. Assuming that DnaB functions like papilloma virus E1 helicase, from the information given in Chapter 16 on ATP-coupled DNA unwinding, calculate how many molecules of ATP would be needed to completely unwind the *E. coli* K12 chromosome.
- 22. Translesion DNA Polymerase IV Experiment** Asako Furukohri, Myron F. Goodman, and Hisaji Maki wanted to discover how the translesion

DNA polymerase IV takes over from DNA polymerase III at a stalled replication fork (see *Journal of Biological Chemistry* **283**:11260–11269, 2008). They showed that DNA polymerase IV could displace DNA polymerase III from a stalled replication fork formed in an in vitro system containing DNA, DNA polymerase III, the β -clamp, and SSB. Devise your own experiment to show how such displacement might be demonstrated. (Hint: Assume that you have protein identification tools that allow you to distinguish easily between DNA polymerase III and DNA polymerase IV.)

- 23. Functional Consequences of Y-Family DNA Polymerase Structure** The eukaryotic translesion DNA polymerases fall into the Y family of DNA polymerases. Structural studies reveal that their fingers and thumb domains are small and stubby (see Figure 28.10). In addition, Y-family polymerase active sites are more open and less constrained where base pairing leads to selection of a dNTP substrate for the polymerase reaction. Discuss the relevance of these structural differences. Would you expect Y-family polymerases to have 3'-exonuclease activity? Explain your answer.
- 24. The Eukaryotic Cell Cycle and Checkpoints** Figure 28.11 depicts the eukaryotic cell cycle. Many cell types exit the cell cycle and don't divide for prolonged periods, a state termed G_0 ; some, for example neurons, never divide again.
- In what stage of the cell cycle do you suppose a cell might be when it exits the cell cycle and enters G_0 ?
 - The cell cycle is controlled by checkpoints, cyclins, and CDKs. Describe how biochemical events involving cyclins and CDKs might control passage of a dividing cell through the cell cycle.
- 25. Recombination Between V_K and J_K Genes and IgG Amino Acid Sequence Diversity** Figure 28.41 gives some examples of recombination in IgG codons 95 and 96, as specified by the V_K and J_K genes. List the codon possibilities and the amino acids encoded if recombination occurred in codon 97. Which of these possibilities is less desirable?

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net>.)

- Using the PSafe module for reverse transcriptase, describe the function of the two magnesium ions in the active site.
- Using the PSafe module for Replication Factor C (RFC), describe how RFC interacts with PCNA to recognize the primer-template junction during DNA replication.

Think-Pair-Share Question

Detecting Mutagens and Their Effects on DNA In broad terms, describe experiments designed to evaluate whether a particular environmental factor (chemical, radiation, etc.) induces mutations in DNA. Focus on detecting mutations that 1) affect DNA in general or 2) affect a specific gene. (Review chapters 11 and 12 for some techniques related to DNA or genome analysis.)

Transcription and the Regulation of Gene Expression

Now that we have all this useful information, it would be nice to do something with it.

From the *Unix Programmer's Manual*

The Rosetta Stone, from Fort St. Julien, El-Rashid (Rosetta) 196 BC (see also 138997), Egyptian Ptolemaic Period (332-30 BC) British Museum, London, UK/The Bridgeman Art Library

◀ The Rosetta stone, inscribed in 196 B.C. The writing on the Rosetta stone is in three forms: hieroglyphs, Demotic (the conventional Egyptian script of the time), and Greek (the Greeks ruled Egypt in 196 B.C.). The Rosetta stone represents the transcription of hieroglyphic symbols into two living languages. Shown here is part of the interface where hieroglyphs and Demotic meet.

Essential Question

Expression of the information encoded in DNA depends on transcription of that information into RNA. **How are the genes of prokaryotes and eukaryotes transcribed to form RNA?**

All cells contain three major classes of RNA that participate in protein synthesis: messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA) (see Chapter 10). Further, all RNAs are synthesized from DNA templates by **DNA-dependent RNA polymerases** in the process known as **transcription**. However, only mRNAs direct the synthesis of proteins. Protein synthesis occurs via the process of **translation**, wherein the instructions encoded in the sequence of bases in mRNA are translated into a specific amino acid sequence by ribosomes, the workbenches of polypeptide synthesis.

Transcription is tightly regulated in all cells. In prokaryotes, only 3% or so of the genes are undergoing transcription at any given time. The metabolic conditions and the growth status of the cell dictate which gene products are needed at any moment. Similarly, differentiated eukaryotic cells express only a small percentage of their genes in fulfilling their biological functions, not the full genetic potential encoded in their chromosomes.

29.1 | How Are Genes Transcribed in Bacteria?

In prokaryotes, virtually all RNA is synthesized by a single species of DNA-dependent RNA polymerase. The only exception is the short RNA primers formed by primase during DNA replication. RNA polymerase uses ribonucleoside 5'-triphosphates (ATP, GTP, CTP, and UTP, represented generically as NTPs) as substrates, linking them in an order specified by base pairing with a DNA template:

Conventions Used in Expressing the Sequences of Nucleic Acids and Proteins

Certain conventions are useful in tracing the course of information transfer from DNA to protein. The strand of duplex DNA that is read by RNA polymerase is termed the **template strand**. Thus, the strand that is not read is the **nontemplate strand**. Because the template strand is read by the RNA polymerase moving 3'→5' along it, the RNA product, called the **transcript**, grows in the 5'→3' direction (see accompanying figure). Note that the nontemplate strand has a nucleotide sequence and direction identical to those of the RNA transcript, except that the transcript has U residues in place of T. Portions of the RNA transcript may eventually be translated into the amino acid sequence of a protein by a process in which successive triplets of bases (termed **codons**), read 5'→3', specify a particular amino acid. Polypeptide chains are synthesized in the N→C direction, and the 5'-end of mRNA encodes the N-terminus of the protein.

By convention, when the order of nucleotides in DNA is shown as a single strand, it is the 5'→3' sequence of nucleotides in the nontemplate strand that is presented. Consequently, if convention

is followed, DNA sequences are written in terms that correspond directly to mRNA sequences, which correspond in turn to the amino acid sequences of proteins as read beginning with the N-terminus.

The enzyme moves along a DNA strand in the 3'→5' direction, selecting the appropriate NTP by base-pairing rules, and linking its 5'-phosphate to the 3'-OH of the previous residue. Thus, the RNA chain grows 5'→3' during transcription, just as DNA chains do during replication. Subsequent hydrolysis of the PP_i product by the pyrophosphatases present in all cells makes the polymerase reaction thermodynamically favorable.

29.1a Bacterial RNA Polymerases Use Their Sigma Subunits to Identify Sites Where Transcription Begins

Transcription is initiated in bacteria by **RNA polymerase holoenzyme**, a complex multimeric protein (about 400 kDa) large enough to be visible in the electron microscope. Its subunit composition is $\alpha_2\beta\beta'\sigma$. After two α -subunits (35 kDa each) dimerize, one recruits β and the other recruits β' to form the clawlike core polymerase structure (Figure 29.1). The two largest subunits, β' (171 kDa) and β (124 kDa), perform most of the enzymatic functions. The β -subunit forms most of the upper jaw of the claw (*cyan* in Figure 29.1) and contains the catalytic Mg²⁺-binding site; β' forms the lower jaw (*yellow* in Figure 29.1). DNA passes through a 2.7-nm channel between the jaws of the claw. Nucleotide substrates reach the catalytic center through a secondary channel entering on the back side of the enzyme. Binding of the σ -subunit to β' allows the RNA polymerase to recognize different DNA sequences that act as **promoters**. A number of related promoter-recognizing proteins, the **sigma (σ) factors**, can serve as the σ -subunit. Promoters are nucleotide sequences that identify the location of *transcription start sites*, where transcription begins. Both β and β' contribute to formation of the catalytic site for RNA synthesis. Dissociation of the σ -subunit from the holoenzyme leaves the **core polymerase** ($\alpha_2\beta\beta'$), which can transcribe DNA into RNA but is unable to recognize promoters and initiate transcription. Bacteriophage T7 expresses a simpler (monomeric) RNA polymerase (Figure 29.2) that shares the functional characteristics of prokaryotic RNA polymerases.

29.1b The Process of Transcription Has Four Stages

Transcription can be divided into four stages: (1) binding of RNA polymerase holoenzyme at promoter sites, (2) initiation of polymerization, (3) chain elongation, and (4) chain termination.

Figure 29.1 Structure of the core RNA polymerase $\alpha_2\beta\beta'$ (PDB id = 2O5I) from the eubacterium *Thermus thermophilus*. The template DNA strand is shown in green, the nontemplate DNA strand in blue, and the RNA transcript in hot pink. The two α chains are orange, the β chain is cyan, and the β' chain is yellow. The active-site Mg^{2+} is shown as a red sphere.

Binding of RNA Polymerase to Template DNA The process of transcription begins when the σ -subunit of RNA polymerase recognizes a promoter sequence (Figure 29.3), and RNA polymerase holoenzyme and the promoter form a **closed promoter complex** (Figure 29.3, Step 2). At this stage, the RNA polymerase-DNA interaction is referred to as the *closed* promoter complex because the dsDNA has not yet been opened (unwound) so that the RNA polymerase can read the base sequence of the DNA template strand and transcribe it into a complementary RNA sequence.

Once the closed promoter complex is established, the RNA polymerase holoenzyme unwinds about 14 base pairs of DNA (base pairs located at positions -12 to $+2$, relative to the transcription start site), forming the very stable **open promoter complex** (Figure 29.3, Step 3). In this complex, the β' subunit has closed around the DNA, forming a clamp. This clamp remains closed during transcription initiation and elongation. Promoter sequences can be identified *in vitro* by **DNA footprinting** (see a Deeper Look box on page 1037): RNA polymerase holoenzyme is bound to a putative promoter sequence in a DNA duplex, and the DNA-protein complex is treated with DNase I. DNase I cleaves the DNA at sites not protected by bound protein, and the set of DNA fragments left after DNase I digestion reveals the promoter (by definition, the promoter is the RNA polymerase holoenzyme binding site).

RNA polymerase binding typically protects a nucleotide sequence spanning the region from -70 to $+20$, where the $+1$ position is defined as the **transcription start site**: the base in the nontemplate DNA strand that is identical with the first base in the RNA transcript. The next base, $+2$, specifies the second base in the transcript. Nontemplate strand bases in the $5'$, or minus, direction from the transcript start site are numbered -1 , -2 , and so on. (Note that there is no zero.) Nontemplate nucleotides in the minus direction are said to lie **upstream** of the transcription start site, whereas nucleotides in the $3'$, or plus, direction are **downstream** of the transcription start site. The transcript start site on the template strand is usually a pyrimidine, so most transcripts begin with a purine. RNA polymerase binding protects 90 bp of DNA, equivalent to a distance of

Figure 29.2 Bacteriophage T7 RNA polymerase (PDB id = 1MSW) in the act of transcription. T7 RNA polymerase is a 99-kDa monomeric protein. The DNA is shown entering the enzyme from the right. The template strand is green, the nontemplate strand is blue, the RNA transcript is hot pink.

Figure 29.3 Sequence of events in the initiation and elongation phases of transcription as it occurs in prokaryotes. Nucleotides in this region are numbered with reference to the base at the transcription start site, which is designated +1.

30 nm along B-DNA. Because RNA polymerase is only 16 nm in its longest dimension, the DNA must be wrapped around the enzyme.

Properties of Bacterial Promoters Promoters recognized by the principal σ factor, σ^{70} , serve as the paradigm for prokaryotic promoters. These promoters vary in size from 20 to 200 bp but typically consist of a 40-bp region located on the 5'-side of the transcription start site. Within the promoter are two **consensus sequence elements**. A **consensus sequence** can be defined as the bases that appear with highest frequency at each position when a series of sequences believed to have common function is compared. The two promoter consensus sequence elements are the **Pribnow box**¹ near -10, whose consensus sequence is the hexameric TATAAT, and a sequence in the **-35 region** containing

¹Named for David Pribnow, who, along with David Hogness, first recognized the importance of this sequence element in transcription.

DNA Footprinting—Identifying the Nucleotide Sequence in DNA Where a Protein Binds

DNA footprinting is a widely used technique to identify the nucleotide sequence within DNA where a specific protein binds, such as the promoter sequence(s) bound by RNA polymerase holoenzyme. In this technique, the protein is incubated with a labeled (*) DNA fragment containing the nucleotide sequence where the protein is believed to bind. (The DNA fragment is labeled at only one end.) Then, a DNA cleaving agent, such as DNase I, is added to the solution containing the DNA-protein complex. DNase I cleaves the DNA backbone in exposed regions—that is, wherever the presence of the DNA-binding protein does not prevent DNase I from binding. A control sample containing only DNA, with no DNA-binding proteins, is also treated with DNase I. When these DNase I digests are analyzed by gel electrophoresis, the set of labeled fragments from the DNA:protein complex show a different electrophoretic pattern than the labeled fragments from the control DNA set. The absence of certain fragments in the digest of the DNA-protein complex reveals the location of the protein-binding site on the DNA (see accompanying figure).

the hexameric consensus TTGACA (Figure 29.4). The Pribnow box and the -35 region are separated by about 17 bp of nonconserved sequence. RNA polymerase holoenzyme uses its σ -subunit to bind to the conserved sequences, and the more closely the -35 region sequence corresponds to its consensus sequence, the greater is the efficiency of transcription of the gene. The highly expressed *rrn* genes in *E. coli* that encode rRNA have a third sequence element in their promoters, the **upstream element (UP element)**, located about 20 bp immediately upstream of the -35 region. (Transcription from the *rrn* genes accounts for more than 60% of total RNA synthesis in rapidly growing *E. coli* cells.) The σ -subunit recognizes the -10 and -35 elements, but the C-terminal domains (CTD) of the α -subunits of RNA polymerase recognize and bind the UP element.

In order for transcription to begin, the DNA duplex must be opened so that RNA polymerase has access to single-stranded template. The efficiency of initiation is inversely proportional to the melting temperature, T_m , in the Pribnow box, suggesting that the A:T-rich nature of this region is aptly suited for easy melting of the DNA duplex and creation of the open promoter complex (see Figure 29.3). Negative supercoiling facilitates transcription initiation by favoring DNA unwinding.

The RNA polymerase σ -subunit is directly involved in melting the dsDNA. Interaction of the σ -subunit with the nontemplate strand maintains the open complex formed between RNA polymerase and promoter DNA, with the σ -subunit acting as a sequence-specific single-stranded DNA-binding protein. Association of the σ -subunit

Figure 29.4 The nucleotide sequences of representative *E. coli* promoters. (In accordance with convention, these sequences are those of the nontemplate strand where RNA polymerase binds.) Consensus sequences for the -35 region, the Pribnow box, and the initiation site are shown at the bottom. The numbers represent the percent occurrence of the indicated base. (Note: The -35 region is only roughly 35 nucleotides from the transcription start site; the Pribnow box [the -10 region] likewise is located at approximately position -10.) In this figure, sequences are aligned relative to the Pribnow box. The purple-shaded box at the right shows that in 51% of the genes, A is at the +1 site and G is there in 42%. Further, C is at the -1 position in 55% of the genes and T is at the +2 position in 48% of the genes.

with the nontemplate strand stabilizes the open promoter complex and leaves the bases along the template strand available to the catalytic site of the RNA polymerase.

Initiation of Polymerization Unlike DNA polymerase, RNA polymerase does not require a primer: It can catalyze the de novo synthesis of polynucleotides. RNA polymerase has two binding sites for NTPs: the initiation site and the elongation site. The first nucleotide binds at the initiation site, base-pairing with the +1 base exposed within the *open promoter complex* (see Figure 29.3, Step 4). The second incoming nucleotide binds at the elongation site, base-pairing with the +2 base. The ribonucleotides are then covalently linked when the 3'-O of the first nucleotide makes a phosphoester bond with the α -phosphorus atom of the second nucleotide, and PP_i is eliminated. Note that the 5'-end of the transcript starts out with a triphosphate attached to it. Movement of RNA polymerase along the template strand (*translocation*) to the next base prepares the RNA polymerase to add the next nucleotide (see Figure 29.3, Step 5). Once an oligonucleotide 9 to 12 residues long has been formed, the σ -subunit dissociates from RNA polymerase, signaling the completion of initiation (see Figure 29.3, Step 6). The core RNA polymerase is highly processive and goes on to synthesize the remainder of the mRNA.

Careers in Chemistry

Dr. Elsa Pao

Dr. Elsa Pao is an optometrist with her own practice. She received her B.S. in Nutritional Science and Clinical Dietetics from UC Berkeley before earning her Doctor of Optometry from the Southern California School of Optometry in Fullerton, CA. During her career, she has diagnosed brain tumors and acted as a principal investigator for clinical trials in her field.

Of all her accomplishments in her field, Dr. Pao values her relationships with her clients and caring for entire families across generations. She feels she had to work harder to overcome the challenges an immigrant faces in the United States and credits her dedicated study of math and science with affording her the opportunity to live a secure and independent life as a contributing member of her community.

As the core RNA polymerase progresses, advancing the 3'-end of the RNA chain, the DNA duplex is unwound just ahead of it. About 12 base pairs of the growing RNA remain base-paired to the DNA template at any time, with the RNA strand becoming displaced as the DNA duplex rewinds behind the advancing RNA polymerase.

Chain Elongation Once a short oligonucleotide chain has been synthesized, the σ -subunit dissociates, and elongation of the RNA transcript is catalyzed by the *core polymerase* that remains. The accuracy of transcription is such that about once every 10^4 nucleotides, an error is made and the wrong base is inserted. Because many transcripts are made per gene and most transcripts are smaller than 10 kb, this error rate is acceptable.

Two possibilities can be envisioned for the path of the growing RNA chain. In one, the RNA chain is wrapped around the DNA as the RNA polymerase follows the template strand around the axis of the DNA duplex, but this possibility seems unlikely due to its potential for tangling the nucleic acid strands (Figure 29.5a). In reality, transcription involves supercoiling of the DNA, so positive supercoils are created ahead of the transcription bubble and negative supercoils are created behind it (Figure 29.5b). To prevent torsional stress from inhibiting transcription, gyrases introduce negative supercoils (and thereby remove positive supercoils) ahead of RNA polymerase. To compensate, topoisomerases remove negative supercoils behind the DNA segment undergoing transcription (Figure 29.5b).

Chain Termination Two types of transcription termination mechanisms operate in bacteria: one that is dependent on a specific ring-shaped motor protein called **Rho termination factor** (for the Greek symbol, ρ) and another, **intrinsic termination**, that is Rho-independent. Intrinsic termination is determined by specific sequences in the DNA called **termination sites**. These sites are not indicated by particular bases showing where transcription halts. Instead, they consist of three structural features whose base-pairing possibilities lead to termination:

1. Inverted repeats, which are typically G:C-rich, so a stable *stem-loop structure* can form in the transcript via intrachain base-pairing (Figure 29.6)
2. A nonrepeating segment that punctuates the inverted repeats
3. A run of six to eight As in the DNA template, coding for Us in the transcript

Termination then occurs as follows: A G:C-rich stem-loop structure, or hairpin, forms in the transcript. The hairpin apparently causes the RNA polymerase to pause, whereupon the A:U base pairs between the transcript and the DNA template strand are

Figure 29.5 Supercoiling versus transcription. **(a)** If the RNA polymerase followed the template strand around the axis of the DNA duplex, no supercoiling of the DNA would occur but the RNA chain would be wrapped around the double helix once every 10 bp. This possibility seems unlikely because it would be difficult to untangle the transcript from the DNA duplex. **(b)** Alternatively, gyrases and topoisomerases could remove the torsional stresses induced by transcription.

Figure 29.6 The termination site for the *E. coli trp* operon (the *trp* operon encodes the enzymes of tryptophan biosynthesis). The inverted repeats give rise to a stem-loop, or hairpin, structure ending in a series of U residues.

displaced through formation of somewhat more stable A:T base pairs between the template and nontemplate strands of the DNA. The result is spontaneous dissociation of the nascent transcript from DNA.

The alternative mechanism of termination—Rho factor-dependent termination—is less common and mechanistically more complex. Rho factor is an ATP-dependent hexameric helicase (50-kDa subunits) that catalyzes the unwinding of RNA:DNA hybrid duplexes (or RNA:RNA duplexes). The rho factor recognizes and binds to C-rich regions in the RNA transcript. These regions must be unoccupied by translating ribosomes for rho factor to bind. Once bound, rho factor advances in the 5'→3' direction until it reaches an RNA polymerase stalled at a **Rho-dependent termination site** (a genomic site downstream from a C>G bubble, defined as a region rich in C residues and poor in G residues) (Figure 29.7). There, Rho mediates the release of the RNA transcript and the dissociation of RNA polymerase from the DNA.

Figure 29.7 The Rho factor mechanism of transcription termination. Rho factor (a) attaches to a recognition site on mRNA and (b) moves along it behind RNA polymerase. (c) When RNA polymerase pauses at the termination site, Rho factor unwinds the DNA:RNA hybrid in the transcription bubble, (d) releasing the nascent mRNA.

Figure 29.8 The general organization of operons. Operons consist of transcriptional control regions and a set of related structural genes, all organized in a contiguous linear array along the chromosome. The transcriptional control regions are the promoter and the operator, which lie next to, or overlap, each other, upstream from the structural genes they control. Operators may lie at various positions relative to the promoter, either upstream or downstream. Expression of the operon is determined by access of RNA polymerase to the promoter, and occupancy of the operator by regulatory proteins influences this access. Induction activates transcription from the promoter; repression prevents it.

29.2 | How Is Transcription Regulated in Bacteria?

In bacteria, genes encoding the enzymes of a particular metabolic pathway are often grouped adjacent to one another in a cluster on the chromosome. This pattern of organization allows all of the genes in the group to be expressed in a coordinated fashion through transcription into a **single polycistronic mRNA** encoding all the enzymes of the metabolic pathway. A **polycistronic mRNA** is a single RNA transcript that encodes more than one polypeptide. *Cistron* is a genetic term for a DNA region representing a protein; *Cistron* and *gene* are essentially equivalent terms.

A regulatory sequence lying adjacent to the DNA being transcribed determines whether transcription takes place. This sequence is termed the **operator** (Figure 29.8). The operator is located next to a promoter. Interaction of a **regulatory protein** with the operator controls transcription of the gene cluster by controlling access of RNA polymerase to the promoter. (Although this is the paradigm for bacterial gene regulation, it must be emphasized that many bacterial genes do not contain operators and are regulated in ways that do not involve protein; operator interactions.) Such co-expressed gene clusters, together with the operator and promoter sequences that control their transcription, are called **operons**.

29.2a Transcription of Operons Is Controlled by Induction and Repression

In bacteria, gene expression is often responsive to small molecules serving as signals of the nutritional or environmental conditions confronting the cell. Increased synthesis of enzymes in response to the presence of a particular substrate is termed **induction**. For example, lactose (Figure 29.9) can serve as both carbon and energy source for *E. coli*. Metabolism of lactose depends on hydrolysis into its component sugars, glucose and galactose, by the enzyme **β -galactosidase**. In the absence of lactose, *E. coli* cells contain very little β -galactosidase (less than 5 molecules per cell). However, lactose availability *induces* the synthesis of β -galactosidase by activating transcription of the ***lac* operon**. One of the genes in the *lac* operon, *lacZ*, is the structural gene for β -galactosidase. When its synthesis is fully induced, β -galactosidase can amount to almost 10% of the total soluble protein in *E. coli*. When lactose is removed from the culture, synthesis of β -galactosidase halts.

The alternative to induction—namely *decreased* synthesis of enzymes in response to a specific metabolite—is termed **repression**. For example, the enzymes of tryptophan biosynthesis in *E. coli* are encoded in the ***trp* operon**. If sufficient Trp is available to the growing bacterial culture, the *trp* operon is not transcribed, so the Trp biosynthetic enzymes are not made; that is, their synthesis is *repressed*. Repression of the *trp* operon

Lactose
(O- β -D-galactopyranosyl (1 $\rightarrow$ 4) β -D-glucopyranose)

Figure 29.9 The structure of lactose, a β -galactoside.

in the presence of Trp is an eminently logical control mechanism: If the end product of the pathway is present, why waste cellular resources making unneeded enzymes?

Induction and repression are two faces of the same phenomenon. In induction, a substrate activates enzyme synthesis. Substrates capable of activating synthesis of the enzymes that metabolize them are called **co-inducers**, or, often, simply **inducers**. Some substrate analogs can induce enzyme synthesis even though the enzymes are incapable of metabolizing them. These analogs are called **gratuitous inducers**. A number of thio-galactosides, such as **IPTG** (isopropyl β -thiogalactoside, Figure 29.10), are excellent gratuitous inducers of β -galactosidase activity in *E. coli*. In repression, a metabolite, typically an end product, depresses synthesis of its own biosynthetic enzymes. Such metabolites are called **co-repressors**.

29.2b The *lac* Operon Is a Paradigm of Operons

In 1961, François Jacob and Jacques Monod proposed the **operon hypothesis** to account for the coordinate regulation of related metabolic enzymes. The operon was considered to be the unit of gene expression, consisting of two classes of genes: the **structural genes** for the enzymes and **regulatory genes** that control expression of the structural genes. The two kinds of genes could be distinguished by mutation. Mutations in a structural gene would abolish one particular enzymatic activity, but mutations in a regulatory gene would affect all of the different enzymes under its control. Mutations of both kinds were known in *E. coli* for lactose metabolism. Bacteria with mutations in either the *lacZ* gene or the *lacY* gene (Figure 29.11) could no longer metabolize lactose—the *lacZ* mutants (*lacZ*[−] strains) because β -galactosidase activity was absent, the *lacY* mutants because lactose was no longer transported into the cell. Other mutations defined another gene, the *lacI* gene. *lacI* mutants were different because they both expressed β -galactosidase activity and immediately transported lactose, *without prior exposure to an inducer*. That is, a single mutation led to the expression of lactose metabolic functions independently of inducer. Expression of genes independently of regulation is termed **constitutive expression**. Thus, *lacI* had the properties of a regulatory gene. The *lac* operon includes the regulatory gene *lacI*; its promoter *p*; and three structural genes, *lacZ*, *lacY*, and *lacA*, with their own promoter *p_{lac}* and operator *O* (Figure 29.11).

Figure 29.11 The *lac* operon. The operon consists of two transcription units. In one unit, there are three structural genes, *lacZ*, *lacY*, and *lacA*, under control of the promoter, *p_{lac}*, and the operator *O*. In the other unit, there is a regulator gene, *lacI*, with its own promoter, *p_{lacI}*. *lacI* encodes a 360-residue, 38.6-kDa polypeptide that forms a tetrameric *lac* repressor protein. *lacZ* encodes β -galactosidase, a tetrameric enzyme of 116-kDa subunits. *lacY* is the β -galactoside permease structural gene, a 46.5-kDa integral membrane protein active in β -galactoside transport into the cell. The remaining structural gene encodes a lactose transacetylase, whose function might allow excess lactose to be transported out of the cell by a multidrug resistance permease that exports acetylated substrates.

29.2c *lac* Repressor Is a Negative Regulator of the *lac* Operon

The structural genes of the *lac* operon are controlled by **negative regulation**. That is, they are transcribed to give an mRNA unless turned off by the *lacI* gene product. This gene product is the ***lac* repressor**, a tetrameric protein (Figure 29.12). Unlike inducers and co-repressors, which are small molecules/metabolites, repressors are proteins. The *lac* repressor has an N-terminal DNA-binding domain; the rest of the protein functions in inducer binding and tetramer formation. In the absence of an inducer, *lac* repressor blocks *lac* gene expression by binding to the operator DNA site upstream from the *lac* structural genes. The *lac* operator is a palindromic DNA sequence (Figure 29.13). **Palindromes**, or inverted repeats, provide a twofold, or dyad, symmetry, a structural feature common at sites in DNA where proteins specifically bind. Despite the presence of *lac* repressor, RNA polymerase can still initiate transcription at the promoter (p_{lac}), but *lac* repressor blocks elongation of transcription, so initiation is aborted. In *lacI* mutants, the *lac* repressor is absent or defective in binding to operator DNA, *lac* gene transcription is

Figure 29.12 The mode of action of *lac* repressor. The structure of the *lac* repressor tetramer with bound IPTG (purple) is also shown (PDB id = 1LBH).

Figure 29.13 The nucleotide sequence of the *lac* operator. **(a)** This sequence comprises 36 bp showing nearly palindromic symmetry. The inverted repeats that constitute this approximate twofold symmetry are shaded in *rose*. **(b)** Position of the *lac* operator, relative to the transcription start site. The bases are numbered relative to the +1 start site for transcription. The G:C base pair at position +11 represents the axis of symmetry. In vitro studies show that bound *lac* repressor protects a 26-bp region from –5 to +21 against nuclease digestion. Bases that interact with bound *lac* repressor are indicated below the operator. Note the symmetry of protection at +1 through +4 TTAA to +18 through +21 AATT.

not blocked, and the *lac* operon is constitutively expressed. Note that *lacI* is normally expressed constitutively from its promoter, so *lac* repressor protein is always available to fill its regulatory role. About 10 molecules of *lac* repressor are present in an *E. coli* cell.

Derepression of the *lac* operon occurs when appropriate β -galactosides occupy the inducer site on *lac* repressor, causing a conformational change in the protein that lowers the repressor’s affinity for operator DNA. As a tetramer, *lac* repressor has four inducer binding sites, and its response to inducer shows cooperative allosteric effects. Thus, as a consequence of the inducer-induced conformational change, the inducer:*lac* repressor complex dissociates from the DNA, and RNA polymerase transcribes the structural genes (see Figure 29.12). Induction reverses rapidly: *lac* mRNA has a half-life of only 3 minutes, and once the inducer is used up through metabolism by the enzymes, free *lac* repressor reassociates with the operator DNA, transcription of the operon is halted, and any residual *lac* mRNA is degraded.

In the absence of inducer, *lac* repressor binds nonspecifically to duplex DNA with an association constant, K_A , of $2 \times 10^6 M^{-1}$ (Table 29.1) and to the *lac* operator DNA sequence with much higher affinity, $K_A = 2 \times 10^{13} M^{-1}$. Thus, *lac* repressor binds 10^7 times better to *lac* operator DNA than to any random DNA sequence. IPTG binds to *lac* repressor with an association constant of about $10^6 M^{-1}$. The IPTG:*lac* repressor complex binds to operator DNA with an association constant, $K_A = 2 \times 10^{10} M^{-1}$. Although this affinity is high, it is three orders of magnitude *less* than the affinity of inducer-free repressor for *lac* operator. There is no difference in the affinity of free *lac* repressor and *lac* repressor with IPTG bound for nonoperator DNA. The *lac* repressor apparently acts by binding to DNA and sliding along it, testing sequences in a one-dimensional search until it finds the *lac* operator. The *lac* repressor then binds there with high affinity until inducer causes this affinity to drop by three orders of magnitude (Table 29.1).

Table 29.1 The Affinity of *lac* Repressor for DNA*

DNA	Repressor	Repressor + Inducer
<i>lac</i> operator	$2 \times 10^{13} M^{-1}$	$2 \times 10^{10} M^{-1}$
All other DNA	$2 \times 10^6 M^{-1}$	$2 \times 10^6 M^{-1}$
Specificity†	10^7	10^4

*Values for repressor:DNA binding are given as association constants, K_A , for the formation of DNA:repressor complex from DNA and repressor.
†Specificity is defined as the ratio (K_A for repressor binding to operator DNA)/(K_A for repressor binding to random DNA).

29.2d CAP Is a Positive Regulator of the *lac* Operon

Transcription by RNA polymerase from some promoters proceeds with low efficiency unless assisted by an accessory protein that acts as a *positive regulator*. One such protein is **CAP**, or **catabolite activator protein**. Its name derives from the phenomenon of catabolite repression in *E. coli*. Catabolite repression is a global control that coordinates gene expression with the total physiological state of the cell: As long as glucose is available, *E. coli* catabolizes it in preference to any other energy source, such as lactose or galactose. Catabolite repression ensures that the operons necessary for metabolism of these alternative energy sources, that is, the *lac* and *gal* operons, remain repressed until the supply of glucose is exhausted. Catabolite repression overrides the influence of any inducers that might be present.

Catabolite repression is maintained until the *E. coli* cells become starved of glucose. Glucose starvation leads to activation of adenyl cyclase, and the cells begin to

A Deeper Look

Quantitative Evaluation of *lac* Repressor:DNA Interactions

The affinity of *lac* repressor for random DNA ensures that essentially all repressor is DNA bound. Assume that *E. coli* DNA has a single specific *lac* operator site for repressor binding and 4.64×10^6 base pairs. Assume also that any nucleotide sequence even one base out of phase with the operator constitutes a nonspecific binding site. Thus, there are 4.64×10^6 nonspecific sites for repressor binding.

The binding of repressor to DNA is given by the association constant, K_A :

$$K_A = \frac{[\text{repressor:DNA}]}{[\text{repressor}][\text{DNA}]}$$

where $[\text{repressor:DNA}]$ is the concentration of repressor:DNA complex, $[\text{repressor}]$ is the concentration of free repressor, and $[\text{DNA}]$ is the concentration of nonspecific binding sites. Rearranging gives the following:

$$\frac{[\text{repressor}]}{[\text{repressor:DNA}]} = \frac{1}{K_A[\text{DNA}]}$$

If the number of nonspecific binding sites is 4.64×10^6 , there are $(4.64 \times 10^6)/(6.022 \times 10^{23}) = 0.77 \times 10^{-17}$ moles of binding sites contained in the volume of a bacterial cell (roughly 10^{-15} liters). Therefore, $[\text{DNA}] = (0.77 \times 10^{-17})/(10^{-15}) = 0.77 \times 10^{-2} M$. Since $K_A = 2 \times 10^6 M^{-1}$ (Table 29.1),

$$\frac{[\text{repressor}]}{[\text{repressor:DNA}]} = \frac{1}{(2 \times 10^6)(0.77 \times 10^{-2})} = \frac{1}{(1.54 \times 10^4)}$$

So, the ratio of free repressor to DNA-bound repressor is 6.5×10^{-5} . Less than 0.01% of *lac* repressor is not bound to DNA, or, stated another way, *more than 99.99% of repressor is bound to DNA!* The behavior of *lac* repressor is characteristic of DNA-binding proteins. These proteins bind with low affinity to random DNA sequences, but with much higher affinity to their unique target sites (Table 29.1).

make cAMP. (In contrast, glucose uptake is accompanied by deactivation of adenylyl cyclase.) The action of CAP as a positive regulator is cAMP-dependent. cAMP is a small-molecule inducer for CAP, and cAMP binding enhances CAP's affinity for DNA. CAP, also referred to as **CRP** (for **cAMP receptor protein**), is a dimer of identical 22.5-kDa polypeptides. The N-terminal domains bind cAMP; the C-terminal domains constitute the DNA-binding site. Two molecules of cAMP are bound per dimer. The CAP-(cAMP)₂ complex binds to specific target sites near the promoters of operons (Figure 29.14). Binding of CAP-(cAMP)₂ to DNA causes the DNA to bend more than 80° (Figure 29.15). This CAP-induced DNA bending near the promoter

Figure 29.15 Binding of CAP-(cAMP)₂ induces a severe bend in DNA about the center of dyad symmetry at the CAP-binding site. The CAP dimer with two molecules of cAMP bound interacts with 27 to 30 base pairs of duplex DNA. Two α -helices of the CAP dimer insert into the major groove of the DNA at the dyad-symmetric CAP-binding site. The two cAMP molecules bound by the CAP dimer are indicated in yellow. Binding of CAP-(cAMP)₂ to its specific DNA site involves H bonding and ionic interactions between protein functional groups and DNA phosphates, as well as H-bonding interactions in the DNA major groove between amino acid side chains of CAP and DNA base pairs (PDB id = 1CGP).

Figure 29.14 The mechanism of catabolite repression and CAP action. Glucose instigates catabolite repression by lowering cAMP levels. cAMP is necessary for CAP binding near promoters of operons whose gene products are involved in the metabolism of alternative energy sources such as lactose, galactose, and arabinose. The binding sites for the CAP-(cAMP)₂ complex are consensus DNA sequences containing the conserved pentamer TGTGA and a less well conserved inverted repeat, TCANA (where N is any nucleotide).

assists RNA polymerase holoenzyme binding and closed promoter complex formation. Contacts made between the CAP–(cAMP)₂ complex and the α -subunit of RNA polymerase holoenzyme activate transcription.

29.2e Negative and Positive Control Systems Are Fundamentally Different

Negative and positive control systems operate in fundamentally different ways (although in some instances both govern the expression of the same gene). Genes under negative control are transcribed unless they are turned off by the presence of a repressor protein. Often, transcription activation is merely the release from negative control. In contrast, genes under positive control are expressed only if an active regulator protein is present. The *lac* operon illustrates these differences. The action of *lac* repressor is negative. It binds to operator DNA and blocks transcription; expression of the operon occurs only when this negative control is lifted through the release of the repressor. In contrast, regulation of the *lac* operon by CAP is positive: Transcription of the operon by RNA polymerase is stimulated by CAP's action as a positive regulator.

Operons can also be classified as **inducible**, **repressible**, or both, depending on how they respond to the small molecules that mediate their expression. Repressible operons are expressed only in the absence of their co-repressors. Inducible operons are transcribed only in the presence of small-molecule co-inducers (Figure 29.16).

29.2f The *araBAD* Operon Is Both Positively and Negatively Controlled by *AraC*

E. coli can use the plant pentose l-arabinose as sole source of carbon and energy. Arabinose is metabolized via conversion to D-xylulose-5-P (a pentose phosphate pathway intermediate and transketolase substrate [see Chapter 22]) by three enzymes encoded in the *araBAD* operon. Transcription of this operon is regulated by both catabolite

Figure 29.16 Control circuits governing the expression of genes. These circuits can be either negative or positive, inducible or repressible.

repression and arabinose-mediated induction. CAP functions in catabolite repression; arabinose induction is achieved via the product of the *araC* gene, which lies next to the *araBAD* operon on the *E. coli* chromosome. The *araC* gene product, the protein AraC, is a 292-residue protein consisting of an N-terminal domain (residues 1 to 170) that binds arabinose and acts as a dimerization motif and a C-terminal (residues 178 to 292) DNA-binding domain. (Proteins are often named for the genes encoding them. By convention, the name of the protein is capitalized but not italicized.) Regulation of *araBAD* by AraC is novel in that it acts both negatively and positively. The *ara* operon has three binding sites for AraC: *araO*₁, located at nucleotides –106 to –144 relative to the *araBAD* transcription start site; *araO*₂ (spanning positions –265 to –294); and *araI*, the *araBAD* promoter. The *araI* site consists of two half-sites; *araI*₁ (nucleotides –56 to –78) and *araI*₂ (–35 to –51). (The *araO*₁ site contributes minimally to *ara* operon regulation.)

The details of *araBAD* regulation are as follows: When AraC protein levels are low, the *araC* gene is transcribed from its promoter *p*_c (adjacent to *araO*₁) by RNA polymerase (Figure 29.17). *araC* is transcribed in the direction away from *araBAD*. When cAMP levels are low and arabinose is absent, an AraC protein dimer binds to two sites,

Figure 29.17 Regulation of the *araBAD* operon by the combined action of CAP and AraC protein. **(a)** The organization of the *araBCD* operon, the proteins it encodes, and their roles in the pathway of arabinose metabolism. **(b)** In the absence of L-arabinose, *araC* monomers bound at *araI*₁ and *araO*₂ dimerize, creating a loop in the *araBCD* operon that restricts transcription. **(c)** When L-arabinose is present and [cAMP] is high, L-arabinose binds to *araC*, causing release of *araO*₂, opening of the DNA loop and association of *araC* with *araI*₂. CAP-(cAMP)₂ binds to the CAP site located between *araO*₁ and *araI*. Protein-protein interactions between *araC*/L-arabinose, CAP-(cAMP)₂, and RNA polymerase result in transcription of the *araBCD* operon and metabolism of arabinose.

*araO*₂ and the *araI*₁ half-site, forming a DNA loop between them and restricting transcription of *araBAD* (Figure 29.17). In the presence of L-arabinose, the monomer of AraC bound to the *araO*₂ site is released from that site; it then associates with the unoccupied *araI* half-site, *araI*₂. L-Arabinose thus behaves as an allosteric effector that alters the conformation of AraC. In the arabinose-liganded conformation, the AraC dimer interacts with CAP-(cAMP)₂ to activate transcription by RNA polymerase. Thus, AraC protein is both a repressor and an activator.

Positive control of the *araBAD* operon occurs in the presence of L-arabinose and cAMP. Arabinose binding by AraC protein causes the release of *araO*₂, opening of the DNA loop, and association of AraC with *araI*₂. CAP-(cAMP)₂ binds at a site between *araO*₁ and *araI*, and together the AraC-(arabinose)₂ and CAP-(cAMP)₂ complexes influence RNA polymerase through protein:protein interactions to create an active transcription initiation complex. Supercoiling-induced DNA looping may promote protein:protein interactions between DNA-binding proteins by bringing them into juxtaposition.

29.2g The *trp* Operon Is Regulated Through a Co-Repressor–Mediated Negative Control Circuit

The *trp* operon of *E. coli* encodes the five polypeptides, *trpE* through *trpA* (Figure 29.18), that assemble into the three enzymes catalyzing tryptophan synthesis from chorismate (Chapter 25). Expression of the *trp* operon is under the control of **Trp repressor**, a dimer of 108-residue polypeptide chains. When tryptophan is plentiful, Trp repressor binds two molecules of tryptophan and associates with the *trp* operator that is located within the *trp* promoter. Trp repressor binding excludes RNA polymerase from the promoter, preventing transcription of the *trp* operon. When Trp becomes limiting, repression is lifted because Trp repressor lacking bound Trp (Trp apo-repressor) has a

Figure 29.18 The *trp* operon of *E. coli*. The *trp* operon is transcribed as a single polycistronic mRNA encoding the leader peptide (*trpL*), anthranilate synthase component I (*trpE*), anthranilate synthase component II (*trpD*), the bifunctional N-(5'-phosphoribosyl anthranilate isomerase/indole-3-glycerol phosphate synthase (*trpC*), tryptophan synthase β-subunit (*trpB*), and tryptophan synthase α-subunit (*trpA*).

lowered affinity for the *trp* promoter. Thus, the behavior of Trp repressor corresponds to a co-repressor–mediated, negative control circuit (see Figure 29.16). Trp repressor not only is encoded by the *trpR* operon but also regulates expression of the *trpR* operon. This is an example of **autogenous regulation (autoregulation)**: regulation of gene expression by the product of the gene.

29.2h Attenuation Is a Prokaryotic Mechanism for Post-Transcriptional Regulation of Gene Expression

In addition to repression, expression of the *trp* operon is controlled by **transcription attenuation**. Unlike the mechanisms discussed thus far, attenuation regulates transcription after it has begun. Charles Yanofsky, the discoverer of this phenomenon, defined attenuation as any regulatory mechanism that manipulates transcription termination or transcription pausing to regulate gene transcription downstream. In prokaryotes, transcription and translation are coupled (see Figure 10.19), and the translating ribosome is affected by the formation and persistence of secondary structures in the mRNA. In many operons encoding enzymes of amino acid biosynthesis, a transcribed 150- to 300-bp leader region is positioned between the promoter and the first major structural gene. Such regions encode a short leader peptide containing multiple codons for the pertinent amino acid. For example, the leader peptide of the *leu* operon has four leucine codons, the *trp* operon has two tandem tryptophan codons, and so forth (Figure 29.19). Translation of these codons depends on an adequate supply of the relevant aminoacyl-tRNA, which in turn rests on the availability of the amino acid. When tryptophan is scarce, the entire *trp* operon from *trpL* to *trpA* is transcribed to give a polycistronic mRNA. But, as [Trp] increases, more and more of the *trp* transcripts consist of only a 140-nucleotide fragment corresponding to the 5'-end of *trpL*. Tryptophan availability is causing premature termination of *trp* transcription, that is, transcription attenuation. Although attenuation occurs when tryptophan is abundant, attenuation is blocked when levels of tryptophan are low and little tryptophanyl-tRNA is available. The secondary structure of the 160-bp leader region transcript is the principal control element in transcription attenuation (Figure 29.20). This RNA segment includes the coding region for the 14-residue leader peptide. Three critical base-paired hairpins can form in this RNA: the **1·2 pause structure**, the **3·4 terminator**, and the **2·3 antiterminator**. The 1·2 pause, 3·4 terminator, and the 2·3 antiterminator represent mutually exclusive alternatives. A significant feature of this coding region is the tandem UGG tryptophan codons.

Transcription of the *trp* operon by RNA polymerase begins and progresses until position 92 is reached, whereupon the 1 : 2 hairpin is formed, causing RNA polymerase to pause in its elongation cycle. While RNA polymerase is paused, a ribosome begins to translate the leader region of the transcript. Translation by the ribosome releases the paused RNA polymerase, and transcription continues, with RNA polymerase and the ribosome moving in unison. As long as tryptophan is plentiful enough that tryptophanyl-tRNA^{Trp} is not limiting, the ribosome is not delayed at the two tryptophan codons and follows closely behind RNA polymerase, translating the message

Figure 29.19 Amino acid sequences of leader peptides in various amino acid biosynthetic operons regulated by attenuation. Color indicates amino acids synthesized in the pathway catalyzed by the operon’s gene products. (The *ilv* operon encodes enzymes of isoleucine, leucine, and valine biosynthesis.)

Figure 29.20 Alternative secondary structures for the leader region (*trpL* mRNA) of the *trp* operon transcript.

soon after it is transcribed. The presence of the ribosome atop segment 2 blocks formation of the 2•3 antiterminator hairpin, allowing the alternative 3•4 terminator hairpin to form (Figure 29.21). Stable hairpin structures followed by a run of Us are features typical of *Rho*-independent transcription termination signals, so the RNA polymerase perceives this hairpin as a transcription stop signal and transcription is terminated at this point. On the other hand, limiting levels of tryptophan and, hence, low availability of tryptophanyl-tRNA^{Trp} causes the ribosome to stall on segment 1. This leaves segment 2 free to pair with segment 3 and to form the 2•3 antiterminator hairpin in the transcript. Because this hairpin precludes formation of the 3•4 terminator, termination is prevented and the entire operon is transcribed. Thus, transcription attenuation is determined by the availability of tryptophanyl-tRNA^{Trp} and its transitory influence over the formation of alternative secondary structures in the mRNA.

29.2i DNA:Protein Interactions and Protein:Protein Interactions Are Essential to Transcription Regulation

Although a variety of control mechanisms regulate transcription, they share common features. First, **DNA:protein interactions** are a central feature in transcriptional control, and the DNA sites where regulatory proteins bind commonly display at least partial dyad symmetry or inverted repeats. Furthermore, DNA-binding proteins themselves are generally even-numbered oligomers (for example, dimers, tetramers) that have an innate, twofold rotational symmetry. Second, **protein:protein interactions** are an essential component of transcriptional activation. We see this latter feature in the activation of RNA polymerase by CAP-(cAMP)₂, for example. Third, the regulator proteins receive cues that signal the status of the environment (for example, Trp, lactose, cAMP) and act to communicate this information to the genome, typically via the medium of conformational changes and DNA:protein interactions.

29.2j Proteins That Activate Transcription Work Through Protein:Protein Contacts with RNA Polymerase

Although transcriptional control is governed by a variety of mechanisms, protein:protein interactions are a universal feature in transcriptional activation. Transcriptional activation can take place when a **transcriptional activator** protein [such

Figure 29.21 The mechanism of attenuation in the *trp* operon.

as CAP-(cAMP)₂] bound to DNA makes protein:protein contacts with RNA polymerase, and the degree of transcriptional activation is proportional to the strength of the protein:protein interaction. Generally speaking, a nucleotide sequence that provides a binding site for a DNA-binding protein can serve as an **activator site** if the DNA-binding protein bound there can interact with promoter-bound RNA polymerase. These interactions can involve either the α -, β -, β' -, or σ -subunits of RNA polymerase. Moreover, if the DNA-bound transcriptional activator makes contacts with two different components of RNA polymerase, there is a synergistic response, seen as markedly elevated transcription. Thus, transcriptional activation at specific genes relies on the presence of one or more activator sites where one or more transcriptional activator proteins can bind and make contacts with RNA polymerase bound at the promoter of the gene. Indeed, transcriptional activators may facilitate the recruitment and binding of RNA polymerase to the promoter. This general principle applies to transcriptional activation in both prokaryotic and eukaryotic cells. In eukaryotes, transcriptional activators typically have discrete domains of protein structure dedicated to DNA binding (DB domains) and transcriptional activation (TA domains).

29.2k DNA Looping Allows Multiple DNA-Binding Proteins to Interact with One Another

Because transcription must respond to a variety of regulatory signals, multiple proteins are essential for appropriate regulation of gene expression. These regulatory proteins are the sensors of cellular circumstances, and they communicate this information to the genome by binding at specific nucleotide sequences. However, DNA is virtually a one-dimensional polymer, and there is little space for a lot of proteins to bind at (or even near) a transcription initiation site. DNA looping permits additional proteins to convene at the initiation site and to exert their influence on creating and activating an RNA polymerase initiation complex (Figure 29.22). The number of participants in transcriptional regulation is greatly expanded by DNA looping. It is important to note that, although illustrations on a printed page are two-dimensional, DNA looping occurs in the three dimensions of space. If you conceptualize DNA looping as three-dimensional, it becomes apparent that

Figure 29.22 Formation of a DNA loop delivers DNA-bound transcriptional activator to RNA polymerase positioned at the promoter. Protein:protein interactions between the transcriptional activator and RNA polymerase activate transcription.

many different proteins, each bound to a DNA site remote from the others, could come together in three-dimensional space to recruit RNA polymerase to a promoter. Interactions between them creates the potential for exquisite control over expression of the gene.

29.3 | How Are Genes Transcribed in Eukaryotes?

Although the mechanism of transcription in bacteria and eukaryotes is fundamentally similar, transcription is substantially more complicated in eukaryotes. One significant difference is that the DNA of eukaryotes (and, interestingly, of Archaea as well) is wrapped around histones to form nucleosomes, and the nucleosomes are further organized into chromatin (see Chapter 11). Nucleosomes control gene expression by controlling access of the transcriptional apparatus to genes. The presence of nucleosomes represses gene expression. Two classes of transcriptional co-regulators are necessary to overcome nucleosome repression: (1) enzymes that covalently modify the nucleosome histone proteins and thereby loosen histone:DNA interactions and (2) ATP-dependent chromatin-remodeling complexes. However, gene activation depends not only on relief from nucleosome repression but also on interaction of RNA polymerase with the promoter. Only those genes activated by specific positive regulatory mechanisms are transcribed. A general understanding of transcription in eukaryotes depends on the understanding of:

- The three classes of RNA polymerase in eukaryotes: RNA polymerases I, II, and III
- The structure and function of RNA polymerase II, the mRNA-synthesizing RNA polymerase
- Transcription regulation, including:
 - General features of gene regulatory sequences: promoters, enhancers, and response elements
 - Transcription initiation by RNA polymerase II
 - The recruitment of RNA polymerase II to promoters and the assembly of transcription initiation complexes there.
 - Alleviation of the repressive effects of nucleosomes through chromatin remodeling and histone modifications.
- A general model for eukaryotic gene activation.

Below, we review these various features of eukaryotic transcription.

29.3a Eukaryotes Have Three Classes of RNA Polymerases

Eukaryotic cells have three classes of RNA polymerase, each of which synthesizes a different class of RNA. All three enzymes are found in the nucleus. **RNA polymerase I** is localized to the nucleolus and transcribes the major ribosomal RNA genes. **RNA polymerase II** transcribes most noncoding RNA genes and all protein-encoding genes, and thus it is responsible for the synthesis of mRNA. **RNA polymerase III** transcribes tRNA genes, the ribosomal RNA genes encoding 5S rRNA, and a variety of other small RNAs, including several involved in mRNA processing and protein transport.

All three RNA polymerase types are large, complex multimeric proteins (500 to 700 kDa), consisting of ten or more types of subunits. Although the three differ in overall subunit composition, they have several smaller subunits in common. Furthermore, all possess two large subunits (each 140 kDa or greater) having sequence similarity to the large β - and β' -subunits of *E. coli* RNA polymerase, indicating that the fundamental catalytic site of RNA polymerase is conserved among its various forms.

In addition to their different functions, the three classes of RNA polymerase can be distinguished by their sensitivity to α -amanitin (Figure 29.23), a bicyclic octapeptide produced by the poisonous mushroom *Amanita phalloides* (the destroying angel mushroom). α -Amanitin blocks RNA chain elongation. Although RNA polymerase I is resistant to this compound, RNA polymerase II is very sensitive and RNA polymerase III is less sensitive.

The existence of three classes of RNA polymerases acting on three distinct sets of genes means that there must be three distinct categories of promoters. Eukaryotic promoters are very different from prokaryotic promoters. All three eukaryotic RNA polymerases interact with their promoters via so-called **transcription factors**—DNA-binding proteins that recognize and accurately initiate transcription at specific promoter sequences. For RNA polymerase I, its templates are the rRNA genes. Ribosomal RNA genes are present in multiple copies. Optimal expression of these genes requires the first 150 nucleotides in the immediate 5'-upstream region.

RNA polymerase III interacts with transcription factors **TFIIIA**, **TFIIB**, and **TFIIC**. Interestingly, TFIIIA and/or TFIIC bind to specific recognition sequences that in some instances are located *within* the coding regions of the genes, not in the 5'-untranscribed region upstream from the transcription start site. TFIIB associates with TFIIIA or TFIIC already bound to the DNA. RNA polymerase III then binds to TFIIB to establish an initiation complex.

29.3b RNA Polymerase II Transcribes Protein-Coding Genes

As the enzyme responsible for the regulated synthesis of mRNA, RNA polymerase II has aroused greater interest than RNA polymerases I and III. RNA polymerase II must be capable of transcribing a great diversity of genes, yet it must carry out its function at any moment only on those genes whose products are appropriate to the needs of the cell in its ever-changing metabolism and growth. The RNA polymerase II enzymes from eukaryotes have been extensively characterized and show a marked similarity in structure, whether from yeast or humans (Figure 29.24). Both yeast and human RNA polymerase II consist of 12 different polypeptides, designated RPB1 through RPB12 and ranging in size from 192 to 8 kDa (Table 29.2). RPB3, RPB4, and RPB7 are unique to RNA polymerase II, whereas RPB5, RPB6, RPB8, and RPB10 are common to all three eukaryotic RNA polymerases.

RNA polymerases adopt a clawlike structure, grasping the DNA duplex as shown in Figure 29.24 for yeast RNA polymerase II. The DNA strands are unwound and separated, and the template strand enters the active site, where template-directed NTP substrate selection and NMP addition to the growing RNA transcript occur. NTP substrates access the active site through a channel below the active site. The DNA:RNA hybrid duplex exits at a right angle from the active site. As the hybrid duplex emerges from the protein structure, the RNA transcript is separated from the DNA template by RPB1 residue Phe²⁵², which acts as a wedge, splitting the position -10 RNA:DNA base pair (the base pair located 10 bases from the active site). The template strand is now free to re-anneal with the nontemplate strand to re-establish the dsDNA structure.

Figure 29.23 The structure of α -amanitin, one of a series of toxic compounds known as amatoxins that are found in the mushroom *Amanita phalloides*.

Figure 29.24 Structure of the yeast RNA polymerase II (PDB id = 1Y77). The template DNA strand is shown in *green*, the nontemplate DNA strand in *blue*. The RNA transcript (*hot pink*) is emerging at the bottom of the structure. RPB1, the largest polypeptide chain, is shown in *orange*, its C-terminal domain (CTD) is to the upper right. The active-site Mg^{2+} is shown as a *red* sphere in the center of the globular part of the enzyme. The atoms of a ribonucleotide substrate analog (GMPCP) are shown as *dark blue* spheres. RNA polymerase II is often referred to more simply as “RNA pol II.”

Table 29.2 Eukaryotic RNA Polymerase II Subunits			
Subunit	Size (kDa)	Features	Prokaryotic Homolog
RPB1†	192	YSPTSPS CTD	β'
RPB2	139	NTP binding	β
RPB3	35	Core assembly	α
RPB4	25	Promoter recognition	σ
RPB5	25	In polymerases I, II, and III	
RPB6	18	In polymerases I, II, and III	
RPB7	19	Unique to polymerase II	
RPB8	17	In polymerases I, II, and III	
RPB9	14	Nonessential	
RPB10	8	In polymerases I, II, and III	
RPB11	14		
RPB12	8	In polymerases I, II, and III	

†RPB stands for RNA polymerase B; RNA polymerases I, II, and III are sometimes called RPA, RPB, and RPC. Adapted from Myer, V. E., and Young, R. A., 1998. RNA polymerase II holoenzymes and subcomplexes. *The Journal of Biological Chemistry* **273**:27757–27760.

The RPB1 subunit has an unusual structural feature not found in prokaryotes: Its **C-terminal domain (CTD)** contains 27 repeats of the amino acid sequence YSPTSPS. The analogous subunit in human RNA polymerase II has this heptapeptide tandemly repeated 52 times. Note that the side chains of five of the seven residues in this repeat have —OH groups, endowing the CTD with considerable hydrophilicity *and* multiple sites for phosphorylation. A number of CTD kinases have been described, targeting different residues at different stages of the transcription process. The CTD domain may project more than 50 nm from the surface of RNA polymerase II. The phosphorylation possibilities represented by the YSPTSPS repeats within the CTD domain indicate the existence of a phosphorylation code that regulates mRNA synthesis and processing. In addition, an arginine residue (R⁸¹⁰) within the CTD can be methylated. Reversible methylation provides a selection mechanism for determining specific gene expression.

The CTD is essential to RNA polymerase II function. Only RNA polymerase II whose CTD is not phosphorylated can initiate transcription. However, transcription elongation proceeds only after protein phosphorylation within the CTD, suggesting that phosphorylation triggers the conversion of an initiation complex into an elongation complex. Such a mechanism would allow protein phosphorylation to regulate gene expression. Following termination of transcription, a phosphatase recycles RNA polymerase II to its unphosphorylated form. The CTD also plays a prominent role in orchestrating subsequent events in the transcription process. A multitude of additional proteins are essential to the formation of a translatable mRNA from the primary RNA polymerase II transcript; these proteins (described later in this chapter) include 5'-capping enzymes, splicing factors, and 3'-polyadenylation complexes. Recruitment of these proteins is dependent upon phosphorylation of Ser residues at positions 2 and 5 in the CTD heptapeptide repeat. Phosphorylation of these Ser residues is also a prerequisite for interactions between the CTD and the histone methyltransferases capable of remodeling nucleosomes into a transcriptionally permissive state.

29.3c The Regulation of Gene Expression Is More Complex in Eukaryotes

Transcription in eukaryotes, like the process in prokaryotes, has four stages: (1) promoter recognition and RNA polymerase II binding, (2) initiation, (3) elongation, and (4) termination. In eukaryotes, not only metabolic activity and cell division but also complex patterns of embryonic development and cell differentiation must be coordinated through the regulation of gene expression. All this coordinated regulation takes place in cells with a large quantity and sequence diversity of DNA. A typical mammalian cell has 1500 times as much DNA as an *E. coli* cell. The structural genes of eukaryotes are rarely organized in clusters akin to operons. Each eukaryotic gene typically possesses a discrete set of regulatory sequences appropriate to the requirements for regulating its transcription. Certain of these sequences provide sites of interaction for general transcription factors, whereas others endow the gene with great specificity in expression by providing targets for specific transcription factors.

29.3d Gene Regulatory Sequences in Eukaryotes Include Promoters, Enhancers, Insulators, and Silencers

Gene expression in eukaryotes is precisely regulated in a time-specific and cell-specific fashion. This regulation depends on coordinated interactions between proteins bound to DNA at **cis-regulatory elements (CREs)**, where *cis* denotes that the sequence element is on the same DNA molecule). Proteins that bind to specific CREs are termed **trans-acting factors**. Over 1600 gene-specific *trans*-acting factors are known, some of which are master transcription regulators that control genes whose expression determines cell type. CREs serve two purposes: (1) they identify promoters and transcription start sites, and (2) they act as platforms for binding of proteins that regulate and execute gene expression. CREs can be located at or near the **transcription start site (TSS)**, the nucleotide where transcription begins), or many thousands of base pairs away (distal CREs). Distal CREs include enhancers, insulators, and silencers, described below.

Efficient transcription of a protein-coding gene by RNA pol II depends on interactions with proteins bound at two distinct CRE sequences: sequences at or near the TSS, termed promoters, and more distantly located enhancers or silencers.

Promoters The promoters of eukaryotic protein-encoding genes are quite complex and variable. Their location is defined by the **core promoter**, a 50- to 100-bp DNA sequence within which lies the transcription start site (TSS). The core promoter serves as a platform for the assembly of the transcriptional apparatus, which is composed of RNA pol II, the **general transcription factors (GTFs)**, and other proteins. The assembled apparatus is megadaltons in size and occupies more than 100 bp around the TSS. About half of the core promoters for human protein-coding genes have an **Inr element**, while about 20% have a **TATA box**. The Inr element has the consensus sequence: *c/g/t-c/g/t-c-a-c/g/t-a/t*, with the bold **A** at position +1, defining the TSS. The TATA box (consensus sequence *T-A-T-A-A-T/A-A/T-A/G*) is usually located at position -31 from the TSS (Figure 29.25). The A:T-rich nature of the TATA box facilitates promoter melting and access of the transcription apparatus to the template strand. Another consensus sequence, the downstream promoter element (**DPE**; *A/G-G-A/T-C/T-A/C/G-T*) is often found in genes with an Inr motif but lacking a TATA box.

DPEs are embedded in the coding region, positioned at +28 to +33 relative to the TSS. The TATA box and Inr serve distinct sets of genes. The TATA box is typically a feature of tissue-specific genes, whereas the Inr is found in housekeeping genes: genes that encode proteins commonly present in all cells and essential to normal function. Housekeeping genes are typically transcribed at more-or-less steady levels, a state referred to as constitutive expression. Sequence elements other than the Inr motif, TATA box, and the DPE also occur as promoters for RNA pol II-transcribed genes, but less frequently. Such regulatory elements include short nucleotide sequences called **response elements (REs)** found near the promoter (the promoter-proximal region). Response elements bind certain specific transcription factors, such as proteins that trigger expression of a related set of genes in response to some physiological signal (hormone) or challenge (temperature shock).

Enhancers and silencers Enhancers and silencers are CREs located quite distant from the genes they regulate, ranging from several kilobase pairs to nearly a megabase pair in some human genes. The typical enhancer has a highly variable DNA sequence less than 100-bp-long and is located in a region of chromatin accessible to DNA-binding proteins because nucleosomes are sparse. These distantly located sequences are recognized by specific DNA-binding proteins that activate transcription above basal levels. The sequences where transcriptional activators bind are termed enhancers; silencers are sequences where transcriptional repressors bind. Searches through the human genome by the Encyclopedia of DNA Elements (ENCODE) Consortium reveal hundreds of thousands of putative enhancers and silencers, far more than the number of protein-coding genes.

As nucleotide sequences distant from the promoter that regulate transcription, enhancers and silencers share many attributes. The focus here is on enhancers and their

Figure 29.25 The Inr and TATA box in selected eukaryotic genes. The consensus sequence of a number of such promoters is presented in the lower part of the figure, the numbers giving the percent occurrence of various bases at the positions indicated.

activation of transcription, but silencers differ only in that they repress transcription. Enhancers (called upstream activation sequences, or UASs in yeast) assist transcription initiation. Enhancers differ from promoters in two fundamental ways. First, the location of enhancers relative to the transcription start site is not fixed. Enhancers may be several thousand nucleotides away from the promoter, and they act to enhance transcription initiation even if positioned downstream from the gene. Second, enhancer sequences are bidirectional in that they function in either orientation. That is, enhancers can be removed and then reinserted in the reverse sequence orientation without impairing their function. Like promoters, enhancers represent modules of consensus sequence. Enhancers are non-specific and they stimulate transcription from any promoter that happens to be in their vicinity. Nevertheless, enhancer function is dependent on recognition by a specific transcription factor. A specific transcription factor bound at an enhancer element stimulates transcription by interacting with promoter-bound RNA pol II. Looping of chromatin must happen in order for this interaction to occur. Repressors share these enhancer properties, except they repress rather than enhance transcription.

Insulators are DNA sequences of 0.1–1 kb that act in two ways: (1) to shield regions of chromatin active in transcription from inactive regions, and (2) to block an enhancer from stimulating transcription from a specific promoter. An insulator sequence can act as an enhancer blocker if it is located somewhere along the DNA sequence between the enhancer and the promoter.

Many genes are subject to multiple regulatory influences. Regulation of such genes is achieved through the presence of an array of different regulatory elements. The metallothionein gene is a good example (Figure 29.26). Metallothionein is a metal-binding protein that protects cells against metal toxicity by binding excess amounts of heavy metals and removing them from the cell. This protein is always present at low levels, but its concentration increases in response to heavy metal ions such as cadmium or in response to glucocorticoid hormones. The metallothionein gene promoter consists of two general promoter elements, namely, a TATA box and a GC box, two basal-level enhancers, four metal response elements (MREs, consensus sequence GCNCCCGGCNCN) where the MRE-binding factor MTF binds, and one glucocorticoid response element (GRE, consensus sequence TGGTACAAATGTTCT). When MTF binds heavy metals such as cadmium and zinc, it activates metallothionein gene expression by binding to the MREs. Similarly, in the presence of the stress hormone cortisol, growth hormone (GR) binds to the metallothionein gene GRE, activating transcription. Nearly 30% of human genes have a GRE. Elements like MRE and GRE function independently of one another; any one can activate transcription of the gene.

29.3e Transcription Initiation by RNA Polymerase II Requires TBP and the GTFs

Transcription initiation in eukaryotes proceeds through assembly of a **preinitiation complex (PIC)** on the promoter DNA. The PIC is composed of more than 100

Figure 29.26 The metallothionein gene possesses several constitutive elements in its promoter (the TATA and GC boxes) as well as specific response elements such as MREs and a GRE. The BLEs are elements involved in basal level expression (constitutive expression). TRE is a tumor response element activated in the presence of tumor-promoting phorbol esters such as TPA (tetradecanoyl phorbol acetate).

polypeptides, including RNA polymerase II, and a set of general transcription factors (**TFIIA**, **TFIIB**, **TFIID**, **TFIIE**, **TFIIF**, **TFIIH**, and **Mediator**, a 1.5-megadalton complex that mediates interactions between RNA pol II and proteins bound at distal CREs.) Although the core promoter can trigger transcription initiation, transcriptional activity is very weak without stimulatory input from distal enhancers (Table 29.3). **TFIID** consists of the **TBP** (the **TATA binding protein**), which directly recognizes the TATA box within the core promoter and a set of **TBP-associated factors (TAFs)**. This **TFIID** complex is the first GTF to recognize and bind to the promoter. **TBP** is the TATA box-binding protein that recognizes the promoter core, making contacts with the DNA minor groove and distorting and bending the DNA so that sequences upstream and downstream of the TAT box come into closer proximity (Figure 29.27a). **TFIIA** stimulates transcription by stabilizing the interaction of **TFIID** and the TATA box. **TFIIB** serves as a bridge between promoter-bound **TFIID** and RNA pol II, positioning the RNA polymerase active site over the promoter. **TFIIE** and **TFIIF** anchor the **TFIIH** CDK kinase module within the preinitiation complex, enhancing various aspects of promoter:PIC interaction. The helicase activity of **TFIIH** aids in creating the transcription bubble. The transition from a state where the PIC is situated over the promoter (the closed initiation complex) occurs when **TFIIB** opens the promoter and the template strand of DNA enters the pol II active-site cleft. The assemblage of RNA polymerase II and these other proteins at the promoter is now termed the **initiation complex**. However, transcription initiation in eukaryotes also requires **Mediator**, which in humans is composed of 26 subunits, the Med proteins.

The role of general transcription factor **TFIID** as a general cofactor for PIC formation can also be assumed by **SAGA**, a megacomplex of about 20 proteins. **SAGA** is named for its Spt, Ada, and Gen5 subunits. Spt is a family of proteins involved in gene expression; Ada is a histone acetyltransferase (HAT, a histone-modifying enzyme); and Gen5 is a lysine acetyltransferase (KAT). **SAGA** also contains TAF (TBP-associated proteins) subunits. Thus, **SAGA**, like **TFIID**, can recognize TATA boxes. **SAGA** is required for the expression of most RNA pol II-transcribed genes.

29.3f The Role of Mediator in Transcription Activation and Repression

Mediator serves as a dynamic bridge between gene-specific transcription co-activators bound to enhancers and the RNA pol II/GTF transcription machinery bound at the promoter. Once DNA becomes accessible through the action of chromatin remodeling complexes (discussed in the following sections), a transcription co-activator

Table 29.3 General Transcription Initiation Factors from Human Cells		
Factor	Number of Subunits	Function
TFIID		
TBP	1	Core promoter recognition (TATA); platform for recruitment of TFIIA, TFIIB, and TAFs
TAFs	13	Core promoter recognition (non-TATA elements); positive and negative regulatory functions; HAT (histone acetyltransferase) activity
TFIIA	2	Stabilization of TBP binding; stabilization of TAF–DNA interactions
TFIIB	1	Binding TBP, RNA polymerase II, and promoter DNA; determines transcription start site.
TFIIF	2	Promoter targeting of polymerase II; destabilization of nonspecific RNA polymerase II–DNA interactions
RNA pol II	13	Enzymatic synthesis of RNA; TFIIE recruitment
TFIIE	2	TFIIH recruitment; modulation of TFIIH helicase, ATPase, and kinase activities; promoter melting
TFIIH	10	Promoter melting using helicase activity; promoter clearance via CTD phosphorylation (2 subunits of TFIIH are Cyclin H and Cdk7, forming a cyclin-CDK pair)
TFIIS	34	Elongation

Figure 29.27 Protein complexes key to transcription initiation. **(a)** Model of the TATA-binding protein (TBP) in complex with a DNA TATA sequence (PDB id = 1YTB). The saddle-shaped TBP (gold) is unusual in that it binds in the minor groove of DNA, sitting on the DNA like a saddle on a horse. TBP binding pries open the minor groove, creating a 100° bend in the DNA axis and unwinding the DNA within the TATA sequence. The other subunits of the TFIID complex (see Table 29.3) sit on TBP, like a person on a saddle. All known eukaryotic genes (those lacking a TATA box as well as those transcribed by RNA polymerase I or III) rely on TBP. **(b)** Front and side views of the overall Mediator–RNA polymerase II–TFIIF complex, as obtained through cryo-electron microscopy, are shown as blue mesh. The location of RNA polymerase II is shown in red. The locations of TBP, TFIID, TFIIA, TFIIB, TFIIF, TFIIE, and TFIIH are indicated. The likely path of upstream and downstream promoter DNA is shown by the dashed line. This relationship of upstream to downstream DNA is established by the severe bend that TBP forces on the DNA. Adapted from Figure 5 in Bernecky, C., Grob, P., Ebmeier, C. C., Nogales, E. and Taatjes, D. J., 2011. Molecular architecture of the human Mediator–RNA polymerase II–TFIIF assembly. *PLoS Biology* 9:e1000603. doi:10.1371/journal.pbio.1000603. Part (a) courtesy of Dylan J. Taatjes. **(c)** The relationship of RNA pol II, the various GTFs, and the Mediator complex to the promoter in the Pre-Initiation Complex (PIC). Note that, in terms of this illustration, the downstream DNA is oriented up and thus, transcript would proceed in a vertical direction, as indicated by the arrow near IIH. Adapted from Box 3 in Allen, B. L., and Taatjes, D. J., 2015. The Mediator complex: a central integrator of transcription. *Nature Reviews Molecular Cell Biology* 16:155–166.

binds to an enhancer and recruits Mediator. Mediator has been described as the ultimate regulator of transcription since it integrates and communicates information from enhancers and transcription co-activators to RNA polymerase at the promoter.

Mediator is a crescent-shaped structure, with a head, middle, and tail (Figure 29.27c). The tail section recognizes and binds the transcription co-activator. Both the head region and the middle region of Mediator bind RNA pol II through interactions with its CTD, with the middle region also associating with general transcription factor TFIIE (Figure 29.28a).

Mediator is a global regulator essential to transcription of virtually every RNA pol II-dependent gene. It is even required for basal transcription of these genes. Mediator also displays HAT activity, which may aid in exposing promoters and subsequent binding of GTFs and RNA pol II. Taken together, the results indicate that Mediator provides a scaffold for assembly of the PIC at the promoter just prior to transcription initiation. Mediator apparently acts as the gateway by which RNA pol II gains access to the promoter.

Transition from the initiation to the elongation phase of RNA synthesis is triggered when TFIIH phosphorylates Ser⁵ within the RNA pol II CTD YSPTSPS heptapeptide repeats. CTD phosphorylation also leads to dissociation of Mediator from the TFIID:promoter complex, as well as escape of RNA pol II, allowing it to fully transcribe the gene. Two of the Mediator subunits are a cyclin-CDK pair (**CycC/CDK8** in yeast or **CCNC/CDK8** in vertebrates). The cyclin-CDK pair, together with subunits Med12 and Med13, form the four-subunit **Mediator kinase module**. This module phosphorylates the CTD as elongation commences. It also serves as a bridge between cell signaling, metabolism, and transcription through phosphorylation of TFs. Phosphorylation of CTD residue Tyr¹ during elongation blocks recruitment of transcription termination factors to pol II. During elongation, the rate of RNA synthesis by pol II is 30 nucleotides/s.

29.3g Mediator as a Repressor of Transcription

Mediator apparently acts in repression of transcription as well as activation. How can Mediator serve two opposing regulatory functions? Perhaps the explanation lies in the ability of a Mediator subcomplex (the MED12 and MED13 proteins, plus CycC/CDK8) to interact with co-repressor bound to a silencer (see Figure 29.28). This Mediator subcomplex is a repressive module that stabilizes Mediator in a conformation that cannot recruit RNA polymerase II to the promoter as long as CycC/Cdk8 is associated with the subcomplex (Figure 29.28b).

29.3h Chromatin-Remodeling Complexes and Histone-Modifying Enzymes Alleviate the Repression Due to Nucleosomes

The central structural unit of nucleosomes, the histone core octamer (see Figure 11.29), is constructed from the eight *histone-fold protein domains* of the eight various histone monomers comprising the octamer. Successive histone octamers are linked via histone H1, which is not part of the octamer. Each histone monomer in the core octamer has an unstructured N-terminal tail that extends outside the core octamer. Interactions between histone tails contributed by core histones in adjacent nucleosomes are an important influence in establishing the higher orders of chromatin organization. Activation of eukaryotic transcription is dependent on two sets of circumstances: (1) relief from the repression imposed by chromatin structure and (2) interaction of RNA polymerase II with the promoter and transcription regulatory proteins. Typically, nucleosome occupancy of enhancer and promoter regions is quite low, such that enhancers and promoters occur in nucleosome-free regions (NFRs). NFRs sometimes exist because of the intrinsic properties of certain DNA sequences or they may arise through the action of chromatin-remodeling complexes. If nucleosomes are present, relief from repression requires factors that can reorganize the chromatin and then alter the nucleosomes so that promoters become accessible to the transcriptional machinery. Two sets of factors are important here: **chromatin-remodeling complexes** that mediate ATP-dependent conformational (noncovalent) changes in nucleosome structure and **histone-modifying enzymes** that introduce covalent modifications into the N-terminal tails of the histone core octamer. Chromatin remodeling and histone modification are closely linked processes.

Figure 29.28 Simple models of Mediator in the regulation of eukaryotic gene transcription. In these models, conformational changes generated through enhancer or silencer recognition are propagated across the entire Mediator structure from tail to head. These conformational changes determine whether or not RNA pol II is bound and transcription occurs. **(a)** Mediator as a transcription activator. Mediator regions are highlighted in color: green for the tail, yellow for the middle, and red for the head. RNA polymerase II and the GTFs are blue. The transcription co-activator is orange. DNA is shown as a black line. **(b)** Mediator as a repressor. If Mediator interacts with a co-repressor (aqua) bound to a silencer and then binds the repressive subcomplex (MED12-MED13-CycC/CDK8), shown in pink here, it fails to recruit RNA polymerase II and the GTFs to the promoter, and expression from the promoter is repressed. (Adapted from Figures 1 and 2 in Björklund, S., and Gustafson, C. M., 2005. The yeast Mediator complex and its regulation. *Trends in Biochemical Sciences* 30:240–244.)

29.3i Chromatin-Remodeling Complexes Are Nucleic Acid–Stimulated Multisubunit ATPases

Chromatin-remodeling complexes are protein assemblies containing ATP-dependent enzymes that loosen the DNA:protein interactions in nucleosomes by sliding, ejecting, inserting, or otherwise restructuring core octamers. In the process, about 50 bp of DNA are peeled away from the edge of the nucleosome, creating a bulge that allows RNA pol II, GTFs, and other transcription factors to access the DNA. Chromatin-remodeling complexes always contain proteins of the SNF2 family of **DEAD/H-box**-containing, nucleic acid–stimulated ATPases. (DEAD signifies the Asp-Glu-Ala-Asp tetrapeptide signature sequence of this protein family; in some of these proteins, a histidine residue (H) replaces the second D in the box.) The various SNF2 chromatin remodelers are assigned to one of four subfamilies, SWI/SNF, ISWI, CHD, and INO80, based on their subunit composition and recognition of various histone modifications: SWI2 types with **bromodomains** that bind acetylated lysines, ISWI types that have separate domains for histone tail and linker DNA binding, CHD types with **chromodomains** that bind methylated lysines, and INO80 types with DNA-binding domains.

During the elongation phase of transcription, RNA pol II must pass by each nucleosome, and such passage is believed to result in the loss and regain of an H2A/H2B dimer from the core octamer. **FACT** (for **facilitates chromatin transcription**) is a heterodimer that acts on some nucleosomes to catalyze H2A/H2B removal and readdition; its activity is markedly increased by covalent modification of H2B Lys¹²⁰.

29.3j Covalent Modification of Histones

Chromatin is also remodeled through the action of enzymes that covalently modify side chains on histones within the core octamer. These modifications either directly decrease DNA:histone associations through disruption of electrostatic interactions or introduce substitutions that can recruit binding of new protein participants that disrupt DNA:histone interactions.

Initial events in transcriptional activation include acetyl-CoA–dependent acetylation of ϵ -amino groups on lysine residues in histone tails by histone acetyltransferases (HATs) (Figure 29.29). The histone transacetylases responsible are essential components of several megadalton-size complexes known to be required for transcription co-activation

Figure 29.29 A schematic diagram of the nucleosome illustrating the various covalent modifications on the N-terminal tails of histones. *acK* = acetylated lysine residue; *meK* = methylated lysine residue; *meR* = methylated arginine residue; *PS* = phosphorylated serine residue. The numbers indicate the positions of the amino acids in the amino acid sequences. Note the prevalence of modifiable sites, particularly acetyltable lysines, on the N-terminal tails of histones H2B, H3, and H4.

(*co-activation* in the sense that they are required along with RNA polymerase II and other components of the transcriptional apparatus). Examples of such complexes include the **TFIID** (some of whose TAF_{II}s have HAT activity), the **SAGA complex** (which also contains TAF_{II}s), and the **ADA complex**. *N*-Acetylation suppresses the positive charge in histone tails, diminishing their interaction with the negatively charged DNA.

Phosphorylation of Ser residues and methylation of Lys residues in histone tails also contribute to transcription regulation (Figure 29.29). Lysine methylation is catalyzed by *S*-adenosylmethionine-dependent **lysine methyltransferases (KMTs)** that can add one, two, or three methyl groups to the ϵ -amino groups of K residues. Mono-, di-, and trimethyllysines are referred to as Kme1, Kme2, or Kme3, respectively. **Lysine demethylases (KDMs)** are O₂-dependent enzymes that release the K methyl groups as either CO₂ or formaldehyde. The nomenclature for K methylation is straightforward: H3K4me3 signifies that lysine 4 on histone H3 is trimethylated. Attachment of small proteins to histone C-terminal lysine residues is an additional form of covalent modification found in nucleosomes. Collectively, these modifications create binding sites for proteins that modulate chromatin structure, such as the chromatin-remodeling complexes with bromodomains that interact specifically with acetylated lysine residues and chromodomains that bind to methylated lysine residues.

29.3k Covalent Modification of Histones Suggests the Existence of a Histone Code

A code based on histone-tail covalent modifications has been proposed as a mechanism that governs gene expression through selective recruitment of proteins. Proteins that cause chromatin compaction (heterochromatin formation) lead to repression; proteins giving easier access to DNA through relaxation of histone:DNA interactions enhance gene expression.

The prominent forms of histone covalent modification are lysine acetylation, lysine methylation, serine phosphorylation, lysine ubiquitination, and lysine sumoylation. The lysine residue at position 9 (K9) in the histone H3 amino acid sequence is methylated in **heterochromatin**, the compacted, repressed state of chromatin. In contrast, lysine 4 (K4) of histone H3 typically is methylated in chromatin where gene expression is active. Different proteins are recruited to these two methylated forms of histone H3. Methylated K9 recruits **heterochromatin protein 1 (HP1)**, which binds via its chromodomain. On the other hand, methylated K4 binds **CHD1**, a chromatin remodeling protein with two chromodomains. (CHD1 is an acronym for **chromodomain, helicase, DNA-binding**.) Ubiquitination of Lys¹²⁰ in the C-terminal tail of H2B favors methylation (and thus transcription activation), whereas ubiquitination of Lys¹¹⁹ in the C-terminal tail of H2A favors repression. Sumoylation of Lys residues tends to repress transcription, since sumoylation antagonizes acetylation.

29.3l Methylation and Phosphorylation Act as a Binary Switch that Regulates Chromatin Dynamics

As cells enter mitosis, the chromatin becomes condensed and histone H3 is not only methylated at K9 but also phosphorylated at the adjacent serine residue, S10. S10 phosphorylation triggers the dissociation of HP1 from the heterochromatin. Thus, phosphorylation of the residue neighboring K9 trumps HP1 binding. Similarly, phosphorylation of the threonine residue (T3) neighboring K4 in the histone H3 tail evicts CHD1 from its site on the methylated K4. Apparently, lysine methylation is the on position for the binary switch that recruits specific proteins to histone tails, and phosphorylation at a neighboring residue turns the switch to the off position by ejecting the bound proteins. There are at least 16 instances of serines or threonines immediately flanking lysine residues in the four histones that constitute the histone core octamer of the nucleosome. The methylation-phosphorylation binary switch may be a general phenomenon in the regulation of chromatin dynamics.

Histone Code or Histone Crosstalk? The effects of histone modifications are more complex and nuanced than the concept of a histone code might suggest. That is, the order of

addition and removal of histone modifications, as well as any preexisting modifications that might be present, are important in determining the transcriptional fate of the gene associated with the nucleosome. The influence of one modification on the likelihood of another is referred to as **histone crosstalk**. For example, phosphorylation of histone H3 S10 by different kinases at different times can affect whether or not acetylation of histone H3 occurs, and whether transcription ensues. Whether code or crosstalk, chromatin structure is dynamically regulated through the multiple possibilities for covalent modification of histone tails. As a consequence of these structural changes, transcription of a particular gene can be profoundly influenced.

29.3m Chromatin Deacetylation Leads to Transcription Repression

Deacetylation of histones is a biologically relevant matter, and enzyme complexes that carry out such reactions have been characterized. Known as **histone deacetylase complexes**, or **HDACs**, they catalyze the removal of acetyl groups from lysine residues along the histone tails, restoring the chromatin to a repressed state. Beyond these effects on transcription, histone modifications determine whether significant cellular events involving DNA allocation through mitosis and meiosis may occur.

29.3n Nucleosome Alteration and Interaction of RNA Polymerase II with the Promoter Are Essential Features in Eukaryotic Gene Activation

Gene activation (the initiation of transcription) can be viewed as a process requiring two principal steps: (1) alterations in nucleosomes (and thus, chromatin) that relieve the general repressed state imposed by chromatin structure, followed by (2) the interaction of RNA pol II and the GTFs with the promoter. Transcription activators initiate the process by recruiting chromatin-altering proteins (the *chromatin-remodeling complexes* and *histone-modifying enzymes* described previously). Once these alterations have occurred, promoter DNA is accessible to TBP:TFIID, the other GTFs, and RNA pol II. Transcription activation, however, requires communication between RNA pol II and the transcription activator for transcription to take place. Mediator fulfills this function. Mediator interacts with both the transcription activator *and* the CTD of RNA pol II. This Mediator bridge provides an essential interface for communication between enhancers and promoters, triggering RNA pol II to begin transcription. A simple model for transcription initiation is shown in Figure 29.30. Once transcription begins, Mediator is replaced by another complex called **Elongator**. *Elongator* has HAT subunits whose activity remodels downstream nucleosomes as RNA pol II progresses along the chromatin-associated DNA.

Promoter-Proximal Pausing The interactions described thus far emphasize regulation of gene expression at the level of RNA pol II recruitment to promoters. However, whole-genome analyses show that, for many genes, RNA pol II is already situated at promoters and appears to be paused there, awaiting signals that will activate the elongation phase of transcription. Thus, the expression of many genes may be regulated at the level of transcription elongation. What distinguishes between these possibilities? It seems that RNA polymerase pausing occurs more often on highly regulated genes because the promoters of these genes might otherwise be blocked by nucleosomes. Polymerase pausing is a mechanism to outcompete nucleosome occlusion of the promoter, so that the gene is poised for expression, as decided by regulatory signals. **Promoter-proximal pausing** by RNA pol II also provides a window of opportunity to ensure that proper regulation of gene expression has occurred and that RNA quality-control mechanisms can verify the fidelity of transcription.

Activation of Elongation Along with TFIIS and other transcription elongation factors, p-TEFb (positive transcription elongation factor b) brings an end to promoter-proximal pausing, allowing RNA pol II to move along the DNA template, elongating the transcript. The key event is the phosphorylation of Ser² in the RNA pol II CTD by the CDK kinase subunit of p-TEFb.

Figure 29.30 A model for the transcriptional regulation of eukaryotic genes. The DNA is a *green* ribbon wrapped around disclike nucleosomes. A specific transcription factor (TF, *pink*) is bound to a regulatory element (either an enhancer or silencer). RNA polymerase II and its associated GTFs (*blue*) are bound at the promoter. The N-terminal tails of histones are shown as wavy lines (*blue*) emanating from the nucleosome discs. A specific transcription factor that is a transcription activator stimulates transcription through interaction with a co-activator whose HAT activity renders the DNA more accessible *and* through interactions with the Mediator complex, which in turn recruits RNA pol II to the promoter. A specific transcription factor that is a repressor interacts with a co-repressor that has HDAC activity that deacetylates histones, restructuring the nucleosomes into a repressed state.

Most Mammalian Genes Lack Core Promoters The promoters of genes that are constitutively expressed, such as housekeeping genes, are relatively nucleosome-free. Significantly, about 70% of the human genome is transcribed, even though protein-encoding genes represent only 2% of the genome. Further, most mammalian genes lack core promoter elements, yet they recruit the complete transcriptional apparatus and are successfully transcribed. And, surprisingly, transcription initiation from most mammalian promoters proceeds in *both* directions, upstream and downstream, a phenomenon called divergent transcription. Genes lacking core promoters are instead rich in upstream CpG islands, and these CpG islands are able to recruit TBP and transcription factors and initiate transcription, but in divergent directions. The RNA products of divergent transcription tend to be short and not very stable. In contrast, genes having core promoter elements are transcribed uni-directionally, as described in this section.

The fact is the process of transcription in cells has a lot of noise: Most DNA is transcribed, but only a small portion of it is represented by protein-coding genes whose transcripts are translated into proteins. Some of the noncoding RNA produced arises from RNA pol II transcription of enhancer DNA and is referred to as **eRNA**. Some of these eRNAs participate in the regulation of RNA pol II transcription. ENCODE has identified tens of thousands of eRNAs in human cells.

Beyond these considerations, various mechanisms regulate gene expression through events that take place subsequent to transcription. **Post-transcriptional gene regulation** mediated by microRNAs (see Section 29.6), as well as **alternative RNA splicing** and nucleotide changes introduced through **RNA editing** (as described in this chapter), are mechanisms targeting transcripts. **Post-translational modifications** of proteins also play a major role in the regulation of gene expression, as assessed at the level of biological activity.

29.4 | How Do Gene Regulatory Proteins Recognize Specific DNA Sequences?

Proteins that recognize nucleic acids do so by the basic rule of macromolecular recognition. That is, such proteins present a three-dimensional shape or contour that is structurally and chemically complementary to the surface of a DNA sequence. When the two molecules come into contact, the numerous atomic interactions that underlie recognition and binding can take place. Nucleotide sequence-specific recognition by the protein involves a set of atomic contacts with the bases and the sugar-phosphate

Human Biochemistry

Storage of Long-Term Memory Depends on Gene Expression Activated by CREB-Type Transcription Factors

Learning can be defined as the process whereby new information is acquired and *memory* as the process by which this information is retained. *Cognition* is the acquisition of knowledge and is a result of learning. The biochemical processes that establish learning and memory were for a long time a mystery. It is now clear that macromolecular changes underpin both learning and memory. Short-term memory (which lasts minutes or hours) requires only the covalent modification of preexisting proteins, but long-term memory (which lasts days, weeks, or a lifetime) depends on gene expression, protein synthesis, and the establishment of new neuronal connections. Research by Eric Kandel of the Howard Hughes Medical Institute was the first to reveal the biochemical basis for memory storage in neurons. He was awarded the 2000 Nobel Prize in Physiology or Medicine for, among other things, his discovery

of the role of transcription factors in long-term memory. His work opened a new arena in molecular biology, the molecular biology of cognition.

The macromolecular synthesis underlying long-term memory storage requires cAMP-response element-binding (CREB) protein-related transcription factors and the activation of cAMP-dependent gene expression. Serotonin (5-hydroxytryptamine, or 5-HT, a hormone implicated in learning and memory) acting on neurons promotes cAMP synthesis, which in turn stimulates protein kinase A to phosphorylate CREB protein-related transcription factors that activate transcription of cAMP-inducible genes. These genes are characterized by the presence of CRE (cAMP response element) consensus sequences containing the 8-bp TGACGTCA palindrome. CREB transcription factors are *bZIP*-type proteins.

backbone. Direct interactions between protein side chains and specific bases in DNA is termed **direct readout**, since the protein is, in effect, reading the DNA sequence. Hydrogen bonding is critical for recognition, with amino acid side chains providing most of the critical contacts with DNA. Protein contacts with the bases of DNA usually occur within the major groove (but not always). Protein contacts with the DNA backbone involve both H bonds and salt bridges with electronegative oxygen atoms of the phosphodiester linkages. Structural studies on regulatory proteins that bind to specific DNA sequences have revealed that the majority of such proteins can be assigned to one of three principal classes based on their possession of one of three kinds of small, distinctive structural motifs: the **helix-turn-helix** (or **HTH**), the **zinc finger** (or **Zn-finger**), and the **leucine zipper-basic region** (or **bZIP**). The latter two motifs are found only in DNA-binding proteins from eukaryotic organisms.

In addition to their DNA-binding domains, these proteins commonly possess other structural domains that function in protein:protein interactions recognitions essential to oligomerization (for example, dimer formation), DNA looping, transcriptional activation, and signal reception (for example, effector binding).

29.4a α -Helices Fit Snugly into the Major Groove of B-DNA

A recurring structural feature in DNA-binding proteins is the presence of α -helical segments that fit directly into the major groove of B-form DNA. The diameter of an α -helix (including its side chains) is about 1.2 nm. The dimensions of the major groove in B-DNA are 1.2 nm wide by 0.6 to 0.8 nm deep. Thus, one side of an α -helix can fit snugly into the major groove. Further, the particular amino acid side chains arrayed along the α -helix find H-bonding partners presented by the edges of the base pairs lining the floor of the major groove. This direct readout of DNA sequence by the protein underlies sequence-specific DNA binding. Although examples of β -sheet DNA recognition elements in proteins are known, the α -helix and B-form DNA are the predominant structures involved in protein-DNA interactions. Significantly, proteins can recognize specific sites in normal B-DNA; the DNA need not assume any unusual, alternative conformation (such as Z-DNA).

29.4b Proteins with the Helix-Turn-Helix Motif Use One Helix to Recognize DNA

The HTH motif is a protein structural domain consisting of two successive α -helices separated by a sharp β -turn (Figure 29.31). Within this domain, the α -helix situated more toward the C-terminal end of the protein, the so-called helix 3, is the DNA

Figure 29.31 An HTH motif protein: *Antp* monomer bound to DNA. Helix 3 (yellow) is locked into the major groove of the DNA by helix 2 (magenta) (PDB id = 9ANT).

recognition helix; it fits nicely into the major groove, with several of its side chains touching DNA base pairs. Helix 2, the helix at the beginning of the HTH motif, creates a stable structural domain through hydrophobic interactions with helix 3 that locks helix 3 into its DNA interface. Proteins with HTH motifs bind to DNA as dimers. In the dimer, the two helix 3 cylinders are antiparallel to each other, such that their N→C orientations match the inverted relationship of nucleotide sequence in the dyad-symmetric DNA-binding site. An example is *Antp*. *Antp* is a member of a family of eukaryotic proteins involved in the regulation of early embryonic development that have in common an amino acid sequence element known as the **homeobox domain**. The homeobox is a DNA motif that encodes a related 60-amino acid sequence (the homeobox domain) found among proteins of virtually every eukaryote, from yeast to man. Genes containing homeoboxes are master control genes regulating cell differentiation, morphogenesis, and development in animals. Embedded within the homeobox domain is an HTH motif. Homeobox domain proteins act as **sequence-specific transcription factors**. Typically, the homeobox portion comprises only 10% or so of the protein's mass, with the remainder of the protein serving in protein:protein interactions essential to transcription regulation. Other DNA-binding proteins with HTH motifs are *lac* repressor, *trp* repressor, and the C-terminal domain of CAP.

How Does the Recognition Helix Recognize Its Specific DNA-Binding Site? The edges of base pairs in dsDNA present a pattern of hydrogen-bond donor and acceptor groups within the major and minor grooves, but only the pattern displayed on the major-groove side is distinctive for each of the four base pairs A:T, T:A, C:G, and G:C. (You can get an idea of this by inspecting the structures of the base pairs in Figure 11.9.) Thus, the base-pair edges in the major groove act as a **recognition matrix** identifiable through H bonding with a specific protein, so it is not necessary to melt the base pairs to read the base sequence. Although formation of such H bonds is very important in DNA:protein recognition, other interactions also play a significant role. For example, the C-5-methyl groups unique to thymine residues are nonpolar knobs projecting into the major groove.

Proteins Also Recognize DNA via Shape Readout Direct readout of the base sequence by a DNA-binding protein is not the only way that proteins recognize specific nucleotide sequences. **Shape readout**, also known as indirect readout, is the term for the ability of a protein to indirectly recognize a particular nucleotide sequence by recognizing local conformational variations resulting from the effects that base sequence has on DNA structure. Superficially, the B-form structure of DNA appears to be a uniform cylinder. Nevertheless, the conformation of DNA over a short distance along its circumference varies subtly according to local base sequence. That is, base sequences generate unique contours that proteins can recognize. Because these contours arise from the base sequence, the DNA-binding protein indirectly reads out the base sequence through interactions with the DNA backbone. In the *E. coli* Trp repressor: *trp* operator DNA complex, the Trp repressor engages in 30 specific hydrogen bonds to the DNA: 28 involve phosphate groups in the backbone; only 2 are to bases. Thus, some sequence-specific DNA-binding proteins are able to recognize an overall DNA conformation caused by the specific DNA sequence. However, it is likely that most proteins use both base readout and shape readout to recognize the specific nucleotide sequences to which they bind.

29.4c Some Proteins Bind to DNA via Zn-Finger Motifs

There are many classes of Zn-finger motifs. The prototype **Zn-finger** is a structural feature formed by a pair of Cys residues separated by two residues, then a run of 12 amino acids, and finally a pair of His residues separated by three residues (Cys-x₂-Cys-x₁₂-His-x₃-His). This motif may be repeated as many as 13 times over the primary structure of a Zn-finger protein. Each repeat coordinates a zinc ion via its two Cys and two His residues (Figure 29.32). The 12 or so residues separating the Cys and His

Figure 29.32 The Zn-finger motif of the C₂H₂ type showing (a) the coordination of Cys and His residues to Zn and (b) the secondary structure. (c) Structure of a classic C₂H₂ zinc finger protein (Zif268) with three zinc fingers bound to DNA (PDB id = 1ZAA).

coordination sites are looped out and form a distinct DNA interaction module, the so-called zinc finger. When Zn-finger proteins associate with DNA, each Zn-finger binds in the major groove and interacts with about five nucleotides, adjacent fingers interacting with contiguous stretches of DNA. Many DNA-binding proteins with this motif have been identified. In all cases, the finger motif is repeated at least two times, with at least a seven- to eight-amino acid linker between Cys/Cys and His/His sites. Proteins with this general pattern are assigned to the **C₂H₂ class** of Zn-finger proteins to distinguish them from proteins bearing another kind of Zn-finger, the **C_x type**, which includes the C₄ and C₆ Zn-finger proteins. The C_x proteins have a variable number of Cys residues available for Zn **chelation**. For example, the vertebrate steroid receptors have two sets of Cys residues, one with four conserved cysteines (C₄) and the other with five (C₅).

Chelation is from the Greek word *chele*, meaning “claw”; it refers to the binding of a metal ion to two or more nonmetallic atoms in the same molecule.

29.4d Some DNA-Binding Proteins Use a Basic Region-Leucine Zipper (*bZIP*) Motif

bZIP is a structural motif characterizing the third major class of sequence-specific, DNA-binding proteins. This motif was first recognized by Steve McKnight in **C/EBP** (for CCAAT and enhancer-binding protein). The DNA-binding domain of C/EBP in the C-terminal region of the protein shows a notable absence of Pro residues, suggesting it might be arrayed in an α -helix. Within this region are two clusters of basic residues: A and B. Further along is a 28-residue sequence. When this latter region is displayed end-to-end down the axis of a hypothetical α -helix, beginning at Leu³¹⁵, an amphipathic cylinder is generated, similar to the one shown in Figure 6.22. One side of this amphipathic helix consists principally of hydrophobic residues (particularly leucines), whereas the other side has an array of negatively and positively charged side chains (Asp, Glu, Arg, and Lys), as well as many uncharged polar side chains (glutamines, threonines, and serines).

The Zipper Motif of *bZIP* Proteins Operates Through Intersubunit Interaction of Leucine Side Chains The leucine zipper motif arises from the periodic repetition of leucine residues within this helical region. The periodicity causes the Leu side chains to protrude from the same side of the helical cylinder, where they can enter into hydrophobic interactions with a similar set of Leu side chains extending from a matching helix in a second polypeptide. These hydrophobic interactions establish a stable noncovalent linkage, fostering dimerization of the two polypeptides (as shown in Figure 29.33). The leucine zipper is not a DNA-binding domain. Instead, it functions in protein dimerization. Leucine zippers have been found in other mammalian transcriptional regulatory proteins, including *Myc*, *Fos*, and *Jun*.

Figure 29.33 Model for a dimeric *bZIP* protein. Two *bZIP* polypeptides dimerize to form a Y-shaped molecule. The stem of the Y is the Leu zipper, and it holds the two polypeptides together. Each arm of the Y is the basic region from one polypeptide. Each arm is composed of two α -helical segments: BR-A and BR-B (basic regions A and B).

Figure 29.34 Model for the heterodimeric *bZIP* transcription factor *c-Fos:c-Jun* bound to a DNA oligomer containing the AP-1 consensus target sequence TGAAGTCA (PDB id = 1FOS).

The Basic Region of *bZIP* Proteins Provides the DNA-Binding Motif The actual DNA contact surface of *bZIP* proteins is contributed by a 16-residue segment that ends exactly 7 residues before the first Leu residue of the Leu zipper. This DNA contact region is rich in basic residues and, hence, is referred to as the **basic region**. Two *bZIP* polypeptides join via a Leu zipper to form a Y-shaped molecule in which the stem of the Y corresponds to a coiled pair of α -helices held by the leucine zipper. The arms of the Y are the basic regions of each polypeptide; they act as a linked set of DNA contact surfaces (Figure 29.33). The dimer interacts with a DNA target site by situating the fork of the Y at the center of the dyad-symmetric DNA sequence. The two arms of the Y can then track along the major groove of the DNA in opposite directions, reading the specific recognition sequence (Figure 29.34). An interesting aspect of *bZIP* proteins is that the two polypeptides need not be identical (Figure 29.34). Heterodimers can form, provided both polypeptides possess a leucine zipper region. An important consequence of heterodimer formation is that the DNA target site need not be a palindromic sequence. The respective basic regions of the two different *bZIP* polypeptides (for example, *Fos* and *Jun*) can track along the major groove reading two different base sequences. Heterodimer formation expands enormously the DNA recognition and regulatory possibilities of this set of proteins.

29.5 How Are Eukaryotic Transcripts Processed and Delivered to the Ribosomes for Translation?

Transcription and translation are concomitant processes in prokaryotes, but in eukaryotes the two processes are spatially separated (see Chapter 10). *Transcription occurs on DNA in the nucleus, and translation occurs on ribosomes in the cytoplasm.* Consequently, transcripts must be transported from the nucleus to the cytosol to be translated. Before exiting the nucleus, these transcripts undergo processing: alterations that convert the newly synthesized RNAs, or *primary transcripts*, into mature messenger RNAs. Indeed, processing is underway even before transcription of the gene is terminated. Also, unlike prokaryotes, in which many mRNAs encode more than one polypeptide (that is, they are polycistronic), eukaryotic mRNAs encode only one polypeptide (that is, they are exclusively monocistronic).

29.5a Eukaryotic Genes Are Split Genes

Most genes in higher eukaryotes are split into coding regions, called **exons**, and non-coding regions, called **introns** (Figure 29.35; see also Figure 10.19). Although the term *exon* is commonly used to refer to the protein-coding regions of an interrupted or split

Figure 29.35 The organization of a split eukaryotic gene. Processing of primary mRNA transcripts includes removal of all introns. Mature mRNAs lack introns.

gene, a more precise definition would specify exons as sequences that are represented in mature RNA molecules. This definition encompasses not only protein-coding genes but also the genes for various RNAs (such as tRNAs or rRNAs) from which intervening sequences must be excised to generate the mature gene product. Introns are the intervening nucleotide sequences that are removed from the primary transcript when it is processed into a mature RNA. Gene expression in eukaryotes entails not only transcription but also the *processing of primary transcripts* to yield the mature RNA molecules we classify as mRNAs, tRNAs, rRNAs, and so forth.

29.5b The Organization of Exons and Introns in Split Genes Is Both Diverse and Conserved

Human genes contain from 0 to 300 introns, but, on average, they have about nine exons and eight introns. The yeast **actin gene** is a simple example, having only a single 309-bp intron that separates the nucleotides encoding the first three amino acids from those encoding the remaining 350 or so amino acids in the protein. The chicken ovalbumin gene is composed of eight exons and seven introns. The two vitellogenin genes of the African clawed toad *Xenopus laevis* are both spread over more than 21 kbp of DNA; their primary transcripts consist of just 6 kbp of message that is punctuated by 33 introns. The chicken pro α -2 collagen gene has a length of about 40 kbp; the coding regions constitute only 5 kb distributed over 51 exons within the primary transcript. The exons are quite small, ranging from 45 to 249 bases in size.

Clearly, the mechanism by which introns are removed and multiple exons are spliced together to generate a continuous, translatable mRNA must be both precise and complex. If one base too many or too few is excised during splicing, the coding sequence in the mRNA will be disrupted. The mammalian DHFR (dihydrofolate reductase) gene is split into six exons spread over more than 31 kbp of DNA. The six exons are spliced together to give a 6-kb mRNA (Figure 29.36). Note that, in three different mammalian species, the size and position of the exons are essentially the same but that the lengths of the corresponding introns vary considerably. Indeed, the lengths of introns in vertebrate genes range from a minimum of about 60 bases to more than 10,000 bp. Many introns have nonsense codons in all three reading frames and thus are untranslatable. Introns are found in the genes of mitochondria and chloroplasts as well as in nuclear genes. Introns do occur in Eubacteria, Archaea, and even in bacteriophage T4, but they are much rarer than in eukaryotes.

29.5c Post-Transcriptional Processing of Messenger RNA Precursors Involves Capping, Methylation, Polyadenylation, and Splicing

The immediate product of eukaryotic transcription, the primary transcript, undergoes a series of covalent modifications collectively called **processing**. These modifications include adding a GMP to the 5'-phosphate end, methylation on various bases and riboses at the 5'-end, addition of multiple A residues (polyadenylation) to the 3'-end,

Figure 29.36 The organization of the mammalian DHFR gene in three representative species. Note that the exons are much shorter than the introns. Note also that the exon pattern is more highly conserved than the intron pattern.

and removal of all introns (splicing). The result is the mature mRNA, which is exported from the nucleus for translation in the cytosol.

Capping and Methylation of Eukaryotic mRNAs The protein-coding genes of eukaryotes are transcribed by RNA polymerase II to form primary transcripts or **pre-mRNAs** that serve as precursors to mRNA. As a population, these RNA molecules are very large and their nucleotide sequences are very heterogeneous because they represent the transcripts of many different genes, hence the designation **heterogeneous nuclear RNA**, or **hnRNA**. Shortly after transcription of hnRNA is initiated, the 5'-end of the growing transcript is capped by addition of a guanylyl residue. This reaction is catalyzed by the nuclear enzyme **guanylyl transferase** using GTP as substrate (Figure 29.37). The **cap structure** is methylated at the 7-position of the G residue. Additional methylations may occur at the 2'-O positions of the two nucleosides following the 7-methyl-G cap and at the 6-amino group of a first base adenine (Figure 29.38). *S*-Adenosylmethionine is the methyl donor in all these reactions. The ribose of first nucleotide after the 5'-G cap is almost always 2'-*O*-methylated (cap 1 structure), and this modification is sometimes found on the next (second) nucleotide as well. These modifications are important for recruitment of translation initiation factors to the mRNA. Methylation of N-6 on A at the 1-position to yield *N*⁶,2'-*O*- makes the mRNA markedly more stable. Further, such methylations alter the local structure of pre-mRNA in a way that makes the RNA more accessible to proteins with single-stranded RNA-binding motifs. Such proteins are important players in pre-mRNA processing and maturation to yield a competent, translatable mRNA.

Transcription Termination in Eukaryotes Transcription by RNA pol II typically continues past the 3'-end of the mature messenger RNA. Primary transcripts show heterogeneity in sequence at their 3'-ends, indicating that the precise point where termination occurs is nonspecific. However, termination does not normally occur until RNA polymerase II has transcribed past a consensus AAUAAA sequence known as the **polyadenylation signal**, encoded in the template DNA as TTATTT.

RNA pol II continues to extend the transcript, but Ser⁵-P in its CTD is now dephosphorylated. **CPSF** (cleavage and polyadenylation specificity factor) recognizes and binds to the AAUAAA polyadenylation signal in the pre-mRNA (Figure 29.39). A second sequence element downstream from AAUAAA, the U/GU-rich region, binds CstF (cleavage stimulation factor). CstF interacts with CPSF, establishing a connection between the AAUAAA and the U/GU-rich region. One of the 6 subunits of CPSF is an endoribonuclease and it cleaves the capped pre-mRNA between the AAUAAA signal and the U/GU-rich region, freeing it from the transcription machinery. Upon 5'→3'- exonuclease cleavage of the transcript remnant clinging to the RNA pol II, the transcription machinery dissociates from the DNA.

Figure 29.37 The capping of eukaryotic pre-mRNAs. Guanylyl transferase catalyzes the addition of a guanylyl residue (G_p) derived from GTP to the 5'-end of the growing transcript, which has a 5'-triphosphate group already there. In the process, pyrophosphate (pp) is liberated from GTP and the terminal phosphate (p) is removed from the transcript. $Gppp + pppApNpNpNp \dots \rightarrow GpppApNpNpNp \dots + pp + p$ (A is often the initial nucleotide in the primary transcript).

Figure 29.38 Methylation of several specific sites located at the 5'-end of eukaryotic pre-mRNAs is an essential step in mRNA maturation. A cap bearing only a single —CH_3 on the guanyl is termed **cap 0**. This methylation occurs in all eukaryotic mRNAs. If a methyl is also added to the 2'-O position of the first nucleotide after the cap, a **cap 1** structure is generated. This is the predominant cap form in all multicellular eukaryotes. Some species add a third —CH_3 to the 2'-O position of the second nucleotide after the cap, giving a **cap 2** structure. Also, if the first base after the cap is an adenine, it may be methylated on its 6- NH_2 . In addition, approximately 0.1% of the adenine bases throughout the mRNA of higher eukaryotes carry methylation on their 6- NH_2 groups.

3'-Polyadenylation of Eukaryotic mRNAs Most eukaryotic mRNAs have 80 to 250 adenine residues attached at their 3'-end, the **poly(A) tail**. (Histone mRNAs are the only common mRNAs that lack poly(A) tails.) These A residues are not encoded in the DNA but are added post-transcriptionally by the enzyme **poly(A) polymerase**, using ATP as a substrate. The consensus AAUAAA is not itself the poly(A) addition site; instead, it defines the position where poly(A) addition occurs (Figure 29.39). The consensus AAUAAA is found 10 to 35 nucleotides upstream from where the nascent primary

Figure 29.39 Poly(A) addition to the 3'-ends of transcripts occurs 10 to 35 nucleotides downstream from a consensus AAUAAA sequence, defined as the **polyadenylation signal**. CPSF (**c**leavage and **p**olyadenylation **s**pecificity **f**actor) binds to this signal sequence and mediates looping of the 3'-end of the transcript through interactions with the **c**leavage **s**timulation **f**actor (CstF) bound at a G/U-rich sequence even further downstream. The endonuclease subunit of CPSF then carries out cleavage of the transcript to create a new 3'-end 10 to 35 nucleotides downstream from the polyadenylation signal. Poly(A) polymerase (PAP) then successively adds 80 to 250 adenyl residues to the new 3'-end. (RNA pol II is also part of the polyadenylation complex at the 3'-end of the transcript, but for simplicity in illustration, its presence is not shown in the lower part of the figure.)

transcript is cleaved by the CPSF endonuclease to generate a new 3'-OH end. This end is where the poly(A) tail is added. The processing events of mRNA capping, poly(A) addition, and splicing of the primary transcript create the mature mRNA. Significantly, both the guanylyl transferase that adds the 5'-cap structure and the enzymes that process the 3'-end of the transcript and add the poly (A) tail are anchored to RNA pol II via interactions with its CTD.

29.5d Nuclear Pre-mRNA Splicing

Within the nucleus, hnRNA forms **ribonucleoprotein particles (RNPs)** through association with a characteristic set of nuclear proteins. These proteins interact with the nascent RNA chain as it is synthesized, maintaining the hnRNA in an untangled, accessible conformation. The capped primary transcript emerging from the RNA pol II transcriptional apparatus is the substrate for splicing. Splicing requires both intron excision and exon ligation. Splicing occurs exclusively in the nucleus. The mature mRNA that results is then exported to the cytoplasm to be translated. Splicing requires precise cleavage at the 5'- and 3'-ends of introns and the accurate joining of the two ends. Consensus sequences define the exon/intron junctions in eukaryotic mRNA precursors, as indicated from an analysis of the splice sites in vertebrate genes (Figure 29.40). Note that the sequences GU and AG are found at the 5'- and 3'-ends, respectively, of introns in pre-mRNAs from higher eukaryotes. In addition to the splice junctions, a conserved sequence within the intron, the **branch site**, is also essential to pre-mRNA splicing. The site lies 18 to 40 nucleotides upstream from the 3'-splice site and is represented in higher eukaryotes by the consensus sequence YNYRAY, where Y is any pyrimidine, R is any purine, and N is any nucleotide.

29.5e The Splicing Reaction Proceeds via Formation of a Lariat Intermediate

The mechanism for splicing nuclear mRNA precursors is shown in Figure 29.41. A covalently closed loop of RNA, the **lariat**, is formed by attachment of the 5'-phosphate group of the intron's invariant 5'-G to the 2'-OH at the invariant branch site A to form

**Figure 29.41** Splicing of mRNA precursors. A representative precursor mRNA is depicted. Exon 1 and Exon 2 indicate two exons separated by an intervening sequence (or intron) with consensus 5', 3', and branch sites. The fate of the phosphates at the 5'- and 3'-splice sites can be followed by tracing the fate of the respective *ps*. The products of the splicing reaction, the lariat form of the excised intron and the united exons, are shown at the bottom of the figure.

a 2'-5' phosphodiester bond. Note that lariat formation creates an unusual branched nucleic acid. The lariat structure is excised when the 3'-OH of the consensus G at the 3'-end of the 5' exon (Exon 1, Figure 29.41) covalently joins with the 5'-phosphate at the 5'-end of the 3' exon (Exon 2). The reactions that occur are transesterification reactions where an OH group reacts with a phosphoester bond, displacing an —OH to form a new phosphoester link. Because the reactions lead to no net change in the number of phosphodiester linkages, no energy input (for example, as ATP) is needed. The lariat product is unstable; the 2'-5' phosphodiester branch is quickly cleaved to give a linear excised intron that is rapidly degraded in the nucleus.

29.5f Splicing Depends on snRNPs

The hnRNA (pre-mRNA) substrate is not the only RNP complex involved in the splicing process. Splicing also depends on a unique set of small nuclear ribonucleoprotein particles called **snRNPs** (pronounced “snurps”). In higher eukaryotes, each snRNP consists of a small RNA molecule 100 to 200 nucleotides long and about 10 different proteins. The RNAs found in snRNPs are uridine-rich. This quality leads to the U designation of the five prominent snRNPs as U1, U2, U4, 5, and U6 snRNP, as shown in Table 29.4. Four of the five snRNPs have a core set of seven **Sm proteins** (Smb/B', SmD1, SmD2, SmD3, SmE, SmF, and SmG). The fifth, U1 SnRNP, has a related set of seven proteins that are designated LSm (for “like Sm”). Each snRNA has a single-stranded, U-rich RNA sequence, the **Sm site**, whose nucleotide sequence is AUUUUUG. The Sm proteins assemble as a very stable heteroheptameric ring around the Sm site, in the order SmE-SmG-SmD3-SmB-SmD1-SmD2-SmF. Thus, the snRNA passes through the central hole in the Sm protein heteroheptamer (Figure 29.42). Each of the snRNPs also binds its own set of unique proteins to complete its ribonucleoprotein structure. These major snRNP species are very abundant, present at greater than 100,000 copies per nucleus. In the U1 SnRNP, the U1 snRNA folds into a secondary structure that leaves the 11 nucleotides at its 5'-end single-stranded. The 5'-end of U1 snRNA is complementary to the consensus sequence at the 5'-splice junction of the pre-mRNA (Figure 29.43), as is a region at the 5'-end of U6 snRNA. The U2 SnRNP snRNA is complementary to the consensus branch site sequence.

29.5g snRNPs Form the Spliceosome

Splicing occurs when the various snRNPs interact with the pre-mRNA to form the **spliceosome**, a multi-megadalton complex the size of a ribosome. The spliceosome is assembled de novo at splice sites. Among its many subunits are ATP-dependent RNA helicases. A pair of Mg^{2+} define the catalytic site of the phosphoryl transfer reactions.

Figure 29.43 Mammalian U1 snRNA can be arranged in a secondary structure where its 5'-end is single-stranded and can base-pair with the consensus 5'-splice site of the intron. Newly transcribed pre-RNAs are vulnerable to premature degradation, and U1 snRNP helps to protect the pre-mRNA from such destruction. (*Adapted from Figure 1 in Rosbash, M., and Seraphin, B., 1991. Who's on first? The U1 snRNP-5' splice site interaction and splicing. Trends in Biochemical Sciences* **16**:187.)

Figure 29.42 Structure of the core domain of the U4 SnRNP. The U4 snRNA (backbone indicated in orange) passes through the central hole in the heteroheptad Sm protein complex, SmG-SmD3-SmB-SmD1-SmD2-SmF. Each of the seven Sm proteins is a different color. (*Adapted from* Figure 1 in Leung, A. K. W., Nagai, K., and Li, J. 2011. Structure of the spliceosomal U4 snRNP core domain and its implication for snRNP biogenesis. *Nature* **473**:536–539; PDB id = 2Y9A).

Table 29.4 The snRNPs Found in Spliceosomes

snRNP	Length (nt)	Splicing Target
U1	165	5' splice
U2	189	Branch
U4	145	5' splice, recruitment of branch point to 5'-splice site
U5	115	
U6	106	

Figure 29.44 Events in spliceosome assembly. U1 snRNP binds at the 5'-splice site, followed by the association of U2 snRNP with the UACUAA* C branch-point sequence. The triple U4/U6-U5 snRNP complex replaces U1 at the 5'-splice site and directs the juxtaposition of the branch-point sequence with the 5'-splice site, whereupon U4 snRNP is released. Lariat formation occurs, freeing the 3'-end of the 5'-exon to join with the 5'-end of the 3'-exon, followed by exon ligation. U2, U5, and U6 snRNPs dissociate from the lariat following exon ligation.

In the course of each splicing reaction, the spliceosome cycles through eight distinct compositional states as various U-snRNPs associate, carry out their assigned roles, and then dissociate. Assembly of the spliceosome begins with the binding of U1 snRNP at the 5'-splice site of the pre-mRNA (Figure 29.44). Each subsequent step in spliceosome assembly requires ATP-dependent RNA rearrangements catalyzed by spliceosomal **DEAD-box ATPases/helicases**. The branch-point sequence (UACUAA in yeast) binds U2 snRNP, and then the triple snRNP complex of U4/U6-U5 replaces U1 at the 5'-splice site. The substitution of base-pairing interactions between U1 and the pre-mRNA 5'-splice site by base-pairing between U6 and the 5'-splice site is just one of the many RNA rearrangements that accompany the splicing reaction. Base-pairings between U6 and U2 RNA bring the 5'-splice site and the branch point RNA sequences into proximity. Interactions between U2 and U6 lead to release of U4 snRNP. The spliceosome is now activated for catalysis.

The spliceosome is a ribozyme: The transesterification reactions that achieve RNA splicing are catalyzed by the U6 snRNA. Mechanistically, transesterifications are metal-catalyzed reactions, and the U6 snRNA sugar-phosphate backbone provides a set of phosphoryl oxygen atoms to coordinate the Mg^{2+} ions that mediate splicing. As shown in Figure 29.41, a transesterification reaction involving the 2'-O of the invariant A residue in the branch-point sequence displaces the 5'-exon from the intron, creating the lariat intermediate. The free 3'-O of the 5'-exon now triggers a second transesterification reaction through attack on the P atom at the 3'-exon splice site. This second reaction joins the two exons and releases the intron as a lariat structure. In addition to the snRNPs, a number of proteins with RNA-annealing functions as well as proteins with ATP-dependent RNA-unwinding activity participate in spliceosome function. The spliceosome is thus a dynamic structure that uses the pre-mRNA as a template for assembly, carries out its transesterification reactions, and then disassembles when the splicing reaction is over.

29.5h Alternative RNA Splicing Creates Protein Isoforms

In one mode of splicing, every intron is removed and every exon is incorporated into the mature RNA without exception. This type of splicing, termed **constitutive splicing**, results in a single form of mature mRNA from the primary transcript. However, many eukaryotic genes can give rise to multiple forms of mature RNA transcripts. The mechanisms for production of multiple transcripts from a single gene include use of different promoters, selection of different polyadenylation sites, **alternative splicing** of the primary transcript, or even a combination of the three.

Protein Isoforms Arise from Different Transcripts of the Same Gene Different transcripts from a single gene make possible a set of related polypeptides, or **protein isoforms**, each with slightly altered functional capability. Such variation serves as a useful mechanism for increasing the apparent coding capacity of the genome. Furthermore, alternative splicing offers another level at which regulation of gene expression can operate. For example, mRNAs unique to particular cells, tissues, or developmental stages could be formed from a single gene by choosing different 5'- or 3'-splice sites or by omitting entire exons. Translation of these mature mRNAs produces cell-specific protein isoforms that display properties tailored to the needs of the particular cell. Such regulated expression of distinct protein isoforms is a fundamental characteristic of eukaryotic cell differentiation and development.

Fast Skeletal Muscle Troponin T Isoforms Are an Example of Alternative Splicing In addition to many other instances, alternative splicing is a prevalent mechanism for generating protein isoforms from the genes encoding muscle proteins (see Chapter 16), allowing distinctive isoforms aptly suited to the function of each muscle. An impressive manifestation of alternative splicing is seen in the expression possibilities for the rat **fast skeletal**

A Deeper Look

Inteins—Bizarre Parasitic Genetic Elements Encoding a Protein-Splicing Activity

Inteins are parasitic genetic elements found within protein-coding regions of genes. These selfish DNA elements are transcribed and translated along with the flanking host gene sequences. The typical intein protein consists of two domains: One domain is capable of self-catalyzed **protein splicing**; the other is an endonuclease that mediates the insertion of the intein nucleotide sequence into host genes. After the full protein is synthesized, the intein catalyzes excision of itself from the host protein *and* ligation of adjacent host polypeptide regions to form the functional protein that the host gene encodes. These adjacent polypeptides are termed **exteins** (**external proteins**) to distinguish them from the intein (internal protein). Inteins have been found across all domains of life—archaea, bacteria, and eukaryotes—although thus far only in unicellular organisms. Inteins vary in size from about 130 to 600 amino acid residues. The protein splicing function of inteins is found in its N-terminal and its C-terminal regions; the endonuclease function that carries out parasitic insertion of the intein sequence into host genes is found in the central part of the intein. Splicing of the protein is an intramolecular process that liberates the intein sequence and ligates the host protein sequences (see accompanying figure for the basic reaction mechanism).

Inteins are usually found as inserts in highly conserved host genes that have essential functions, such as genes encoding DNA or RNA polymerases, proton-translocating ATPases, or other vital metabolic enzymes. Their location in such genes means that evolutionary loss of the intein via deletion or genetic rearrangement is more difficult. The endonuclease activity of the intein recognizes a 14- to 40-bp sequence in a potential host gene and cleaves the DNA there. During repair of the double-stranded DNA break, the intein gene is copied into the cleavage site, thereby establishing the parasitic genetic element in the host gene.

Transcription and translation of the combined intein-host gene flanking sequences leads to synthesis of a fused intein-extein protein. The intein splices itself out when (1) the C-terminal residue of the N-extein is shifted to the O (or S) atom of a neighboring intein Ser (or Cys) residue, (2) the N-extein C-terminal carbonyl undergoes nucleophilic attack by the O (or S) atom of a Ser (or Cys) residue at the end of the C-extein in a transesterification reaction that creates a branched protein intermediate, (3) cyclization of the intein C-terminal asparagine residue excises the intein, and (4) the two exteins are properly united via a peptide bond when the N-extein C-terminus spontaneously shifts to the C-extein N-terminus to form an intact host protein. An example of a protein-coding gene containing an intein is the gene for Prp8, a core subunit of spliceosomes. Prp8 mediates rearrangements of the spliceosome catalytic core.

Fast skeletal troponin T gene and spliced mRNAs

Figure 29.45 Organization of the fast skeletal muscle troponin T gene and the 64 possible mRNAs that can be generated from it. Exons are constitutive (yellow), combinatorial (green), or mutually exclusive (blue or orange). Exon 1 is composed of 5'-untranslated (UT) sequences, and Exon 18 includes the polyadenylation site (AATAAA) and 3'-UT sequences. The TATA box indicates the transcription start site. The amino acid residues encoded by each exon are indicated below. Many exon-intron junctions fall between codons. The sawtooth exon boundaries indicate that the splice site falls between the first and second nucleotides of a codon, the concave/convex exon boundaries indicate that the splice site falls between the second and third nucleotides of a codon, and flush boundaries between codons signify that the splice site falls between intact codons. Each mRNA includes all constitutive exons, 1 of the 32 possible combinations of Exons 4 to 8, and either Exon 16 or 17.

muscle troponin T gene (Figure 29.45). This gene consists of 18 exons, 11 of which are found in all mature mRNAs (exons 1 through 3, 9 through 15, and 18) and thus are **constitutive**. Five exons, those numbered 4 through 8, are **combinatorial** in that they may be individually included or excluded, in any combination, in the mature mRNA. Two exons, 16 and 17, are mutually exclusive: One or the other is always present, but never both. Sixty-four different mature mRNAs can be generated from the primary transcript of this gene by alternative splicing. Because each exon represents a cassette of genetic information encoding a segment of protein, alternative splicing is a versatile way to introduce functional variation within a common protein theme.

29.5i RNA Editing: Another Mechanism That Increases the Diversity of Genomic Information

RNA editing is a process that changes one or more nucleotides in an RNA transcript by deaminating a base, either A→I (adenine to inosine, through deamination at the 6-position in a purine ring) or C→U (cytosine to uracil, through deamination at the 4-position in a pyrimidine ring). These changes alter the coding possibilities in a transcript. An A-to-I change leads to an interpretation of I as G during translation when I pairs with C. The C-to-U change replaces the previous C:G pairing with U:A pairing at that position. RNA editing has the potential to increase protein diversity by (1) altering amino acid coding possibilities, (2) introducing premature stop codons, or (3) changing splice sites in a transcript. If RNA splicing is cutting-and-pasting, then these single-base changes are aptly termed RNA editing.

A-to-I editing is carried out by **adenosine deaminases** that act on RNA (the **ADAR** family of RNA-editing enzymes). ADARs act only on double-stranded regions of RNA. Typically, such regions form when an exon region containing an A to be edited base-pairs with a complementary base sequence in an intron known as the **editing site complementary sequence**, or **ECS**. ADARs are abundant in the nervous system of animals. A prominent example of RNA editing occurs in transcripts encoding mammalian glutamate receptors (GluRs). Deamination of the GluR-B gene transcript changes a glutamine codon CAG to CIG, which is read by the translational machinery as an arginine codon (CGG), dramatically altering the conductance properties of the membrane receptor produced from the edited transcript, as compared to the receptor produced from the unedited transcript.

C-to-U editing is carried out on single-stranded regions of transcripts by an **editosome** core structure consisting of a cytosine deaminase and an adapter protein that

brings the deaminase and the transcript together. A prominent example of C-to-U editing targets a single C residue in a 14-kb transcript encoding the 4536-residue apolipoprotein B100 protein (see Chapter 24). ApoB RNA editing changes codon 2153 (a CAA [glutamine] codon) to a UAA stop codon, which leads to a shortened protein product, ApoB48, consisting of the N-terminal 48% of apoB100. In humans, apoB100 is made in the liver and found in liver-derived VLDL serum lipoprotein complexes. In contrast, apoB48 is made in intestinal cells and found in intestinal-derived lipid complexes.

29.6 | Can Gene Expression Be Regulated Once the Transcript Has Been Synthesized?

Much emphasis has been placed on the regulation of gene expression through mechanisms at the gene promoter that determine whether or not a gene will be transcribed. In reality, many protein-coding genes are transcribed into RNA but their transcripts are never translated to form proteins. Indeed, post-transcriptional regulation of gene expression is a pervasive form of regulation, affecting virtually every cellular process from metabolism to development and cancer. MicroRNAs (miRNAs; see Chapter 10) are important players in post-transcriptional gene regulation.

29.6a miRNAs Are Key Regulators in Post-Transcriptional Gene Regulation

miRNAs are a large family of small (~21 nucleotides), noncoding RNAs found in animals, plants, and protists. Humans have about 2300 miRNA genes and they are predicted to target the expression of about 60% of all protein-coding genes. miRNAs are synthesized mainly by RNA pol II transcription. Their coding sequences are found in intergenic regions of DNA, in the introns of protein-coding genes, and even in exons.

miRNA Synthesis and Processing miRNAs are synthesized as **pri-miRNAs** (primary miRNAs), primary transcripts hundreds or thousands of nucleotides long that are processed in the nucleus by the **microprocessor** protein complex. Microprocessor is composed of **Drosha** (an RNase III family member), a dimer of the dsRNA-binding protein **DGCR8**, and other factors. Microprocessor converts the pri-miRNAs into 70-nucleotide stem-loop structures called **pre-miRNAs** (precursor miRNAs). Pre-miRNAs are exported to the cytosol, where **Dicer** (Chapter 12) processes the stem of the pre-miRNA to yield an approximately 20-nucleotide-long miRNA/miRNA* duplex (the * denotes the strand that is discarded). The miRNA strand represents the mature miRNA.

miRNA Mechanism of Action The mature miRNA is incorporated into a miRNA-induced silencing complex (**miRNA-RISC**) through interaction with **AGO2** (Figure 29.46). AGO2 contains three domains: PAZ, MID (which recognizes the 5'-end of the miRNA), and PIWI, the site of an RNase H-like enzyme activity. The 5'-terminal end of the miRNA binds in a deep pocket of AGO2 at the MID-PIWI junction. The PIWI domain also interacts with **GW182**, a 182-kDa protein having a glycine- and tryptophan-rich (GW) N-terminal domain and an RNA-recognition motif (RRM) at its C-terminus. AGO2 and GW182 are the primary proteins in the miRNA-RISC, but they recruit additional proteins, such as **PABP**, poly(A)-binding protein (see Figure 30.29), a protein that binds to the poly(A) tail of mRNAs. miRNA-RISC mediates the interaction of the miRNA with its mRNA targets.

In most cases, miRNAs target the 3'-untranslated region (3'-UTR) of the mRNAs they regulate. As the key site for post-transcriptional gene regulation, the 3'-UTR can be viewed as the post-transcriptional equivalent of the gene promoter. It is here that the macromolecular interactions underlying post-transcriptional regulatory decisions take place. In almost every case, the miRNA base-pairs imperfectly with its target sequence in the 3'-UTR of the mRNAs it regulates. Effective mRNA targeting requires base-pairing of nucleotides 2 to 8 of the miRNA with the mRNA. Nucleotides 2 to 8 are termed the **seed region**. Because the RNase function of AGO2 cleaves only perfectly

Figure 29.46 Domain organization of human Argonaute 2 (AGO2), GW182, and poly(A)-binding protein (PABP). The AGO2 PAZ (Piwi-Argonaute-Zwilli) domain is found in other proteins involved in post-transcriptional gene silencing. The GW-repeat domain of GW182 interacts with AGO2. The C-terminal GW182 domain has an RNA recognition motif (RRM). PABP has four RRM domains and a conserved C-terminal domain, PABC. Mammalian PABP binds directly to the silencing region of human GW182 proteins via PABC. (Adapted from Figure 1 in Fabian, M. R., Sonenberg, N., and Filipowicz, W., 2010. Regulation of mRNA stability and translation by miRNAs. *Annual Review of Biochemistry* 79:351–379.)

paired RNA duplexes, miRNA-RISC interaction with the mRNA does not result directly in RNA degradation. Further, because the miRNA-mRNA base-pairing is not perfect, miRNAs are non-specific. They can interact with the 3'-UTRs of multiple mRNA targets; keep in mind that these 3'-UTRs are very extensive, 700 nucleotides or more in human mRNAs, affording many opportunities for miRNA interactions.

miRNA Achieves Post-Transcriptional Gene Silencing in Two Ways miRNA interaction with a transcript prevents its translation into protein, a phenomenon termed **post-transcriptional gene silencing** because the gene will not be expressed. A key aspect of eukaryotic mRNA translation is closing the loop: the formation of an mRNA circle maintained through RNA:protein interactions. Closing the loop is achieved through translation factors binding at the capped 5'-end of the mRNA and then interacting with PABP bound to the poly(A) tail of the mRNA. Because of the proximity of the 5'- and 3'-ends of the mRNA when the loop is closed, miRNA-RISC binding at the 3'-UTR can interfere with recruitment of ribosomes to translate the mRNA, a mode of miRNA action referred to as **translation repression**. In addition, miRNA-RISC complexes destabilize mRNAs through deadenylation at their 3'-ends, decapping at their 5'-ends, and subsequent 5'→3' exonucleolytic degradation. The miRNA-RISC complex disrupts the closed loop through competing interactions with PABP, exposing the mRNA to decapping enzymes and exonucleases. Thus, the second mode of miRNA action is promoting **mRNA decay**.

lncRNAs Long noncoding RNAs (lncRNAs) are a class of RNA molecules defined by their lack of any protein-coding potential and a length greater than 200 nucleotides. lncRNAs are very abundant, numbering in the tens of thousands in mammals. lncRNAs resemble mRNA transcripts and indeed arise from RNA pol II transcription of DNA, either via divergent transcription or transcription of DNA regions between genes (so-called intergenic regions). Potentially, lncRNAs can base-pair with

complementary regions in DNA and/or interact with RNA-binding proteins. Nevertheless, despite much research, it remains an open question whether or not lncRNAs have any biological function.

29.6b Targeted RNA Degradation by Exosomes

The amount of specific mRNAs or proteins present in a cell at any time represents a balance between the rates of macromolecular synthesis and degradation. Regulated degradation of mRNAs (discussed here) and proteins is a rapid and effective way to control the cellular levels of these macromolecules. Because indiscriminate degradation of RNAs and proteins could have detrimental consequences within the cell, such degradation typically is compartmentalized. Targeted degradation of RNAs and proteins is enclosed within ringlike or cylindrical macromolecular complexes—the **exosome**² for RNA and the **proteasome** for proteins (see Chapter 31). The catalytically active component of an exosome is an **RNase PH** family member that processively degrades RNA in the 3'→5' direction. In addition to this exonucleolytic activity, RNA endonuclease activity has been found in exosomes.

Exosomes have a fundamental structural pattern: a ring of six subunits surrounding a central cavity, with one or more of the subunits having RNase PH activity. Superimposed on top of the hexameric RNase PH ring are three different proteins with **S1 RNA-binding domains** (RBD proteins), as shown in Figure 29.47. Collectively, these nine proteins constitute the exosome complex. Depending on the cellular compartment—nucleus, nucleolus, or cytosol—other proteins associate with the exosome complex. These proteins determine the substrates degraded—rRNA, mRNA, tRNA, or any of the variety of small RNAs. RNAs to be degraded are threaded into the central cavity. The architecture of the exosome restricts substrate access and compartmentalizes the RNase activity so that indiscriminate degradation of cellular RNase is avoided. Only RNAs targeted to the exosome are destroyed. The exosome is a key player in RNA quality control, ensuring that misprocessed RNAs and ribonucleoprotein complexes are degraded.

Figure 29.47 Structure of the human exosome complex (PDB id = 2NN6). The exosome complex is composed of nine different polypeptide chains. A hexameric ring of polypeptides (each a different color in this image) surrounds a central cavity. This cavity is capped by a set of three S1 RBD proteins (all colored *hot pink* here). The human exosome core is catalytic inactive, but it serves as a platform for the association of additional subunits that have 3'-exonuclease activity.

²Cell biologists use the word “exosome” to refer to cell-derived vesicles found in biological fluids, so some confusion surrounds the use of this term.

29.7 | Can We Propose a Unified Theory of Gene Expression?

The stages of eukaryotic gene expression—from transcriptional activation, transcription, transcript processing, nuclear export of mRNA, to translation—have traditionally been presented as a linear series of events, that is, as a pathway of discrete, independent steps. However, it now is clear that each stage is part of a continuous process, with physical and functional connections between the various transcriptional and processing machineries. This realization led George Orphanides and Danny Reinberg

Figure 29.48 A unified theory of gene expression. Each step in gene expression, from transcription to translation, is but a stage within a continuous process. RNAP stands for RNA polymerase II. Each stage is physically and functionally connected to the next, ensuring that all steps proceed in an appropriate fashion and overall regulation of gene expression is tightly integrated. (Adapted from Figure 2 in Orphanides, G., and Reinberg, D., 2002. A unified theory of gene expression. *Cell* 108:439–451.)

to propose a unified theory of gene expression. The principal tenet of this theory is that eukaryotic gene expression is a continuous process, from transcription through processing and protein synthesis: DNA→RNA→protein (Figure 29.48). Furthermore, regulation occurs at multiple levels in this continuous process, in a coordinated fashion. Tom Maniatis and Robin Reed provide additional support for this theory by pointing out that eukaryotic gene expression depends on an interacting network of multicomponent protein machines—nucleosomes, HATs, and the remodeling apparatus; RNA polymerase II and its associated factors, which include capping, splicing, and polyadenylation enzymes; and the proteins involved in mRNA export to the cytoplasm for translation on ribosomes, the topic of the next chapter. Translation is not inevitable. If a noncoding RNA base-pairs with the mRNA, translation will be thwarted. For example, base pairing with a microRNA will result in gene silencing (see Chapter 10 and Section 29.6a). Base pairing with a small interfering RNA (siRNA, Chapter 10) leads to gene knockdown by RNAi through mRNA destruction by the RISC protein complex (see Figure 12.21). Recall that gene silencing is a post-transcriptional regulatory mechanism that prevents translation of an mRNA, whereas RNAi carries out post-transcriptional destruction of mRNAs.

It should be mentioned that eukaryotic cells have elaborate systems for mRNA surveillance; these systems destroy any messages containing errors, such as the **nonsense mediated decay (NMD)** system. NMD degrades any message that has premature nonsense, or stop, codons. Furthermore, the regulation of mRNA levels through selective destruction provides another mechanism for the post-transcriptional regulation of gene expression.

Foundational Biochemistry Things You Should Know after Reading Chapter 29.

- All RNAs are synthesized from DNA templates by DNA-directed RNA polymerases.
- The synthesis of RNA from DNA templates is called transcription.
- Prokaryotes have a single version of RNA polymerase.
- RNA is synthesized in the 5'→3' direction, as RNA polymerase moves along the DNA in a 3'→5' direction.
- The strand of DNA that is transcribed by RNA polymerase is called the template strand.
- The nucleotide sequence of the RNA transcript is identical to the nucleotide sequence of the nontemplate DNA strand (except with U instead of T).
- Bacterial RNA polymerase has an $\alpha_2\beta\beta'\sigma$ subunit composition.
- The σ -subunit recognizes gene promoters, which identify the transcription start site for prokaryotic genes.
- Transcription has four stages:
 - RNA polymerase holoenzyme binding to DNA at promoter sites.
 - Initiation of polymerization.
 - Elongation by the $\alpha_2\beta\beta'$ RNA polymerase core.
 - Termination of polymerization.
- Bacterial promoters contain two consensus sequence elements: the Pribnow box and the -35 region.
- Initiation of polymerization begins formation of an open promoter complex.
- Two transcription termination mechanisms operate in bacteria: Rho (ρ)-mediated termination and intrinsic termination at specific termination sites.
- Bacterial genes are often grouped together in operons.
- Transcription of operons is controlled through induction and repression.
- Operons are units of gene expression that consist of structural genes and regulatory genes.
- *lac* repressor is a negative regulator of the *lac* operon.
- CAP is a positive regulator of the *lac* operon.
- Negative and positive control systems are fundamentally different.
- The *araBAD* operon is both positively and negatively controlled by AraC.
- The *trp* operon is repressed if the Trp repressor protein binds tryptophan.
- Attenuation, a prokaryotic mechanism for post-transcriptional gene regulation, is achieved through formation of alternative secondary structures in the *trp* operon transcript.
- DNA:protein interactions and protein:protein interactions are essential in transcription regulation.
- Proteins that activate transcription exert their effects through protein:protein contacts with RNA polymerase.
- DNA looping allows multiple DNA-binding proteins to convene at the promoter.
- Eukaryotes have three RNA polymerases:
 - RNA polymerase I transcribes rRNA genes.
 - RNA polymerase II transcribes protein-coding genes.
 - RNA polymerase III transcribes tRNA genes and other small RNA genes, including 5S rRNA.
- RNA polymerase II is composed of 12 different subunits.
- The C-terminal domain (CTD) of the RPB1 subunit of RNA polymerase II contains multiple repeats of the amino acid sequence YSPTSPS.

- The CTD multiple YSPTSPS repeats provide multiple phosphorylation sites.
- A phosphorylation code controls RNA polymerase II, regulating mRNA synthesis and processing.
- The regulation of gene expression is more complex in eukaryotes compared to prokaryotes.
- Efficient gene transcription by RNA pol II depends on interactions with proteins bound at two *cis*-regulatory elements (CREs): promoters near the transcription start site (TSS) and more distantly located enhancers.
- About 70% of the human genome is transcribed, even though protein-encoding genes represent only 2% of the genome.
- Inr is the site of transcription initiation.
- Typical eukaryotic promoters contain modules of short, conserved sequences, such as the TATA box and DPEs.
- The location of enhancers (also called upstream activating sequences) is not fixed relative to the promoter.
- Many genes are subject to multiple regulatory influences achieved through an array of different CREs.
- Transcription initiation by RNA pol II requires TBP and the GTFs.
- Formation of the pre-initiation complex (PIC) and promoter opening establishes an initiation complex.
- Transcription initiation also depends on interactions between RNA pol II and Mediator.
- Mediator also functions in repression of transcription.
- Chromatin-remodeling complexes and histone-modifying enzymes alleviate repression due to nucleosomes.
- Chromatin-remodeling complexes are huge, ATP-dependent enzymes that loosen DNA–protein interactions in nucleosomes.
- The various covalent modifications of histones can modulate histone–DNA interactions and create binding sites for recruitment of additional proteins.
- Methylation and phosphorylation act as a binary switch that regulates chromatin dynamics.
- Chromatin deacetylation leads to gene repression.
- Gene regulatory proteins recognize specific DNA sequences through DNA:protein interactions that may or may not involve direct readout of base sequence.
- The three prominent motifs in DNA-binding proteins include the HTH (helix-turn-helix), the Zn finger, and the *bZIP*.
- Eukaryotic genes are split into coding regions (exons) and noncoding regions (introns).
- Post-transcriptional processing of eukaryotic genes includes capping, methylation, 3'-polyadenylation, and splicing.
- Intron excision by the splicing reaction proceeds through formation of a lariat intermediate.
- Splicing depends on a set of snRNPs, each of which contains in its core a specific 100- to 200-nucleotide U-rich RNA chain and a heteroheptamer of Sm proteins.
- The spliceosome is a metal ion-dependent ribozyme.
- Spliceosomes also contain DEAD-box ATPases/helicases that rearrange transcript secondary structure so that the splicing reaction can occur.
- Alternative splicing dramatically increases the number of protein isoforms possible from a single transcript.
- RNA editing through A→I or C→U deamination reactions also increases the diversity of proteins encoded by a transcript.
- Post-transcriptional regulation of gene expression affects virtually all cellular processes.
- miRNAs are key regulators in post-transcriptional gene expression.
- miRNAs are transcribed from intergenic regions of DNA, introns, and even exons.
- miRNAs act as part of miRNA-RISC complexes.
- The miRNAs in miRNA-RISC complexes base-pair imperfectly with sequences in the 3'-UTR of mRNA.
- miRNAs lead to either transcription repression or mRNA decay.
- lncRNAs are an abundant class of RNA transcripts whose biological significance is unclear.
- A unified theory of gene expression describes the events through the sequential participation of multicomponent molecular machines: chromatin decompaction, regulated transcription through RNA polymerase II-Mediator interactions, capping, methylation, polyadenylation, splicing, mRNA packaging and export from the nucleus, and either translation by ribosomes, destruction by RNAi, or silencing by miRNAs in the cytosol.
- The RNA exosome degrades RNAs.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. Template–Transcript Relationships** The 5'-end of an mRNA has the sequence

...AGAUCGUAUGGCGAUCUCGACGAAGACUC-
CUAGGGAAUCC...

What is the nucleotide sequence of the DNA template strand from which it was transcribed? If this mRNA is translated beginning with the first AUG codon in its sequence, what is the N-terminal amino acid sequence of the protein it encodes? (See Table 30.1 for the genetic code.)

- 2. The Events in Transcription Initiation** Describe the sequence of events involved in the initiation of transcription by *E. coli* RNA polymerase. Include in your description all the features a gene must have for proper recognition and transcription by RNA polymerase.

- 3. Substrate Binding by RNA Polymerase** RNA polymerase has two binding sites for ribonucleoside triphosphates: the initiation site and the elongation site. The initiation site has a greater K_m for NTPs than the elongation site. Suggest what possible significance this fact might have for the control of transcription in cells.
- 4. Comparison of Prokaryotic and Eukaryotic Transcription** Make a list of the ways that transcription in eukaryotes differs from transcription in prokaryotes.
- 5. Transcription Components** For each of the following items, give their function in transcription and associated processes.
 - a. $\alpha_2\beta\beta'\sigma$
 - b. TATAAT
 - c. RPB1 through 12
 - d. (YSPTSPS)₂₇ or 52

- e. CREs
 - f. MREs
 - g. GREs
 - h. TBP
 - i. KMTs
 - j. HTH
 - k. Cys-x₂-Cys-x₁₂-His-x₃-His
 - l. AAUAAA
6. **DNA Recognition by DNA-Binding Proteins** DNA-binding proteins may recognize specific DNA regions either by reading the base sequence or by shape readout. How do these two modes of protein:DNA recognition differ?
 7. **The Size of Gene Promoters** (Integrates with Chapter 11.) The metallothionein promoter is illustrated in Figure 29.26. How long is this promoter, in nm? How many turns of B-DNA are found in this length of DNA? How many nucleosomes (approximately) would be bound to this much DNA? (Consult Chapter 11 to review the properties of nucleosomes.)
 8. **Heterodimer Formation by bZIP Proteins** Describe why the ability of bZIP proteins to form heterodimers increases the repertoire of genes whose transcription might be responsive to regulation by these proteins.
 9. **Alternative Splicing Possibilities** Suppose exon 17 were deleted from the fast skeletal muscle troponin T gene (Figure 29.45). How many different mRNAs could now be generated by alternative splicing? Suppose that exon 7 in a wild-type troponin T gene were duplicated. How many different mRNAs might be generated from a transcript of this new gene by alternative splicing?
 10. **Alternative Splicing Possibilities** Determine the number of possible transcripts if a gene contains five, six, or seven introns.
 11. **Histone Modifications and Histone:DNA Interactions** Figure 29.29 illustrates some of the various covalent modifications that occur on histone tails. How might each of these modifications influence DNA: histone interactions?
 12. **Histone Modification** Lysine residues in proteins are typically positively charged. Methylation of the amino group on the side chain of lysine does not abolish this positive charge. How then does methylation affect the interaction possibilities of these lysine residues?
 13. **Inducer Binding to lac Repressor** (Integrates with Chapter 15.) Predict from Figure 29.12 whether the interaction of *lac* repressor with inducer might be cooperative. Would it be advantageous for inducer to show cooperative binding to *lac* repressor? Why?
 14. **Post-transcriptional Modification of Eukaryotic mRNAs** What are the advantages of capping, methylation, and polyadenylation of eukaryotic mRNAs?
 15. **The RNA Polymerase Mechanism of Action** (Integrates with Chapter 28.) Figure 29.24 shows only one Mg²⁺ ion in the RNA polymerase II active site. However, more recent studies reveal the presence of two. Why is the presence of two Mg²⁺ ions significant?
 16. **Chromatin Remodeling Exposes DNA** (Integrates with Chapter 11.) The SWI/SNF chromatin-remodeling complex peels about 50 bp from the nucleosome. Assuming B-form DNA, how long is this DNA segment? In forming nucleosomes, DNA is wrapped in turns about the histone core octamer. What fraction of a DNA turn around the core octamer does 50 bp of DNA comprise? How does 50 bp of DNA compare to the typical size of eukaryotic promoter modules and response elements?
 17. **RNA Splicing Branch Sites** Section 29.5d discusses the conserved sequences at branch sites in RNA molecules that undergo splicing. Consider the sequences shown below and indicate which ones are branch sites.
 - a. CUUGAC
 - b. CGUAGU
 - c. UUUAAU
 - d. TCCAAC
 - e. GGUAAU
 - f. UACGAG

 18. **The Lariat Intermediate in RNA Splicing** Draw the structures that comprise the lariat branch point formed during mRNA splicing: the invariant A, its 5'-R neighbor, its 3'-Y neighbor, and its 2'-G neighbor.
 19. **HTH DNA-Binding Proteins and B-DNA Dimensions** (Integrates with Chapters 6 and 11.) The α -helices in HTH (helix-turn-helix motif) DNA-binding proteins are formed from seven- or eight-amino acid residues. What is the overall length of these α -helices? How does their length compare with the diameter of B-form DNA?
 20. **Separating RNA from DNA** (Integrates with Chapter 4.) During the transcription process, the emerging RNA molecule is separated from the DNA template by RPB1 (see Section 29.3b). Residue Phe²⁵² of RPB1 is responsible for this separation. Explain why Phe is ideal for this purpose. Which other amino acids might replace Phe in carrying out this function?
 21. **Exploring the Structure of RNA Polymerase** Bacteriophage T7 RNA polymerase bound to two DNA strands and an RNA strand, as shown in pdb file 1MSW, provides a glimpse of transcription. View this structure at <https://www.rcsb.org> to visualize how the template DNA strand is separated from the nontemplate strand and transcribed into an RNA strand. Which Phe residue of the enzyme plays a significant role in DNA strand separation? In which domain of the polymerase is this Phe located? (You might wish to consult Yin, Y. W., and Steitz, T. A., 2002. Structural basis for the transition from initiation to elongation transcription in T7 RNA polymerase. *Science* 298:1387–1395 to confirm your answer.)
 22. **Structure of α -Amanitin** (Integrates with Chapter 4.) Figure 29.23 shows the structure of the cyclic polypeptide α -amanitin. Which five amino acids or derivatives of amino acids are present in this structure?
 23. **α -Amanitin Inhibition of RNA Polymerase II** RNA polymerase II is inhibited by α -amanitin. This mushroom-derived toxin has no effect on the enzyme's affinity for NTP substrates, but it dramatically slows polymerase translocation along the DNA. Go to <https://www.rcsb.org> to view pdb file 1K83, which is the structure of RNA polymerase II with bound α -amanitin. Locate α -amanitin within this structure, and discuss why its position is consistent with its mode of inhibition.
 24. **Exploring the Structure of a DNA-Bound bZIP Transcription Factor** C/EBP β is a bZIP transcription factor in neuronal differentiation, learning and memory process, and other neuronal and glial functions. The structure of the bZIP domain of C/EBP β bound to DNA is shown in pdb file 1GU4. Explore this structure to discover the leucine zipper dimerization domain and the DNA-binding basic regions. On the left side of the <https://www.rcsb.org> 1GU4 page under "Display Files," click "pdb file" to see the atom-by-atom coordinates in the three-dimensional structure (scroll down past "Remarks" to find this information). Toward the end of this series, find the amino acid sequence of the C/EBP β domain used in this study. Within this amino acid sequence, find the leucine residues of the leucine zipper and the basic residues in the DNA-binding basic region.
 25. **Protein:DNA Interactions with Catabolite Activator Protein** Figure 29.15 highlights in red the DNA phosphate oxygen atoms. Some of them interact with catabolite activator protein (CAP). What kind of interactions do you suppose predominate, and what kinds of CAP amino acid side chains might be involved in these interactions?
 26. **Chromatin Decompaction and Gene Expression** Chromatin decompaction is a preliminary step in gene expression (Figure 29.48). How is chromatin decompacted?

Think-Pair-Share Question

Splicing of RNA Consider the RNA sequence shown. Using the information discussed in Sections 29.5d and 29.5e:

- Identify possible 5' splicing sites, branch sites, and 3' splicing sites.
- Suggest possible splicing products from this RNA.

Georg Gerster/Science Source

We are a spectacular, splendid manifestation of life. We have language and can build metaphors as skillfully and precisely as ribosomes make proteins. We have affection. We have genes for usefulness, and usefulness is about as close to a “common goal” of nature as I can guess at. And finally, and perhaps best of all, we have music.

Lewis Thomas (1913–1994)
“The Youngest and Brightest Thing Around”
in *The Medusa and the Snail* (1979)

◀ The Maya encoded their history in hieroglyphs carved on stelae and temples like these ruins in Yucatan Peninsula, Mexico. They were finally translated when it became apparent that the glyphs are pictorial signs representing words or syllables in the Mayan language. The 800 or so Mayan glyphs can be arranged to form sentences capable of expressing any fact or concept.

Essential Question

Ribosomes synthesize proteins by reading the nucleotide sequence of mRNAs and polymerizing amino acids in an N→C direction. **How is the nucleotide sequence of an mRNA molecule translated into the amino acid sequence of a protein molecule?**

We turn now to the problem of how the sequence of nucleotides in an mRNA molecule is translated into the specific amino acid sequence of a protein. The question is: “What is the **genetic code** that allows the information specified in the sequence of bases to be translated into the amino acid sequence of a polypeptide?” That is, how is the 4-letter language of nucleic acids translated into the 20-letter language of proteins? It is easy to see how base-pairing establishes a one-to-one correspondence that allows the template-directed synthesis of polynucleotide chains in the processes of replication and transcription. However, there is no obvious chemical affinity between the purine or pyrimidine bases and the 20 different amino acids. Nor is there any obvious structural or stereochemical connection between polynucleotides and amino acids that might guide the translation of information.

Francis Crick reasoned that **adapter molecules** must bridge this information gap. These adapter molecules must interact specifically with both nucleic acids (mRNAs) and amino acids. At least 20 different adapter molecules would be needed, at least one for each amino acid. The various adapter molecules would be able to read the genetic code in an mRNA template and align the amino acids according to the template’s directions so that they could be polymerized into a unique polypeptide. Transfer RNAs (tRNAs; Figure 30.1) are these adapter molecules (see Chapter 10). Amino acids are attached to the 3′-OH at the 3′-CCA end of tRNAs as aminoacyl esters. The formation of these aminoacyl-tRNAs, so-called **charged tRNAs**, is catalyzed by specific **aminoacyl-tRNA synthetases**. There is one of these enzymes for each of the 20 amino acids and each aminoacyl-tRNA synthetase loads its amino acid only onto tRNAs designed to carry it. In turn, these tRNAs specifically recognize unique sequences of bases in the mRNA through complementary base pairing.

Key Questions

- 30.1 What Is the Genetic Code?
- 30.2 How Is an Amino Acid Matched with Its Proper tRNA?
- 30.3 What Are the Rules in Codon–Anticodon Pairing?
- 30.4 What Is the Structure of Ribosomes, and How Are They Assembled?
- 30.5 What Are the Mechanics of mRNA Translation?
- 30.6 How Are Proteins Synthesized in Eukaryotic Cells?
- 30.7 Do Protein Synthesis Inhibitors Have Clinical Applications?

Figure 30.1 Generalized secondary structure of tRNA molecules. Circles represent nucleotides in the tRNA sequence. The numbers given indicate the standardized numbering system for tRNAs (which differ in total number of nucleotides). Dots indicate places where the number of nucleotides may vary in different tRNA species. All tRNAs have the invariant 3-base sequence CCA at their 3'-ends. The amino acid is attached here to the ribose of the terminal A. Recall from Chapter 10 that tRNA molecules often have modified or unusual bases.

Figure 30.2 (a) An overlapping versus a nonoverlapping code. (b) A continuous versus a punctuated code.

30.1 | What Is the Genetic Code?

Once it was realized that the sequence of bases in a gene specified the sequence of amino acids in a protein, various possibilities for such a genetic code were considered. How many bases are necessary to specify each amino acid? Is the code overlapping or nonoverlapping (Figure 30.2)? Is the code punctuated or continuous? Mathematical considerations favored a triplet of bases as the minimal code word, or **codon**, for each amino acid: A doublet code based on pairs of the four possible bases, A, C, G, and U, has $4^2 = 16$ unique arrangements, an insufficient number to encode the 20 amino acids. A triplet code of four bases has $4^3 = 64$ possible code words, more than enough for the task.

30.1a The Genetic Code Is a Triplet Code

The genetic code is a triplet code read continuously from a fixed starting point in each mRNA. Typically, the fixed starting point is the first nucleotide in the codon that specifies the first amino acid in the protein being synthesized. The genetic code it is defined by the following:

1. A group of three bases codes for one amino acid.
2. The code is not overlapping. It begins at a particular nucleotide and is read in groups of three from that first nucleotide. Alternative readings starting from the second or third nucleotide are not permitted by the translation machinery (Figure 30.2a).
3. The base sequence is read continuously from the fixed starting point without punctuation (Figure 30.2b). That is, the mRNA sequences contain no “commas” signifying appropriate groupings of triplets. Successive triplets define the **reading frame**. If the reading frame is displaced by one base, it remains shifted throughout the subsequent message; no “commas” are present to restore the “correct” frame.

30.1b Codons Specify Amino Acids

The complete translation of the genetic code is presented in Table 30.1. This code is often referred to as the Universal Genetic Code because, with few exceptions, it is invariant across all forms of life. Codons, like other nucleotide sequences, are read 5'→3'. Codons represent triplets of bases in mRNA or, replacing U with T, triplets along the nontranscribed (nontemplate) strand of DNA.

Several noteworthy features characterize the genetic code:

1. *All the codons have meaning.* Of the 64 codons, 61 specify particular amino acids. The remaining 3—UAA, UAG, and UGA—specify no amino acid and, thus, they are **nonsense codons**. Nonsense codons serve as **termination codons**; they are stop signals indicating that the end of the protein has been reached.
2. *The genetic code is unambiguous.* Each of the 61 sense codons encodes only one amino acid.
3. *The genetic code is degenerate.* Recall that a triple code yields 64 codons for 20 amino acids. Most codons (61 of 64) code for some amino acid. With the exception of Met and Trp, every amino acid is coded by more than one codon. Several—Arg, Leu, and Ser—are represented by six different codons. Codons coding for the same amino acid are called **synonymous codons**.
4. *Codons representing the same amino acid or chemically similar amino acids tend to be similar in sequence.* Often the third base in a codon is irrelevant, so, for example, all four codons in the GGX family specify Gly, and the UCX family specifies Ser (Table 30.1). This feature is known as **third-base degeneracy**. Note also that codons with a pyrimidine as second base likely encode amino acids with hydrophobic side chains, and codons with a purine in the second-base position typically specify polar

Table 30.1 The Genetic Code						Third-Base Degeneracy Is Color-Coded		
First Position (5'-end)	Second Position				Third Position (3'-end)	Third-Base Relationship	Third Bases with Same Meaning	Number of Codons
U	U	C	A	G	U C A G	Third base irrelevant	U, C, A, G	32 (8 families)
	UUU Phe	UCU Ser	UAU Tyr	UGU Cys		Purines	A or G	12 (6 pairs)
	UUC Phe	UCC Ser	UAC Tyr	UGC Cys		Pyrimidines	U or C	14 (7 pairs)
	UUA Leu	UCA Ser	UAA Stop	UGA Stop		Three out of four	U, C, A	3 (AUX = Ile)
C	UUG Leu	UCG Ser	UAG Stop	UGG Trp	U C A G	Unique definitions	G only	2 (AUG = Met) (UGG = Trp)
	CUU Leu	CCU Pro	CAU His	CGU Arg		Unique definition	A only	1 (UGA = Stop)
	CUC Leu	CCC Pro	CAC His	CGC Arg				
	CUA Leu	CCA Pro	CAA Gln	CGA Arg				
A	CUG Leu	CCG Pro	CAG Gln	CGG Arg	U C A G			
	AUU Ile	ACU Thr	AAU Asn	AGU Ser				
	AUC Ile	ACC Thr	AAC Asn	AGC Ser				
	AUA Ile	ACA Thr	AAA Lys	AGA Arg				
G	AUG Met*	ACG Thr	AAG Lys	AGG Arg	U C A G			
	GUU Val	GCU Ala	GAU Asp	GGU Gly				
	GUC Val	GCC Ala	GAC Asp	GGC Gly				
	GUA Val	GCA Ala	GAA Glu	GGA Gly				
	GUG Val	GCG Ala	GAG Glu	GGG Gly				

*AUG signals translation initiation as well as coding for Met residues.

- or charged amino acids. The two negatively charged amino acids, Asp and Glu, are encoded by GAX codons; GA–pyrimidine gives Asp and GA–purine specifies Glu. The consequence of these similarities is that mutations are less likely to be harmful because single base changes in a codon will result either in no change or in a substitution with an amino acid similar to the original amino acid. The degeneracy of the code is evolution’s buffer against mutational disruption.
5. *The genetic code is universal.* Although certain minor exceptions in codon usage occur (see A Deeper Look box “Natural and Unnatural Variations in the Standard Genetic Code,” Section 30.1), the more striking feature of the code is its universality: Codon assignments are virtually the same throughout all organisms—Archaea, bacteria, and eukaryotes. This conformity means that all extant organisms use the same genetic code, providing strong evidence that they all evolved from a common primordial ancestor.

Careers in Chemistry

Dr. Alison Brown

Dr. Alison Brown currently serves as the Program Director for the National Institutes of Health’s National Heart, Blood, and Lung Institute. Her work focuses on the social determinants of health, social health disparities, and obesity prevention.

Dr. Brown’s educational training includes a Bachelor’s in Chemistry from Spelman, a Master’s in Nutrition and Applied Physiology from Columbia, and a Ph.D. from the Friedman School of Nutrition

Science and Policy at Tufts University. Her hard work provided the foundation needed to do the important work she does today at the crossroads between health and social research. At the NIH, Dr. Brown manages grants, heads committees, and translates scientific research into policy changes. Making use of her extensive qualifications, Dr. Brown ensures that the scientific research she oversees adheres to policies that benefit the general public.

A Deeper Look

Natural and Unnatural Variations in the Standard Genetic Code

The genomes of some lower eukaryotes, prokaryotes, and mitochondria show some exceptions to the standard genetic code (Table 30.1) in codon assignments. The phenomenon is more common in mitochondria. For example, the termination codon UGA codes for tryptophan in mitochondria from various animals, protozoans, and fungi. AUA, normally an Ile codon, codes for methionine in some animal and fungal mitochondrial genomes, and AGA (an Arg codon) is a termination codon in vertebrate mitochondria but is a Ser codon in fruit fly mitochondria. Mitochondria in several species of yeast use the CUX codons to specify Thr instead of Leu. Some yeast and algal mitochondria use CGG, normally an Arg codon, as a stop codon.

Less common are genomic codon variations within the genomes of prokaryotic and eukaryotic cells. Among the lower eukaryotes, certain ciliated protozoans (*Tetrahymena* and *Paramecium*) use UAA and UGA as glutamine codons rather than stop codons. Instances in prokaryotes include use of the stop codon UGA to specify Trp by *Mycoplasma*. Perhaps most interesting is the use of some UGA codons by both prokaryotes and eukaryotes (including humans) to specify **selenocysteine (Sec)**, an analog of cysteine in which the sulfur atom is replaced by a selenium atom. Indeed, the identification of Sec residues in proteins from bacteria, archaea, and eukaryotes has led some people to nominate Sec as the twenty-first amino acid! (Pyrrolysine, encoded by the stop codon AUG in certain archaea and bacteria, has been touted as the twenty-second amino acid; it is not present in humans.) Sec formation requires a novel Sec-specific tRNA known as tRNA^{Sec}. This tRNA^{Sec} is loaded with a Ser residue by seryl-tRNA synthetase, the aminoacyl-tRNA synthetase for serine. Then, the enzyme selenocysteine synthase catalyzes a reaction wherein the Ser-O is replaced by Se. Translation of UGA codons by selenocysteinyl-tRNA^{Sec} depends on the presence of specific stem-loop secondary structures in the mRNA called **SECIS elements** that recode the UGA codon from stop to Sec. SECIS elements are recognized by specific proteins that recruit selenocysteinyl-tRNA^{Sec} to the UGA codon during protein synthesis. Most selenoproteins (proteins containing selenocysteine) are involved in oxidation–reduction reactions, and Sec participates

directly in the catalytic mechanism. Sec provides a more reactive functionality than Cys.

It is also possible now to manipulate the genetic code, tRNAs, and aminoacyl-tRNA synthetases to introduce amino acids never before imagined into proteins of interest. Bacterial, yeast, and mammalian cells, as well as cell-free systems for synthetic biology, have been engineered so that genetically encoded unnatural amino acids with desired physical, chemical, or biological properties can be placed at any position in a protein. Hundreds of such unnatural amino acids, each with a chemically unique side chain, can be incorporated into proteins using virtually any codon and an appropriately engineered tRNA–aminoacyl-tRNA synthetase pair.

30.2 How Is an Amino Acid Matched with Its Proper tRNA?

Two codes lie at the heart of translation. The more familiar one is codon recognition, achieved by aminoacyl-tRNAs. In order for accurate translation to occur, the appropriate aminoacyl-tRNA must read the codon through base pairing via its **anticodon loop** (see Figure 30.1). Once an aminoacyl-tRNA has been synthesized, the amino acid part makes no contribution to accurate translation of the mRNA. That is, the amino acid is passively chauffeured by its tRNA and becomes inserted into a growing peptide chain following codon–anticodon recognition between the mRNA and tRNA.

While base-pairing allows a tRNA to recognize a codon, how is an amino acid loaded onto its **cognate tRNAs** (those tRNAs having anticodons that can read one or more of the codons specifying that particular amino acid)?

30.2a Aminoacyl-tRNA Synthetases Interpret the Second Genetic Code

A **second genetic code** must exist, the code by which each aminoacyl-tRNA synthetase matches up its amino acid with tRNAs that base-pair with those codons for its amino acid. To interpret this second genetic code, an aminoacyl-tRNA synthetase discriminates between the 20 amino acids and the many tRNAs and uniquely picks out its proper substrates—one specific amino acid and the tRNA(s) appropriate to it—from among the more than 400 possible combinations. The appropriate tRNAs are those having anticodons that recognize the codons specifying the particular amino acid. It is imperative that the proper amino acids be loaded onto the various tRNAs so that the mRNA can be translated with fidelity. Although the primary genetic code is key to understanding the central dogma of molecular biology that dictates how DNA encodes proteins, the second genetic code is just as crucial to the fidelity of information transfer.

Eukaryotic cells and some bacteria have 20 different aminoacyl-tRNA synthetases, one for each amino acid. Each of these enzymes catalyzes ATP-dependent attachment of its specific amino acid to the 3'-end of its cognate tRNA molecules (Figure 30.3). The products of the reaction are an aminoacyl-tRNA, AMP, and PP_i. Ever-present pyrophosphatases quickly hydrolyze the pyrophosphate product to give two P_i. This highly exergonic reaction provides the overall thermodynamic driving force for aminoacyl-tRNA synthesis. The aminoacyl-tRNA synthetase reaction serves two purposes:

1. It activates the amino acid so that it will readily react to form a peptide bond.
2. It bridges the information gap between amino acids and codons.

The underlying mechanisms of molecular recognition used by each aminoacyl-tRNA synthetase to bring the proper amino acid to its cognate tRNA are the embodiment of the second genetic code. An exception to these rules is the fact that most bacteria and archaea do not have specific aminoacyl-tRNA synthetases for Asn and/or Gln. Instead, the Asp- and Glu-tRNA synthetases are used to load Asp and Glu onto tRNA^{Asn} and tRNA^{Gln}, respectively. Then these aminoacyl groups are amidated by tRNA-dependent amidotransferases to yield Asn-tRNA^{Asn} and Gln-tRNA^{Gln} for protein synthesis.

Most aminoacylated-tRNAs are destined to deliver their amino acids to the translational apparatus for use in protein synthesis. However, aminoacylated-tRNAs also serve as aminoacyl donors for a number of other purposes. For example, aminoacyl-tRNAs are involved in tagging the N-termini of proteins for degradation (see Figure 31.11), in the delivery of amino acids for peptidoglycan synthesis (see Figure 7.29), as substrates for amino acid addition to membrane lipids (as in the formation of lysyl-phosphatidylglycerol, thereby dramatically altering the charge of this membrane lipid), and as substrates in antibiotic biosynthesis (for example, the synthesis of valinomycin).

30.2b Evolution Has Provided Two Distinct Classes of Aminoacyl-tRNA Synthetases

Despite their common enzymatic function, aminoacyl-tRNA synthetases are a diverse group of proteins in terms of size, amino acid sequence, and oligomeric structure. In higher eukaryotes, some aminoacyl-tRNA synthetases are assembled into

Figure 30.3 The aminoacyl-tRNA synthetase reaction. (a) The overall reaction. (b) Aminoacyl-tRNA formation proceeds in two steps: (i) formation of an aminoacyl-adenylate and (ii) transfer of the activated amino acid moiety of the mixed anhydride to either the 2'-OH (class I aminoacyl-tRNA synthetases) or 3'-OH (class II aminoacyl-tRNA synthetases) of the ribose on the terminal adenylic acid at the 3'-CCA terminus common to all tRNAs. Those aminoacyl-tRNAs formed as 2'-aminoacyl esters undergo a transesterification that moves the aminoacyl function to the 3'-O of tRNA. Only the 3'-esters are substrates for protein synthesis.

large multiprotein complexes. The aminoacyl-tRNA synthetases fall into two fundamental classes on the basis of similar amino acid sequence motifs, oligomeric state, and acylation function (Table 30.2): class I and class II. Class I aminoacyl-tRNA synthetases first add the amino acid to the 2'-OH of the terminal adenylylated residue of tRNA before shifting it to the 3'-OH; class II enzymes add it directly to the 3'-OH (Figure 30.3). The catalytic domains of these enzymes evolved from two different ancestral predecessors. Aminoacyl-tRNA synthetases are ranked among the oldest

proteins because the different classes of these enzymes were present very early in evolution. Class I and class II aminoacyl-tRNA synthetases interact with the tRNA 3'-terminal CCA and acceptor stem in a mirror-symmetric fashion with respect to each other (Figure 30.4). Class I enzymes bind to the tRNA acceptor stem helix from the minor-groove side, whereas class II enzymes bind it from the major-groove side.

Both class I and class II aminoacyl-tRNA synthetases can be represented as two-domain structures, as can their L-shaped tRNA substrates, which have the acceptor stem/CCA-3'-OH at one end and the anticodon stem-loop at the other (see Figures 11.35 and 30.5). This L-shaped tertiary structure of tRNAs separates the 3'-CCA acceptor end from the anticodon loop by a distance of 7.6 nm. The two domains of tRNAs have distinct functions: The 3'-CCA end is the site of aminoacylation, and the anticodon-containing domain interacts with the mRNA template. The two domains of tRNAs interact with the separate domains in the synthetases. One of the two major aminoacyl-tRNA synthetase domains is the catalytic domain (which defines the difference between class I and class II enzymes); this domain interacts with the tRNA 3'-CCA end. The other major domain in aminoacyl-tRNA synthetases is highly variable and interacts with parts of the tRNA beyond the acceptor-TΨC stem-loop domain, including, in some cases, the anticodon.

30.2c Aminoacyl-tRNA Synthetases Can Discriminate Between the Various tRNAs

Aside from the need to uniquely recognize their cognate amino acids, aminoacyl-tRNA synthetases must be able to discriminate between the various tRNAs. The structural features that permit the synthetases to recognize and aminoacylate their cognate tRNA(s) are *not* universal. That is, a common set of rules does not govern tRNA recognition by these enzymes. Most surprising is the fact that the recognition features are not limited to the anticodon and, in some instances, do not even include the anticodon. For most tRNAs, a set of sequence elements is recognized by its specific aminoacyl-tRNA synthetase, rather than a single distinctive nucleotide or base pair. These elements include one or more of the following: (1) at least one base in the anticodon; (2) one or more of the three base pairs in the acceptor stem; and (3) the base at canonical position 73 (the unpaired base preceding the CCA end), referred to as the **discriminator base** because this base is invariant in the tRNAs for a particular amino acid. Figure 30.5 presents a ribbon diagram of a tRNA molecule showing the location of nucleotides that contribute to specific recognition by the respective aminoacyl-tRNA synthetases for each of the 20 amino acids. Interestingly, the same set of tRNA features that serves as positive determinants for binding and aminoacylation of the tRNA by its cognate aminoacyl-tRNA synthetase may act as negative

Table 30.2 The Two Classes of Aminoacyl-tRNA Synthetases

Class I	Class II
Arg	Ala
Cys	Asn
Gln	Asp
Glu	Gly
Ile	His
Leu	Lys
Met	Phe
Trp	Pro
Tyr	Ser
Val	Thr

Figure 30.4 Mirror-symmetric interactions of class I versus class II aminoacyl-tRNA synthetases with their tRNA substrates. The two different classes of aminoacyl-tRNA synthetases bind to opposite faces of tRNA molecules. **(a)** The structure of the class I glutamyl-tRNA^{Gln} synthetase: tRNA^{Gln} complex with a bound active-site inhibitor (orange; PDB id = 1EUQ). Note that the enzyme is on the left side of the tRNA in this view. **(b)** The structure of the class II threonyl-tRNA^{Thr} synthetase: tRNA^{Thr} complex with AMP (red) at the active site (PDB id = 1QF6). Note that most of the aminoacyl-tRNA synthetase structure is on the right side of the tRNA. The relative orientation of the tRNA is the same in both structures, with the 3'-CCA end of the tRNA pointed away from the viewer.

Figure 30.5 Ribbon diagram of tRNA tertiary structure. Numbers represent the consensus nucleotide sequence (see Figure 30.1). The locations of nucleotides recognized by the various aminoacyl-tRNA synthetases are indicated; shown within the boxes are one-letter designations of the amino acids whose respective aminoacyl-tRNA synthetases interact at the discriminator base (position 73), acceptor stem, variable pocket and/or loop, or anticodon. The inset shows additional recognition sites in those tRNAs having a variable loop that forms a stem-loop structure. (Adapted from Figure 2 in Saks, M. E., Sampson, J. R., and Abelson, J. N., 1994. The transfer RNA problem: a search for rules. *Science* 263:191–197.)

Figure 30.6 Major identity elements in four tRNA species. Each base in the tRNA is represented by a circle. Numbered filled circles indicate positions of identity elements within the tRNA that are recognized by its specific aminoacyl-tRNA synthetase. (Adapted from Schulman, L. H., and Abelson, J., 1988. Recent excitement in understanding transfer RNA identity. *Science* 240:1591–1592.)

determinants that prohibit binding and aminoacylation by other (noncognate) aminoacyl-tRNA synthetases. Because no common set of rules exists, the second genetic code is an **operational code** based on aminoacyl-tRNA synthetase recognition of varying sequence and structural features in the different tRNA molecules during the operation of aminoacyl-tRNA synthesis. Some examples of this code are given in Figure 30.6.

30.2d *Escherichia coli* Glutaminyl-tRNA^{Gln} Synthetase Recognizes Specific Sites on tRNA^{Gln}

E. coli glutaminyl-tRNA^{Gln} synthetase, a class I enzyme, provides a good illustration of aminoacyl-tRNA synthetase:cognate tRNA interactions. This glutaminyl-tRNA^{Gln} synthetase shares a continuous interaction with its cognate tRNA that extends from the anticodon to the acceptor stem along the entire inside of the L-shaped tRNA (Figure 30.7). Specific recognition elements include enzyme contacts with the discriminator base, acceptor stem, and anticodon, particularly the central U in the CUG anticodon. The carboxylate group of Asp²³⁵ makes sequence-specific H bonds in the tRNA minor groove with the guanine 2-NH₂ group in the base pair G3:C70 of the acceptor stem. A mutant glutaminyl-tRNA^{Gln} synthetase with Asn substituted for Asp at position 235 shows relaxed specificity; that is, it now will acylate noncognate tRNAs with Gln.

30.2e The Identity Elements Recognized by Some Aminoacyl-tRNA Synthetases Reside in the Anticodon

Alteration of the anticodons of either tRNA^{Trp} or tRNA^{Val} to CAU, the anticodon for the methionine codon AUG, transforms each of the tRNAs into a substrate for methionyl-tRNA synthetase, and they are loaded with methionine. Similarly, reversing the methionine CAU anticodon of tRNA^{Met} to UAC transforms it into a substrate for valyl-tRNA^{Val} synthetase. Clearly, methionyl-tRNA synthetase and valyl-tRNA synthetase rely on the anticodon in selecting tRNAs for loading.

30.2f A Single G:U Base Pair Defines tRNA^{Ala}s

The noncanonical base pair, G3:U70, is the singular feature by which alanyl-tRNA^{Ala} synthetase recognizes tRNAs as its substrates. All tRNA^{Ala} representatives, from archaea to eukaryotes, possess this G3:U70 acceptor stem base pair. Altering this unusual G3:U70 base pair of tRNA^{Ala} to G:C, A:U, or even U:G abolishes its ability to be aminoacylated with alanine. On the other hand, provided the G3:U70 base pair is present, alanyl-tRNA^{Ala} synthetase aminoacylates a 24-nucleotide stem-loop analog of tRNA^{Ala} (Figure 30.8). The key feature of the G3:U70 base pair is the 2-NH₂ group of G3. In the RNA A-form double-helical structure adopted by the tRNA acceptor stem, the G3 2-NH₂ group is exposed in the minor groove of the helix, and if the G3 pairing partner is a U, this 2-NH₂ group lacks an H-bonding partner (Figure 30.8). Thus, an unpaired G 2-amino group at the right place in a tRNA acceptor stem marks a tRNA for aminoacylation by alanyl-tRNA^{Ala} synthetase. Interactions between alanyl-tRNA^{Ala} synthetase and the G3:U70 base pair cause conformational changes along the tRNA acceptor stem. These changes direct the entry of the 3'-CCA acceptor end into the enzyme's active site. The 3'-CCA acceptor ends of tRNAs lacking a G3:U70 base pair are not reoriented to the alanyl-tRNA^{Ala} synthetase active site and thus are not aminoacylated.

Figure 30.7 Structure of *E. coli* glutamyl-tRNA^{Gln} synthetase complexed with tRNA^{Gln} and ATP (PDB id = 1GSG). The protein:tRNA contact region extends along one side of the entire length of this extended protein. The acceptor stem of the tRNA and the ATP (green) fit into a cleft at the top of the protein in this view. The enzyme also interacts extensively with the anticodon (lower tip of tRNA^{Gln}).

Figure 30.8 Identification of the key feature that determines whether or not a tRNA is aminoacylated by alanyl-tRNA^{Ala} synthetase. **(a)** Secondary structure of the tRNA^{Ala} having the GGC anticodon (tRNA^{Ala}/GGC) (left) and its stem microhelix^{Ala} analog (right). The microhelix^{Ala} consists of nucleotides 1 through 13 of tRNA^{Ala}/GGC connected directly to 66 through 76 to recreate the tRNA^{Ala} 7 bp acceptor stem. Because the microhelix analog has the characteristic G3:U70 base pair found in tRNA^{Ala}, it is aminoacylated by alanyl-tRNA^{Ala} synthetase. **(b)** The key determinant, the unbonded 2-NH₂ group of the G3 in the G3:U70 base pair, would lie within the minor groove of an A-form RNA double helix. Figure 30.9 Codon–anticodon pairing. Complementary trinucleotide sequence elements align in antiparallel fashion.

30.3 | What Are the Rules in Codon–Anticodon Pairing?

Protein synthesis depends on the codon-directed binding of the proper aminoacyl-tRNAs so that the right amino acids are sequentially aligned according to the specifications of the mRNA undergoing translation. This alignment is achieved via codon–anticodon pairing in antiparallel orientation (Figure 30.9). However, considerable degeneracy exists in the genetic code at the third position. Conceivably, this degeneracy could be handled in either of two ways: (1) Codon–anticodon recognition could be highly specific so that a complementary anticodon is required for each of the 61 sense codons, or (2) fewer than 61 anticodons could be used for the sense codons if certain allowances were made in the base-pairing rules. Then, some anticodons could recognize more than one codon. As early as 1965, it was known that poly(U) bound *all* Phe-tRNA^{Phe} molecules even though UUC is also a Phe codon. The phenylalanine-specific tRNAs could recognize either UUU or UUC. Also, one particular yeast tRNA^{Ala} was able to bind to three codons: GCU, GCC, and GCA.

Interestingly, the tRNA anticodon is the site of the most diverse and chemically complex post-transcriptional modifications found in RNA. These modifications play a key role in codon-anticodon recognition.

30.3a Francis Crick Proposed the Wobble Hypothesis for Codon–Anticodon Pairing

Francis Crick considered these results and tested alternative base-pairing possibilities by model building. He hypothesized that the first two bases of the codon and the last two bases of the anticodon form canonical Watson–Crick A:U or G:C base pairs, but pairing between the third base of the codon and the first base of the anticodon follows less stringent rules. That is, a certain amount of play, or **wobble**, might be allowed in base pairing at this position. The third base of the codon is sometimes referred to as the **wobble position**.

Crick’s investigations suggested a set of rules for pairing between the third base of the codon and the first base of the anticodon (Table 30.3). The wobble rules indicate that a first-base anticodon U could recognize either an A or G in the codon third-base position; first-base anticodon G might recognize either U or C in the third-base position of the codon; and first-base anticodon I (inosine (6-OH purine)) might interact with U, C, or A in the codon third position (Figure 30.10). Thus, the first base of the anticodon indicates whether the tRNA can read one, two, or three different codons. Anticodons beginning with A or C read only one codon, those beginning with G or U read two, and anticodons beginning with I can read three codons.

The wobble rules also predict that four-codon families (like Pro or Thr), where any of the four bases may be in the third position, require at least two different tRNAs. However, all members of the set of tRNAs specific for a particular amino acid—termed **isoacceptor tRNAs**—are served by one aminoacyl-tRNA synthetase.

30.3b Some Codons Are Used More Than Others

Because more than one codon exists for most amino acids, the possibility for variation in codon usage arises. Indeed, variation in codon usage accommodates the fact that the DNA of different organisms varies in relative A:T/G:C content. Nevertheless, even in organisms of average base composition, codon usage may be biased. Table 30.4 gives some examples from *E. coli* and humans reflecting the nonrandom usage of codons. Of more than 109,000 Leu codons tabulated in a set of human genes, CUG was used in excess of 48,000 times, CUC more than 23,000 times, but UUA just 6000 times.

The occurrence of codons in *E. coli* mRNAs correlates well with the relative abundance of the tRNAs that read them. Preferred codons are represented by the most abundant isoacceptor tRNAs. Furthermore, mRNAs for proteins that are synthesized in abundance tend to employ preferred codons. Rare tRNAs correspond to rarely used codons, and messages containing such codons might experience delays in translation.

Table 30.3 Base-Pairing Possibilities at the Third Position of the Codon	
Base on the Anticodon	Bases Recognized on the Codon
U	A, G
C	G
A	U
G	U, C
I	U, C, A

Figure 30.10 Pairing of anticodon inosine (I, *left*) with C, U, or A as the codon third base. Note that I is in the keto tautomeric form.

Table 30.4 Representative Examples of Codon Usage in *E. coli* and Human Genes

Amino Acid	Codon	<i>E. coli</i> Gene Frequency/1000	Human Gene Frequency/1000
Leu	CUA	3.2	6.1
	CUC	9.9	20.1
	CUG	54.6	42.1
	CUU	10.2	10.8
	UUA	10.9	5.4
	UUG	11.5	11.1
Pro	CCA	8.2	15.4
	CCC	4.3	20.6
	CCG	23.8	6.8
	CCU	6.6	16.1
Ala	GCA	15.6	14.4
	GCC	34.4	29.7
	GCG	32.9	7.2
	GCU	13.4	18.9
Lys	AAA	36.5	21.9
	AAG	12.0	35.2
Glu	GAA	43.5	26.4
	GAG	19.2	41.6

The results are expressed as the frequency of occurrence of a codon per 1000 codons tabulated in 1562 *E. coli* genes and 2681 human genes. (Because *E. coli* and human proteins differ somewhat in amino acid composition, the frequencies for a particular amino acid do not correspond exactly between the two species.)

30.3c Nonsense Suppression Occurs When Suppressor tRNAs Read Nonsense Codons

Mutations that alter a sense codon to one of the three nonsense codons—UAA, UAG, or UGA—result in premature termination of protein synthesis and the release of truncated (incomplete) polypeptides. The nonsense codons are named ochre (UAA), amber (UAG), and opal (UGA). Geneticists found that second mutations elsewhere in the genome were able to *suppress* the effects of nonsense mutations so that the organism survived, a phenomenon termed **nonsense suppression**. The molecular basis for nonsense suppression was a mystery until it was realized that **suppressors** were mutations in tRNA genes that altered the anticodon so that the mutant tRNA could now read a particular stop codon and insert an amino acid. For example, alteration of the anticodon of a tRNA^{Tyr} from GUA to CUA allows this tRNA to read the *amber* stop codon, UAG, and insert Tyr. **Suppressor tRNAs** are typically generated from minor tRNA species within a set of isoacceptor tRNAs, so their recruitment to a new role via mutation does not involve loss of an essential tRNA; that is, the mutation is not particularly deleterious to the organism. A suppressor tRNA, as a mutant tRNA, may even carry and introduce an amino acid different from the one borne by the wild-type tRNA.

30.4 | What Is the Structure of Ribosomes, and How Are They Assembled?

Protein biosynthesis is achieved by the process of **translation**. Translation converts the language of genetic information embodied in the base sequence of a messenger RNA molecule into the amino acid sequence of a polypeptide chain. During translation, proteins are synthesized on ribosomes by linking amino acids together in the specific linear order stipulated by the sequence of codons in an mRNA. Ribosomes are the agents of protein synthesis.

Ribosomes are compact ribonucleoprotein particles found in the cytosol of all cells, as well as in the matrix of mitochondria and the stroma of chloroplasts. The general structure of ribosomes is described in Chapter 10; here we consider their structure in light of their function in synthesizing proteins. Ribosomes are mechanochemical systems that move along mRNA templates, orchestrating the interactions between successive codons and the corresponding anticodons presented by aminoacyl-tRNAs. As they align successive amino acids via codon–anticodon recognition, ribosomes also catalyze the formation of peptide bonds between the growing peptide chain and incoming amino acids.

30.4a Prokaryotic Ribosomes Are Composed of 30S and 50S Subunits

E. coli ribosomes are representative of the structural organization of the prokaryotic versions of these supramolecular protein-synthesizing machines (Table 30.5, see also Figure 10.21). The *E. coli* ribosome is a roughly globular particle with a diameter of 25 nm, a sedimentation coefficient of 70S, and a mass of about 2520 kDa. It consists of two unequal subunits that dissociate from each other at Mg²⁺ concentrations below 1 mM. The smaller, or **30S**, subunit is composed of 21 different proteins and a single rRNA, **16S ribosomal RNA (rRNA)**. The larger **50S** subunit consists of 31 different proteins and two rRNAs: **23S rRNA** and **5S rRNA**. Ribosomes are roughly two-thirds RNA and one-third protein by mass. An *E. coli* cell contains around 20,000 ribosomes, constituting about 20% of the dry cell mass.

Ribosomal Proteins There is one copy of each ribosomal protein per 70S ribosome, excepting protein L7/L12 (L7 and L12 have identical amino acid sequences and differ only in the degree of N-terminal acetylation). Only one protein is common to both the small and large subunit: S20 and L26 are identical. The largest ribosomal protein is S1 (557 residues, 61.2 kDa); the smallest is L34 (46 residues, 5.4 kDa). The sequences of

Table 30.5 Structural Organization of *E. coli* Ribosomes

	Ribosome	Small Subunit	Large Subunit
Sedimentation coefficient	70S	30S	50S
Mass (kDa)	2520	930	1590
Major RNAs		16S = 1542 bases	23S = 2904 bases
Minor RNAs			5S = 120 bases
RNA mass (kDa)	1664	560	1104
RNA proportion	66%	60%	70%
Protein number		21 polypeptides*	31 polypeptides†
Protein mass (kDa)	857	370	487
Protein proportion	34%	40%	30%

*The S proteins

†The L proteins

ribosomal proteins share little similarity. These proteins are typically rich in the cationic amino acids Lys and Arg and have few aromatic amino acid residues, properties appropriate to proteins intended to interact strongly with polyanionic RNAs.

rRNAs The rRNAs of *E. coli* are encoded by a set of seven operons (Figure 30.11). Each of these operons is transcribed into a 30S rRNA precursor that includes several tRNAs. RNase III and other nucleases cleave these precursors to generate 23S, 16S, and 5S rRNA, as well as several tRNAs that are unique to each operon. Transcription of rRNA genes accounts for 80% to 90% of total cellular RNA synthesis. Ribosomal RNAs show extensive potential for intrachain hydrogen bonding and assume secondary structures reminiscent of tRNAs, although substantially more complex (see Figures 11.38 and 11.39). About two-thirds of rRNA is double-helical. Double-helical regions are punctuated by short, single-stranded stretches, generating hairpin conformations that dominate the molecule; four distinct domains can be discerned in the secondary structure of 16S rRNA and six in 23S rRNA. The three-dimensional

Figure 30.11 The seven ribosomal RNA operons in *E. coli*. Numerals to the right of the brackets indicate the number of species of tRNA encoded by each transcript.

Figure 30.12 Tertiary structure of the 16S rRNA within the *Thermus thermophilus* 30S ribosomal subunit (PDB id = 2J02). This view is of the face that interacts with the 50S subunit (see Figures 30.13 and 30.15). H = head; Be = beak; N = neck; P = platform; Sh = shoulder; Sp = spur; Bo = body; these labels describe structural features of the 16S rRNA. Like *E. coli*, *T. thermophilus* is Gram-negative bacterium.

structures of both the 30S and 50S ribosomal subunits show that the general shapes of the ribosomal subunits are determined by the conformation of the rRNA molecules within them. Figure 30.12 illustrates the three-dimensional structure of 16S rRNA within the 30S subunit. The overall form of the 30S structure is essentially that of the rRNA (compare Figures 30.12 and 30.13a). The same relationship is true for the 23S plus 5S rRNA and the large ribosomal subunit (compare Figures 11.39 and 30.13b). Ribosomal proteins serve a largely structural role in ribosomes; their primary function is to brace and stabilize the rRNA conformations within the ribosomal subunits.

30.4b Ribosomes Spontaneously Self-Assemble In Vitro

Ribosomal subunit self-assembly is one of the paradigms for the spontaneous formation of supramolecular complexes from their macromolecular components. If the individual proteins and rRNAs composing ribosomal subunits are mixed together in vitro under appropriate conditions of pH and ionic strength, spontaneous self-assembly into functionally competent subunits takes place without the intervention of any additional factors or chaperones. The rRNA acts as a scaffold upon which the various ribosomal proteins convene. Ribosomal proteins bind in a specified order.

30.4c Ribosomes Have a Characteristic Anatomy

Ribosomal subunits have a characteristic three-dimensional architecture that has been revealed by image reconstructions from cryoelectron microscopy, X-ray crystallography, and X-ray and neutron solution scattering. Such analyses provide images as depicted in Figure 30.13. The 30S, or small, subunit features a head and a base, or body, from which a platform projects. A cleft is defined by the spatial relationship between the head, base, and platform (Figure 30.13a). The mRNA passes across this cleft. The platform represents the central domain of the 30S subunit; it contains one-third of the 16S rRNA. This central domain binds mRNA and the anticodon stem-loop end of aminoacyl-tRNAs, providing the framework for decoding the genetic information in mRNA by mediating codon–anticodon recognition. As such, this central domain of the 30S subunit serves as the **decoding center**. This center is composed only of 16S rRNA; no ribosomal proteins are involved in decoding the message.

The 50S, or large, subunit is a mitt-like globular structure with three distinctive projections: a central protuberance, the stalk containing protein L1, and a winglike ridge known as the L7/L12 region (Figure 30.13b). The large subunit binds the aminoacyl-acceptor ends of the tRNAs and is responsible for catalyzing formation of the peptide bond between successive amino acids in the polypeptide chain. This catalytic center, the **peptidyl transferase**, is located at the bottom of a deep cleft. From it, a 10-nm-long tunnel passes outward through the back of the large subunit. The process of protein folding begins within the tunnel, which can accommodate a protein of 30 or so amino acids, depending on its conformation.

The small and large subunits associate with each other in the manner shown in Figure 30.13c and d. The contacts between the 30S and 50S subunits are rather limited, and the subunit interface contains mostly rRNA, with relatively little contribution from ribosomal proteins. The decoding center in the 30S subunit is aligned somewhat with the peptidyl transferase and the tunnel in the large subunit, and the growing peptidyl chain is threaded through this tunnel as protein synthesis proceeds. Even though the ribosomal proteins are arranged peripherally around the rRNAs in ribosomes, rRNA occupies 30% to 40% of the ribosomal subunit surface areas.

Both subunits are involved in **translocation**, the process by which the mRNA moves through the ribosome, one codon at a time. (Although it is physically more likely for the mRNA to move through the ribosome, the descriptions of the events in protein synthesis that follow imply that the ribosome moves along the mRNA.)

Figure 30.13 Structure of the *T. thermophilus* ribosomal subunits and 70S ribosome, as deduced by X-ray crystallography. Prominent structural features are labeled. **(a)** 30S (PDB id = 2J02) and **(b)** 50S (PDB id = 2J03) subunits. These views show the sides of these two that form the interface between them when they **(c)** come together to form a 70S subunit. **(d)** A side view of the 70S ribosome; the white area represents the region where mRNA and tRNAs are bound and peptide bond formation occurs. The tunnel through the 50S subunit that the growing peptide chain transits is shown as a dashed line. The approximate dimensions of the 30S subunit are $5.5 \times 22 \times 22$ nm; the 50S subunit dimensions are $15 \times 20 \times 20$ nm.

30.4d The Cytosolic Ribosomes of Eukaryotes Are Larger Than Prokaryotic Ribosomes

Eukaryotic cells have ribosomes in their mitochondria (and chloroplasts) as well as in the cytosol. The mitochondrial and chloroplastic ribosomes resemble prokaryotic ribosomes in size, overall organization, structure, and function, a fact reflecting the prokaryotic origins of these organelles. Although eukaryotic cytosolic ribosomes are larger and considerably more complex, they retain the core structural and functional properties of their prokaryotic counterparts, confirming that the fundamental ribosome organization and operation has been conserved across evolutionary time. The rRNA genes of eukaryotes are present in the form of several hundred tandem clusters; these clusters define the **nucleolus**, a distinct region of the nucleus where these clusters are located and where transcription of rRNA genes occurs. As in prokaryotes, 80% to 90% of eukaryotic transcription is rRNA synthesis. Higher eukaryotes have more complex ribosomes than lower eukaryotes. For example, the yeast cytosolic ribosomes have major rRNAs of 3392 (large subunit) and 1799 nucleotides (small subunit); the major rRNAs of human cytosolic ribosomes are 5034 and 1870 nucleotides, respectively. Table 30.6 lists the properties of human cytosolic ribosomes. Comparison of base sequences and secondary structures of rRNAs from different organisms (Section 11.7c) suggests that evolution has worked to conserve the secondary structure of these molecules, although not necessarily the nucleotide sequences creating such structure. That is, the retention of a base pair at a particular location seems more important than whether the base pair is G:C or A:U.

Figure 30.14 The basic steps in protein synthesis. The ribosome has three distinct binding sites for tRNA: the A, or acceptor, site; the P, or peptidyl, site; and the E, or exit, site. The figure shows peptidyl-RNA occupying the P site.

Table 30.6 Structural Organization of Human Cytosolic Ribosomes			
	Ribosome	Small Subunit	Large Subunit
Sedimentation coefficient	80S	40S	60S
Mass (megaDa)	4.3	1.4	2.9
Major RNAs		18S = 1870 bases	28S = 5034 bases
Minor RNAs			5.8S = 156 bases 5S = 121 bases
RNA mass (megaDa)	2.5	0.7	1.8
RNA proportion	60%	50%	65%
Protein number		33 polypeptides	47 polypeptides
Protein mass (megaDa)	1.7	0.7	1.0
Protein proportion	40%	50%	35%

30.5 | What Are the Mechanics of mRNA Translation?

In translating an mRNA, a ribosome must move along it in the 5'→3' direction, recruiting aminoacyl-tRNAs whose anticodons match up with successive codons and joining amino acids in peptide bonds in a polymerization process that forms a particular protein. Like chemical polymerization processes, protein biosynthesis in all cells is characterized by three distinct phases: initiation, elongation, and termination. At each stage, the energy driving the assembly process is provided by GTP hydrolysis, and specific soluble protein factors participate in the events. These soluble proteins are often **G-protein family** members that use the energy released upon hydrolysis of bound GTP to fuel switchlike conformational changes. Such conformational changes are at the heart of the mechanical steps necessary to move a ribosome along an mRNA and to deliver an aminoacyl-tRNA into appropriate register with a codon.

30.5a Translation Can Be Organized into Three Steps: Initiation, Elongation, and Termination

Initiation involves binding of mRNA by the small ribosomal subunit, followed by association of a particular **initiator aminoacyl-tRNA** that recognizes the first codon. This codon often lies within the first 30 nucleotides or so of mRNA spanned by the small subunit. The large ribosomal subunit then joins the initiation complex, preparing it for the elongation stage.

Elongation includes the synthesis of all peptide bonds from the first to the last, as the ribosome moves along the mRNA, recruiting the cognate aminoacyl-tRNAs that deliver successively each of the multitude of amino acids in a polypeptide. The ribosome remains associated with the mRNA throughout elongation, moving along it and translating its message into an amino acid sequence. This is accomplished via a repetitive cycle of events in which successive aminoacyl-tRNAs are added to the ribosome: mRNA complex as directed by codon binding, the 50S subunit catalyzes peptide bond formation, and the polypeptide chain grows by one amino acid at a time.

Three tRNA molecules may be associated with the ribosome:mRNA complex at any moment. Each lies in a distinct site (Figure 30.14). The **A**, or **acceptor, site** is the binding site for an incoming aminoacyl-tRNA. The **P**, or **peptidyl, site** is occupied by peptidyl-tRNA, the tRNA carrying the growing polypeptide chain. The elongation reaction transfers the peptide chain from the peptidyl-tRNA in the P site to the aminoacyl-tRNA in the A site. This transfer occurs through covalent attachment of the α-amino group of the aminoacyl-tRNA to the α-carboxyl group of the peptidyl-tRNA, forming a new peptide bond. The ribosome now moves (translocates) precisely one codon further along the mRNA. Accompanying this translocation is the movement of the new, longer peptidyl-tRNA from the A site into the P site. The A site, left vacant by this translocation,

Figure 30.15 The three tRNA-binding sites on ribosomes. The view shows the ribosomal surfaces that form the interface between the (a) 30S and (b) 50S subunits in a 70S ribosome (as if a 70S ribosome has been opened like a book to expose facing pages). The A (green), P (blue), and E (yellow) sites are occupied by tRNAs. The decoding center on the 30S subunit (a) lies behind the top of the tRNAs in the A and P sites (which is where the anticodon ends of the tRNAs are located). The peptidyl transferase center on the 50S subunit (b) lies at the lower tips (acceptor ends) of the A- and P-site tRNAs. (a: PDB id = 2J02; b: PDB id = 2J03.)

can accept the next incoming aminoacyl-tRNA. The **E**, or **exit**, **site**, is transiently occupied by the unloaded, or deacylated, tRNA, which has lost its peptidyl chain through the peptidyl transferase reaction. These events are summarized in Figure 30.14. The contributions made to each of the three tRNA-binding sites by each ribosomal subunit are shown in Figure 30.15.

Termination is triggered when the ribosome reaches a stop codon on the mRNA. At this point, the polypeptide chain is released and the ribosomal subunits dissociate from the mRNA.

Protein synthesis proceeds rapidly. In vigorously growing bacteria, about 20 amino acid residues are added to a growing polypeptide chain each second. So an average protein molecule of about 300 amino acid residues is synthesized in only 15 seconds. Eukaryotic protein synthesis is only about 10% as fast. Protein synthesis is also highly accurate: An inappropriate amino acid is incorporated only once in every 10^4 codons. We focus first on protein synthesis in *E. coli*, the system for which we know the most.

30.5b Peptide Chain Initiation in Bacteria Requires a G-Protein Family Member

The components required for peptide chain initiation include (1) mRNA; (2) 30S and 50S ribosomal subunits; (3) a set of proteins known as **initiation factors**; (4) GTP; and (5) a specific charged tRNA, **f-Met-tRNA_i^{fMet}**.

Initiator tRNA tRNA_i^{fMet} is a particular tRNA for reading an AUG (or GUG, or even UUG) codon that signals the start site, or N-terminus, of a polypeptide chain; the subscript _i signifies initiation. This tRNA_i^{fMet} does not read internal AUG codons, so it does not participate in chain elongation. Instead, that role is filled by another methionine-specific tRNA, referred to as tRNA^{Met}, which cannot replace tRNA_i^{fMet} in peptide chain initiation. (However, both of these tRNAs are loaded with Met by the same methionyl-tRNA synthetase.) The structure of *E. coli* tRNA_i^{fMet} has several distinguishing features (Figure 30.16). Collectively, these features identify this tRNA as essential to initiation and inappropriate for chain elongation.

The synthesis of all *E. coli* polypeptides begins with the incorporation of a modified methionine residue, *N*-formyl-Met, as N-terminal amino acid. However, in about half of the *E. coli* proteins, this Met residue is removed once the growing polypeptide is ten or so residues long; as a consequence, many mature proteins in *E. coli* lack N-terminal Met.

The methionine contributed in peptide chain initiation by tRNA_i^{fMet} is unique in that its amino group has been formylated. This reaction is catalyzed by a specific enzyme, **methionyl-tRNA_i^{fMet} formyl transferase** (Figure 30.17). Note that the addition of the formyl group to the α -amino group of Met creates an N-terminal block resembling a peptidyl grouping. That is, the initiating Met is transformed into a minimal analog of a peptidyl chain.

Figure 30.16 The secondary structure of *E. coli* *N*-formyl-methionyl-tRNA_i^{fMet}. The features distinguishing this initiator tRNA from noninitiator tRNAs are highlighted.

Figure 30.17 Methionyl-tRNA_i^{fMet} formyl transferase catalyzes the transformylation of methionyl-tRNA_i^{fMet} using N¹⁰-formyl-THF as formyl donor. The tRNA for reading Met codons within a protein (tRNA^{Met}) is not a substrate for this transformylase.

Figure 30.18 Various Shine–Dalgarno sequences recognized by *E. coli* ribosomes. These sequences lie about ten nucleotides upstream from their respective AUG initiation codon and are complementary to the UCCU core sequence element of *E. coli* 16S rRNA. G:U as well as canonical G:C and A:U base pairs are involved here.

mRNA Recognition and Alignment In order for the mRNA to be translated accurately, its sequence of codons must be brought into proper register with the translational apparatus. Recognition of translation initiation sequences on mRNAs involves the 16S rRNA component of the 30S ribosomal subunit. Base pairing between a pyrimidine-rich sequence at the 3'-end of 16S rRNA and complementary purine-rich tracts at the 5'-end of prokaryotic mRNAs positions the 30S ribosomal subunit in proper alignment with an initiation codon on the mRNA. The purine-rich mRNA sequence, the **ribosome-binding site**, is often called the **Shine–Dalgarno sequence** in honor of its discoverers. Figure 30.18 shows various Shine–Dalgarno sequences found in prokaryotic mRNAs, along with the complementary 3'-tract on *E. coli* 16S rRNA. The 3'-end of 16S rRNA resides in the head region of the 30S small subunit, and the double-helical duplex formed by the Shine–Dalgarno sequence and the 16S rRNA 3'-end fits snugly in a chamber between the 30S subunit head and platform domains.

Initiation Factors Initiation involves interaction of the **initiation factors (IFs)** with GTP, N-formyl-Met-tRNA_i^{fMet}, mRNA, and the 30S subunit to give a **30S initiation complex** to which the 50S subunit then adds to form a **70S initiation complex**. The initiation factors are soluble proteins required for assembly of proper initiation complexes. Their properties are summarized in Table 30.7.

Events in Initiation Initiation begins when a 30S subunit:(IF-3:IF-1) complex binds mRNA and a complex of IF-2, GTP, and f-Met-tRNA_i^{fMet}. The sequence of events is summarized in Figure 30.19. Although IF-3 is absolutely essential for mRNA binding by the 30S subunit, it is not involved in locating the proper translation initiation site on the message. The presence of IF-3 on 30S subunits also prevents them from reassociating with 50S subunits. IF-3 must dissociate before the 50S subunit will associate with the mRNA:30S subunit complex.

IF-2 delivers the initiator f-Met-tRNA_i^{fMet} in a GTP-dependent process. The 30S subunit is aligned with the mRNA such that the initiation codon is situated within the 30S part of the P site. Upon binding, f-Met-tRNA_i^{fMet} enters this 30S portion of

Table 30.7 Properties of *E. coli* Initiation Factors

Factor	Mass (kDa)	Molecules/Ribosome	Function
IF-1	9	0.15	Binds to 30S A site and prevents tRNA binding
IF-2	97		G-protein that binds fMet-tRNA _i ^{fMet} ; interacts with IF-1
IF-3	23	0.25	Binds to 30S E site; prevents 50S binding

Figure 30.19 The sequence of events in peptide chain initiation.

the P site. Codon recognition by fMet-tRNA_i^{fMet} changes the conformation of the 30S complex, stabilizing binding of the fMet-tRNA_i^{fMet} and destabilizing IF-3 binding. GTP hydrolysis is necessary to form an active 70S ribosome. GTP hydrolysis is triggered when the 50S subunit joins and is accompanied by IF-1 and IF-2 release. The A site of the 70S initiation complex is ready to accept an incoming aminoacyl-tRNA; the 70S ribosome is poised to begin chain elongation.

30.5c Peptide Chain Elongation Requires Two G-Protein Family Members

The requirements for peptide chain elongation are (1) an mRNA:70S ribosome:peptidyl-tRNA complex (peptidyl-tRNA in the P site), (2) aminoacyl-tRNAs, (3) a set of proteins known as **elongation factors**, and (4) GTP. Elongation begins as soon as the second codon in the mRNA is read by the next aminoacyl-tRNA. Chain elongation can be divided into three principal steps:

1. Codon-directed binding of the incoming aminoacyl-tRNA at the A site. Decoding center regions of 16S rRNA make sure the proper aminoacyl-tRNA is in the A site by direct surveillance of codon–anticodon base pairing geometry.
2. Peptide bond formation: transfer of the peptidyl chain from the tRNA bearing it to the—NH₂ group of the new amino acid.
3. Translocation: Following peptide bond formation, the ribosome translocates precisely one codon further along the mRNA. Translocation also shifts the one-residue-longer peptidyl-tRNA to the P site to make room for the next aminoacyl-tRNA at the A site.

30.5d The Elongation Cycle

The properties of the soluble proteins essential to peptide chain elongation are summarized in Table 30.8. These proteins are present in large quantities, reflecting the great importance of protein synthesis to cell vitality. For example, **elongation factor Tu (EF-Tu)** is the most abundant protein in *E. coli*, accounting for 5% of total cellular protein. EF-Tu and EF-G, along with IF-2, are all members of the G-protein family of GTPases (see Figures 15.20, 32.21, and 32.22.) As such, the conformation of the GTP-bound and GDP-bound forms of these proteins are significantly different, allowing them to act as conformational switches that, in turn, can trigger dramatic conformational changes in the ribosome to which they are bound. These ribosomal conformational changes lie at the heart of the mechanical processes of protein synthesis by a ribosome translocating along an mRNA.

Table 30.8 Properties of <i>E. coli</i> Elongation Factors			
Factor	Mass (kDa)	Molecules/Cell	Function
EF-Tu	43	70,000	G protein that binds aminoacyl-tRNA and delivers it to the A site
EF-Ts	74	10,000	Guanine-nucleotide exchange factor (GEF) that replaces GDP on EF-Tu with GTP
EF-G	77	20,000	G protein that promotes translocation of mRNA

30.5e Aminoacyl-tRNA Binding and the Peptidyl Transferase Reaction

EF-Tu binds aminoacyl-tRNA and GTP. There is only one EF-Tu species serving all the different aminoacyl-tRNAs, and aminoacyl-tRNAs are accessible to the A site of active 70S ribosomes only in the form of aminoacyl-tRNA:EF-Tu:GTP complexes. The ternary aa-tRNA:EF-Tu:GTP complex binds to the L7/L12 stalk region of the 50S ribosomal subunit. Once correct base pairing between codon and anticodon has been established within the A site, the GTP is hydrolyzed to GDP and P_i by EF-Tu. Because the sites of codon–anticodon recognition and GTP hydrolysis are 7.5 nm apart, conformational changes in the ribosome must convey the information of cognate tRNA recognition to the EF-Tu GTPase site. Indeed, conformational adjustments in the 50S ribosome driven by codon–anticodon recognition allow the phosphate group of residue A2662 in 23S rRNA to activate the intrinsic GTPase activity of EF-Tu through interactions with His⁸⁴ in EF-Tu. The region of the 50S ribosomal subunit where 23S rRNA A2662 is located is near where EF-Tu binds and is referred to as the **GTPase-activating center**, or **GAC**. As a result of these events, the aminoacyl end of the tRNA is properly oriented in the peptidyl transferase site of the 50S subunit, and the EF-Tu molecule is released as a EF-Tu:GDP complex (Figure 30.20).

Figure 30.20 (a) The cycle of events in peptide chain elongation on *E. coli* ribosomes. (b) The molecular graphic at the upper right is an EF-Tu:aminoacyl-tRNA complex (PDB id = 1TTT). EF-Tu is shown as a ribbon diagram and the tRNA as a ball-and-stick structure.

Dissociation of EF-Tu allows the aminoacyl end of the aminoacyl-tRNA to swing into the peptidyl transferase center, positioning its amino acid for addition to the growing peptide chain.

Elongation factor Ts (EF-Ts) is a **guanine-nucleotide exchange factor (GEF)** that catalyzes the recycling of EF-Tu by mediating the displacement of GDP and its replacement by GTP. EF-Ts forms a transient complex with EF-Tu by displacing GDP, whereupon GTP displaces EF-Ts from EF-Tu (Figure 30.20).

The Decoding Center: A 16S rRNA Function Analysis of the structures of the 70S ribosome:tRNA complexes and isolated 30S subunits has revealed the decoding center in the 30S subunit. This decoding center, where anticodon loops of the A- and P-site tRNAs and the codons of the mRNA are matched up, is primarily a property of 16S rRNA. Figure 30.21 reveals the location of the decoding center and highlights the interface between an mRNA UUU codon, the GAA anticodon of a cognate tRNA^{Phe}, and the elements of the ribosome. 16S rRNA nucleotides A1493, A1492, G530, C518, and C1054 interact extensively with the minor groove of the UUU:AAG duplex; residues Ser⁵⁰ and Pro⁴⁸ of ribosomal protein S12 also participate (Figure 30.21b). A1492 and A1493 are part of 16S rRNA helix 44; G530 and C518 are from 16S helix 18. Triggered conformational changes within these 16S rRNA regions are key to codon–anticodon recognition.

Peptidyl Transfer Peptidyl transfer, or **transpeptidation**, is the central reaction of protein synthesis, the actual peptide bond-forming step. No energy input (for example, in the form of ATP) is needed; the ester bond linking the peptidyl moiety

Figure 30.21 The decoding center of the 30S ribosomal subunit is composed only of 16S rRNA. **(a)** The 30S subunit, as viewed from the 50S subunit. The cyan circle shows the latch structure of the 30S subunit that encircles and encloses the mRNA. The mRNA enters along the path indicated by the arrow and follows a groove along this face of the subunit. The location of the decoding center is indicated by the red circle. (Adapted from Figure 3 in Schluzen, F., et al., 2000. Structure of the functionally activated small ribosomal subunit at 3.3 Å resolution. *Cell* **102**:615–623.) **(b)** 30S ribosomal subunit interactions with the codon–anticodon duplex during cognate tRNA recognition. (Adapted from Figure 2 in Ogle, J. M., and Ramakrishnan, V., 2005. Structural insights into translational fidelity. *Annual Review of Biochemistry* **74**:129–177.)

to tRNA is intrinsically reactive. As noted earlier, *peptidyl transferase*, the activity catalyzing peptide bond formation, is associated with the 50S ribosomal subunit. Indeed, this reaction is a property of the 23S rRNA in the 50S subunit.

23S rRNA Is the Peptidyl Transferase Enzyme Peptide bond formation is catalyzed by the large rRNA in the large ribosomal subunit (e.g., the 23S rRNA in prokaryotic 50S ribosomal subunits) through its **peptidyl transferase center (PTC)**. No ribosomal proteins lie within 1.5 nm of the PTC; thus, none can participate in the reaction mechanism. In kinetic terms, the catalytic power of ribosomes is modest: A ribosome, through the rRNA comprising its PTC, accelerates the peptide-bond forming reaction rate 4×10^6 -fold over the uncatalyzed reaction. Peptidyl transfer requires that the acceptor ends (the aminoacylated ends) of both A- and P-site tRNAs interact with the PTC of the 50S subunit. Because the growing peptidyl chain doesn't move during peptidyl transfer, the acceptor end of the A-site aminoacyl-tRNA must move into the P site as its aminoacyl function picks up the peptidyl chain. At the same time, the acceptor end of the deacylated P-site tRNA is shunted into the E site (see Figure 30.15).

The Catalytic Power of the Ribosome Comes from Tight Binding of Its Peptidyl-tRNA and Aminoacyl-tRNA Substrates Structurally, the PTC can be described as a funnel-shaped active-site crater where the 3'-acceptor ends of the peptidyl-tRNA and aminoacyl-tRNA meet. This crater lies directly above the entrance to the peptide exit tunnel. Nucleotides at the 3'-ends of the tRNAs base-pair with bases in the PTC. G2251 and G2252 of the PTC (Figure 30.22) base-pair with C75 and C74, respectively, of the P-site tRNA. PTC G2553 forms a base pair with C75 of the A-site tRNA. Significantly, PTC C2501 interacts with A76 of the P-site tRNA, and nearby U2506 interacts with A76 of the A-site tRNA. These interactions and others lead to tight binding of the substrates by the ribosome in a manner such that the reactive groups (aminoacyl and peptidyl) are juxtaposed and properly oriented for reaction to occur. Collectively, functional groups provided by the PTC, the peptidyl-tRNA, and the aminoacyl-tRNA establish a network of H bonds and electrostatic interactions that stabilize the highly polar transition state (Figure 30.23). In effect, interactions of the tRNAs with the rRNA of the PTC create a highly organized environment that facilitates peptide bond synthesis. Ribosome-catalyzed protein synthesis relies more on proximity and orientation of substrates than on chemical catalysis. The role of the PTC in protein synthesis is to align the tRNA-linked substrates so that the reaction is facilitated.

Figure 30.22 The peptidyl transferase active site: Base-pairing between cytosine residues of A-site tRNA (yellow) and P-site tRNA (orange) with 23S rRNA bases (pale green; PDB id = 1VQN). The α -amino group of the aminoacyl group on the aminoacyl-tRNA (blue) is positioned for the attack on the ester carbonyl carbon of the peptidyl group of the P-site tRNA (green). (Adapted from Figure 2 in Beringer, M., and Rodnina, M. V., 2007. The ribosomal peptidyl transferase. *Molecular Cell* 26:311–321.)

Figure 30.23 The protein synthesis reaction proceeds via deprotonation of the α -amino group of the aminoacyl-tRNA, followed by nucleophilic attack of the $\alpha\text{-NH}_2$ on the peptidyl-tRNA carbonyl carbon to form a highly polar tetrahedral intermediate. Proton transfer to the 3'-O of the tRNA that contributed the peptidyl chain leads to release of this tRNA in the deacylated form and formation of a one-residue-longer peptidyl-tRNA.

Translocation Three things remain to be accomplished in order to return the active 70S ribosome:mRNA complex to the starting point in the elongation cycle, in preparation for addition of the next amino acid:

1. The deacylated tRNA must be removed from the P site.
2. The peptidyl-tRNA must be moved (translocated) from the A site to the P site.
3. The ribosome must move one codon down the mRNA so that the next codon is positioned in the A site.

In the process of translocation, the tRNAs and the mRNA must move a distance of about 5 nm relative to the ribosome, a shift requiring large-scale conformational changes. Translocation is a two-step process. First, the acceptor stems of the tRNAs move from the A and P sites on the 50S subunit to the 50S P and E sites, respectively, while their anticodon stems remain fixed in the 30S A and P sites. Ratchet-like rotation of the 30S and 50S subunits relative to one another drives this tRNA acceptor-stem repositioning, as transmitted through 30S interactions with the L1 stalk of the 50S subunit (see Figure 30.13). In the second step, the mRNA and the tRNAs move relative to the 30S subunit, bringing the one-residue-longer peptidyl-tRNA into the 30S P site and positioning the next codon within the 30S A site for translation. The translocation protein **elongation factor G (EF-G)** and GTP are required for this second step. EF-G, a G-protein family GTPase-driven conformational switch, couples the energy of GTP hydrolysis to these movements. As the mRNA and the anticodon ends of tRNAs move together with respect to the 30S subunit, the mRNA is passively dragged one codon further through the ribosome. This translocation of the mRNA relative to the 30S subunit delivers the next codon to the 30S A site. Swiveling of the head region of the 30S subunit underlies relocation of the mRNA and tRNAs. The ribosomal components are now back in proper register for the another round of elongation.

EF-G binds to the ribosome as an EF-G:GTP complex. GTP hydrolysis is essential not only for translocation but also for subsequent EF-G dissociation. Because EF-G and EF-Tu compete for a common binding site on the ribosome (the **factor-binding center**, also known as the **GAC** or **GTPase-activating center**) adjacent to the A site, EF-G release is a prerequisite for return of the 70S ribosome:mRNA to the beginning point in the elongation cycle.

In this simple model of peptidyl transfer and translocation, the ends of both tRNAs move relative to the two ribosomal subunits in two discrete steps, with the acceptor ends moving first and then the anticodon ends. Furthermore, the readjustments needed to reposition the ribosomal subunits relative to the mRNA and to one another imply that the 30S and 50S subunits rotate relative to one another in ratchetlike fashion. This model provides a convincing explanation for why ribosomes are universally organized into a two-subunit structure: The small and large subunits must move relative to each other in a ratchetlike fashion, as opposed to moving as a unit, in order to carry out the process of translation.

30.5f GTP Hydrolysis Fuels the Conformational Changes That Drive Ribosomal Functions

Two GTPs are hydrolyzed for each amino acid residue incorporated into peptide during chain elongation: one upon EF-Tu-mediated binding of aa-tRNA and one more in translocation. The role of GTP (with EF-Tu as well as EF-G) is mechanical, in analogy with the role of ATP in driving muscle contraction (see Chapter 16). GTP binding induces conformational changes in ribosomal components that actively engage these components in the mechanics of protein synthesis; subsequent GTP hydrolysis followed by GDP and Pi release relax the system back to the initial conformational state so that another turn in the cycle can take place. The energy expenditure for protein synthesis is at least four high-energy phosphoric anhydride bonds per amino acid. In addition to the two provided by GTP, two from ATP are expended in amino acid activation via aminoacyl-tRNA synthesis (see Figure 30.3).

A Deeper Look

Molecular Mimicry—The Structures of EF-Tu: Aminoacyl-tRNA, EF-G, and RF-3

EF-Tu and EF-G compete for binding to ribosomes. EF-Tu has the unique capacity to recognize and bind any aminoacyl-tRNA and deliver it to the ribosome in a GTP-dependent reaction. EF-G catalyzes GTP-dependent translocation. The structure of the EF-Tu:tRNA complex is remarkably similar to the structure of EF-G (EF-Tu:tRNA is shown on the left in the figure; EF-G is in the center). The EF-Tu:tRNA structure is *Thermus aquaticus* EF-Tu:Phe-tRNA^{Phe} complexed with GMPCP (*purple*); GMPCP is a nonhydrolyzable analog of GTP (PDB id = 1TTT). The EF-G structure has GDP bound (*purple*; PDB id = 1DAR). Note that parts of the EF-G structure mimic the structure of the tRNA molecule. Both EF-Tu and EF-G bind to the factor-binding center, which is located on the L7/L12 side of 50S ribosomal subunit. Part of this center has an associated

GTPase function that plays an integral role in GTP hydrolysis and release of these factors.

Nature has extended this mimicry with RF-3, a ribosome-binding protein essential to the termination phase of protein synthesis. RF-3 is a GTP-binding protein that looks like a tRNA (the structure of RF-3 with bound GDP (*purple*) is shown on the right in the figure; PDB id = 2H5E).

One view of early evolution suggests that RNA was the primordial macromolecule, fulfilling all biological functions, including those of catalysis and information storage that are now assumed for the most part by proteins and DNA. The mimicry of EF-Tu:tRNA by EF-G may represent a fossil of early macromolecular evolution when the proteins first began to take over some functions of RNA by mimicking shapes known to work as RNAs.

EF-Tu:tRNA (*left*); EF-G (*center*); and RF-3 (*right*).

30.5g Peptide Chain Termination Requires Yet Another G-Protein Family Member

The elongation cycle of polypeptide synthesis continues until the 70S ribosome encounters a stop codon. At this point, polypeptidyl-tRNA occupies the P site and the arrival of a stop or nonsense codon in the A site signals that the end of the polypeptide chain has been reached (Figure 30.24). These nonsense codons are not read by any terminator tRNAs but instead are recognized by specific proteins known as **release factors (RFs)**, so named because they promote polypeptide release from the ribosome. The release factors bind at the A site. **RF-1** recognizes UAA and UAG, whereas **RF-2** recognizes UAA and UGA. RF-1 and RF-2 are members of the guanine nucleotide exchange factor (GEF) family of proteins, which includes EF-Ts. Like EF-G, RF-1 and RF-2 interact well with the ribosomal A-site structure. Furthermore, these release factors read the nonsense codons through specific tripeptide sequences that serve as the RF protein equivalent of the tRNA anticodon loop. There is about one molecule each of RF-1 and RF-2 per 50 ribosomes. Ribosomal binding of RF-1 or RF-2 is competitive with EF-G. RF-1 or RF-2 recruit a third release factor, **RF-3**, complexed with GTP; this protein is a structural mimic of tRNA. RF-3 is the fourth G-protein family member (the other three are IF-2, EF-Tu, and EF-G) involved in protein synthesis. All share the same ribosomal binding site. The state of the peptidyl-tRNA in the P site determines which is bound and, importantly, the progression of protein synthesis through initiation, elongation, and termination.

The presence of release factors with a nonsense codon in the A site creates a 70S ribosome:RF-1 (or RF-2):RF-3-GTP:termination signal complex that transforms the ribosomal peptidyl transferase into a hydrolase. That is, instead of catalyzing the transfer of the polypeptidyl chain from a polypeptidyl-tRNA to an acceptor aminoacyl-tRNA, the peptidyl transferase hydrolyzes the ester bond linking the polypeptidyl chain to its tRNA carrier. Both RF-1 and RF-2 have a conserved GGQ sequence located in a loop that enters the PTC. This GGQ sequence faces nucleotide A76 of the P-site tRNA; the closest 23S rRNA residues are A2451 and A2602. RF-1 and RF-2 promote conformational adjustments that expose the peptidyl-tRNA ester to attack by a water molecule. The conserved Gln in the release factor GGQ motif positions this hydrolytic water molecule through hydrogen-bonding interactions. The peptidyl transferase transfers the polypeptidyl chain to this water molecule instead of an aminoacyl-tRNA. Peptide release is followed by expulsion of RF-1 (or RF-2) from the ribosome (Figure 30.24). This leaves a ribosome:mRNA:P-site tRNA complex that must be disassembled by a protein **ribosome recycling factor (RRF)** with the help of EF-G. The structure of RRF resembles the letter “L”; thus, this protein is also structurally akin to a tRNA.

We can now appreciate the role played by GTP in initiation, elongation, and termination of protein synthesis. IF-2, EF-Tu, EF-G, and RF-3 are all GTP-binding proteins, and all are part of the G-protein superfamily (see Figure 15.20). IF-2, EF-Tu, EF-G, and RF-3 interact with the same site on the 50S subunit, the *factor-binding center*, in the 50S cleft. This factor-binding center activates the GTPase activity of these factors, once they become bound.

30.5h The Ribosomal Subunits Cycle Between 70S Complexes and a Pool of Free Subunits

Ribosomal subunits cycle rapidly through protein synthesis. In actively growing bacteria, 80% of the ribosomes are engaged in protein synthesis at any instant. Once a polypeptide chain is synthesized and the nascent polypeptide chain is released, the 70S ribosome dissociates from the mRNA and separates into free 30S and 50S subunits (Figure 30.25). Intact 70S ribosomes are inactive in protein synthesis because only free 30S subunits can interact with the initiation factors. Binding of initiation factor IF-3 by 30S subunits and interaction of 30S subunits with 50S subunits are mutually exclusive. 30S subunits with bound initiation factors associate with mRNA, but 50S subunit addition requires IF-3 release from the 30S subunit.

Figure 30.24 The events in peptide chain termination. **(a)** A nonsense codon in the A site leads to binding of RF1 and RF3-GTP, hydrolysis of the peptidyl-tRNA bond, and release of the nascent polypeptide. RRF drives dissociation of the mRNA and deacylated tRNA in the P site. **(b)** The ribosome:RF-2 termination complex. The view here shows only the 30S subunit-tRNA complex, as if it were folded down and away from the 50S subunit, opening the ribosome as if you were opening your car's glove compartment door. RF-2 is shown in yellow, the P-site tRNA in orange, the E-site tRNA in red, mRNA in dark blue, the 30S proteins in cyan, and the 30S ribosomal subunit 16S rRNA in light purple. Lower: The ribosome-bound conformation of RF-2, with its GGQ motif, is shown alone as the lower image in (b). These structures are derived from PDB id = 3F1E. (Adapted from Korostelev, A., et al., 2008. Crystal structure of a translation termination complex formed with release factor RF2. *Proceedings of the National Academy of Sciences, U.S.A.* **105**:19684–19689.)

A Deeper Look

Tethered Ribosomes Open New Possibilities in Synthetic Biology

As noted, ribosomal subunits normally cycle between free 30S and 50S subunits and complete 70S ribosomes assembled by initiation factors in the presence of mRNA. Intact 70S ribosomes are inactive. The two-part nature of ribosomes is evident in their division of labor, with the decoding center located in the 30S subunit and the peptidyl transferase center in the 50S subunit. In addition, a precise choreography of substantial conformational changes takes place within and between the ribosomal subunits as they translate an mRNA, recruiting aminoacyl-tRNAs as dictated by codons and joining amino acids one after another to form polypeptide chains. For these reasons, ribosomes are universally composed of two subunits. Thus, the discovery by Alexander Mankin and his colleagues that ribosomes whose subunits were tethered together could still synthesize proteins is extraordinary. The Mankin laboratory created tethered ribosomes by connecting 16S and 23S rRNA gene sequences by a flexible RNA linker and expressing this co-joined super rRNA molecule in *E. coli* cells. The cells were able to assemble functional 70S-sized ribosomes on this super rRNA platform. These tethered single-particle ribosomes (called Ribo-T) translated mRNA normally. In a further

refinement, by changing the sequence within the Shine-Dalgarno complementary region at the 3'-end of the 16S rRNA segment of the super RNA, they could make Ribo-T ribosomes that would only translate mRNAs bearing mutant Shine-Dalgarno sequences, thereby controlling which messages Ribo-T would translate. Introduction of such mutations into the 16S small subunit rRNA and others into the 23S large subunit RNA of tethered ribosomes allows these ribosomes to be dedicated exclusively to translation of desired synthetic mRNAs and production of highly tailored protein products. This breakthrough has enormous potential for synthetic biology: The process of translation may now be engineered using expanded genetic codes and noncanonical amino acids to create polypeptide-like molecules with all sorts of novel chemistries.

30.5i Polyribosomes Are the Active Structures of Protein Synthesis

Active protein-synthesizing units consist of an mRNA with several ribosomes attached to it. Such structures are **polyribosomes**, or, simply, **polysomes** (Figure 30.26). All protein synthesis occurs on polysomes. In the polysome, each ribosome is traversing the mRNA and independently translating it into polypeptide. The further a ribosome has moved along the mRNA, the greater the length of its associated polypeptide product. In prokaryotes, as many as 10 ribosomes may be found in a polysome. Ultimately, as many as 300 ribosomes may translate an mRNA, so as many as 300 enzyme molecules may be produced from a single transcript. Eukaryotic polysomes typically contain fewer than 10 ribosomes.

30.6 | How Are Proteins Synthesized in Eukaryotic Cells?

Eukaryotic mRNAs are characterized by two post-transcriptional modifications: the 5'-terminal **7methyl-GTP cap** and the 3'-terminal **poly(A) tail** (Figure 30.27). The 7methyl-GTP cap is essential for mRNA binding by eukaryotic ribosomes and also enhances the stability of these mRNAs by preventing their degradation by 5'-exonucleases. The poly(A) tail enhances both the stability and translational efficiency of eukaryotic mRNAs. The Shine–Dalgarno sequences found at the 5'-end of prokaryotic mRNAs are absent in eukaryotic mRNAs.

30.6a Peptide Chain Initiation in Eukaryotes

As might be expected, eukaryotic protein synthesis is considerably more complex than prokaryotic protein synthesis. More than 100 different RNA molecules and 200 proteins are required just for the core translational machinery in *Caenorhabditis elegans*, a simple animal. Despite such complexity, the overall process is similar to prokaryotic protein synthesis. The events in eukaryotic peptide chain initiation are summarized in Figure 30.28, and the properties of **eukaryotic initiation factors**, symbolized **eIFs**, are presented in Table 30.9. The eukaryotic initiator tRNA is a unique tRNA functioning only in initiation. Like the prokaryotic initiator tRNA, the eukaryotic version carries only Met. However, unlike prokaryotic f-Met-tRNA_i^{fMet}, the Met on this tRNA is not formylated. The eukaryotic initiator tRNA is usually designated **tRNA_i^{Met}**, with the “i” indicating initiation.

In particular, initiation of protein synthesis is significantly more complicated in eukaryotes. It can be divided into three fundamental stages:

Stage 1: Eukaryotic protein synthesis begins with formation of the **43S preinitiation complex** from the 40S ribosomal subunit and the Met-tRNA_i^{Met}:eIF2-GTP ternary complex (Stage 1, Figure 30.28). Initiation factors eIF1, eIF1A, eIF3, and eIF5 bind to a 40S ribosomal subunit. eIF1 and eIF1A binding induces a conformational change in the 40S subunit that renders it competent for Met-tRNA_i^{Met} binding. Met-tRNA_i^{Met}

Figure 30.27 The characteristic structure of eukaryotic mRNAs. Untranslated regions ranging between 40 and 150 bases in length occur at both the 5'- and 3'-ends of the mature mRNA. An initiation codon at the 5'-end, invariably AUG, signals the translation start site.

Figure 30.28 The three stages in the initiation of translation in eukaryotic cells. See Table 30.9 for a description of the functions of the eukaryotic initiation factors (eIFs). *Stage 1:* Formation of the 43S preinitiation complex from Met-tRNA_i^{Met}, GTP, eIFs 1, 2, and 3, and the 40S ribosomal subunit. *Stage 2:* Formation of 43S:mRNA complex (48S initiation complex) from the 43S preinitiation complex, the capped and polyadenylated mRNA, eIF4B, eIF4F, and PABP. (Detailed organization of the 48S initiation complex is shown in Figure 30.29.) *Stage 3:* eIF5B-mediated joining of the 60S ribosomal subunit to form the 80S initiation complex.

Table 30.9 Properties of Eukaryotic Translation Initiation Factors

Factor	Subunit	Size (kDa)	Function
eIF1		15	Enhances initiation complex formation
eIF1A		17	Stabilizes Met-tRNA _i binding to 40S ribosomes
eIF2		125	GTP-dependent Met-tRNA _i binding to 40S ribosomes
	α	36	Regulated by phosphorylation
	β	50	Binds Met-tRNA _i
	γ	55	Binds GTP, Met-tRNA _i
eIF2B		270	Promotes guanine nucleotide exchange on eIF2
eIF2C		94	Stabilizes ternary complex in presence of RNA
eIF3		800	A multisubunit scaffolding complex that recruits eIFs, mRNA and Met-tRNA _i , and the 40S subunit to form the 43S PIC
eIF4F		243	Binds to mRNA caps and poly(A) tails; consists of eIF4A, eIF4E, and eIF4G; RNA helicase activity unwinds mRNA 2° structure
eIF4A		46	Binds RNA; ATP-dependent RNA helicase; promotes mRNA binding to 40S ribosomes
eIF4E		24	Binds to 5'-terminal 7methyl-GTP cap on mRNA
eIF4G		173	A scaffolding protein that associates the mRNA with ribosome-bound eIF3, binds to PABP
eIF4B		80	Binds mRNA; promotes RNA helicase activity and mRNA binding to 40S ribosomes
eIF4H		25	Acts with eIF4B to stimulate eIF4A helicase activity
eIF5		49	Promotes GTPase of eIF2, ejection of eIF2 and eIF3
eIF5B		175	Ribosome-dependent GTPase activity; mediates 40S and 60S joining, homologous with prokaryotic IF2
eIF6			Dissociates 80S; binds to 60S

(in the form of an eIF2:GTP:Met-tRNA_i^{Met} ternary complex) then binds to the eIF1/1A/3:40S subunit complex, followed by eIF5. (Unlike in prokaryotes, binding of Met-tRNA_i^{Met} by eukaryotic ribosomes occurs in the absence of mRNA, so Met-tRNA_i^{Met} binding is not codon-directed.) In mammals, eIF3 is an 800-kDa multimer containing at least 13 different subunits. The eIF3 complex binds to the solvent-exposed side of the 40S subunit, away from the face that interacts with mRNA and the 60S subunit. A prominent role of eIF3 is to serve as a platform and scaffold for the recruitment of mRNA and other proteins involved in translation initiation.

Stage 2: in eukaryotic translation initiation leads to formation of the **48S initiation complex** (Figure 30.28). This stage involves binding of the 43S preinitiation complex to mRNA and migration of the 40S ribosomal subunit to the correct AUG initiation codon. Binding of mRNA by the 43S preinitiation complex requires a set of proteins including **eIF4 group** and the **(poly)A-binding protein (PABP)**. Collectively, these proteins recognize the 5'-terminal cap and 3'-terminal poly(A) tail of an mRNA, unwind any secondary structure in the mRNA, and transfer the mRNA to the 43S preinitiation complex. The eIF4 group includes eIF4B and eIF4F. eIF4F is a trimeric complex consisting of eIF4A (an ATP-dependent RNA helicase), eIF4E (which binds the 5'-terminal 7methyl-GTP of mRNAs), and eIF4G. Because eIF4G interacts with PABP (Figure 30.29), eIF4G serves as the bridge between the cap-binding eIF4E, the poly(A) tail of the mRNA, and the 40S subunit (through interaction with eIF3). These interactions between the 5'-terminal 7methyl-GTP cap and the 3'-poly(A) tail initiate scanning of the 40S subunit in search of an AUG codon. Both eIF1 and eIF1A are necessary for opening the mRNA-binding channel of the 40S subunit so that scanning in search of an initiation codon can take place. The scanning mechanism operates by inspecting every triplet of bases within the 5'-leader region of mRNA for complementarity with the tRNA_i^{Met} anticodon.

eIF4E, the mRNA cap-binding protein of eIF4F, is a key regulatory element in eukaryotic translation. eIF4F binding to the cap structure is necessary for association of eIF4B and formation of the 48S preinitiation complex. Translation is inhibited when the eIF4E subunit of eIF4F binds with **4EBP** (the eIF4E binding protein). Growth factors stimulate protein synthesis by causing the phosphorylation of 4EBP. For example, mammalian target of rapamycin complex 1 (mTORC-1)-mediated phosphorylation of 4EBP causes it to release bound eIF4E, which then can bind to the 5'-cap of an mRNA, triggering translation initiation. Amino acid levels, glucocorticosteroid hormones, and resistance exercise all affect protein synthesis through effects on mTORC-1.

Note that recruitment of both the 5'-cap and 3'-poly(A) tail of the mRNA to eIF4G (Figure 30.29) brings the two ends of the mRNA together. Thus, protein:protein interactions between poly(A)-bound PABP and the N-terminus of eIF4G bring the 3'- and 5'-ends of the mRNA into close proximity, creating an mRNA circle. These interactions ensure that only appropriately processed transcripts are translated. Further, closing the circle helps protect the mRNA from exonucleolytic degradation.

Stage 3: Formation of the **80S initiation complex**. When the 48S preinitiation complex stops at an AUG codon, GTP hydrolysis in the eIF2:Met-tRNA_i^{Met} ternary complex causes ejection of the initiation factors bound to the 40S ribosomal subunit. eIF5B acts here by stimulating the GTPase activity of eIF2. Ejection of the eIFs is followed by 60S subunit association to form the 80S initiation complex, whereupon translation begins (Figure 30.28, stage 3). eIF2:GDP is recycled to eIF2:GTP by eIF2B (eIF2B is a *guanine nucleotide exchange factor*).

30.6b Control of Eukaryotic Peptide Chain Initiation Is One Mechanism for Post-Transcriptional Regulation of Gene Expression

Regulation of gene expression can occur post-transcriptionally through control of mRNA translation, as indicated by the effects of mTORC-1 mentioned earlier. Phosphorylation/dephosphorylation of translational components is a dominant mechanism for control of protein synthesis. Several initiation factors—eIF2 α , eIF2B, eIF4E,

Figure 30.29 The 48S initiation complex. mRNA is shown as a *black line*, its 5'-cap as a *black circle*, and its coding region as a *yellow bar* beginning with AUG and ending with UAA; downstream lies the poly(A) tail. The initiator Met-tRNA_i is shown as a pitchfork bound to the AUG initiation codon. The various initiation factors are shown by their numerical and letter codes. Mnk is a stress- and mitogen-activated protein kinase that phosphorylates eIF4E, increasing its affinity for the 5'-cap.

Figure 30.30 Control of eIF2 functions through reversible phosphorylation of a Ser residue on its α -subunit. The phosphorylated form of eIF2 (eIF2-P) enters a tight complex with eIF2B and is unavailable for initiation.

30.6c Peptide Chain Elongation in Eukaryotes Resembles the Prokaryotic Process

Eukaryotic peptide elongation occurs in very similar fashion to the process in prokaryotes. An incoming aminoacyl-tRNA enters the ribosomal A site while peptidyl-tRNA occupies the P site. Peptidyl transfer then occurs, followed by translocation of the ribosome one codon further along the mRNA. Two elongation factors, eEF1 and eEF2, mediate the elongation steps. eEF1 consists of two components: eEF1A and eEF1B. eEF1A is the eukaryotic counterpart of EF-Tu; it serves as the aminoacyl-tRNA binding factor and requires GTP. eEF1B is the eukaryotic equivalent of prokaryotic EF-Ts; it catalyzes the exchange of bound GDP on eEF1:GDP for GTP so that active eEF1:GTP can be regenerated. EF2 is the eukaryotic translocation factor. eEF2 (like its prokaryotic kin, EF-G) binds GTP, and GTP hydrolysis accompanies translocation. The diphthamide group of eEF2 (see the Human Biochemistry box)

Human Biochemistry

Diphtheria Toxin ADP-Ribosylates eEF2

Diphtheria arises from infection by *Corynebacterium diphtheriae* bacteria carrying bacteriophage *corynephage* β . Diphtheria toxin is a phage-encoded enzyme secreted by these bacteria that is capable of inactivating a number of GTP-dependent enzymes through covalent attachment of an ADP-ribosyl moiety derived from NAD⁺. That is, diphtheria toxin is an NAD⁺-dependent ADP-ribosylase. One target of diphtheria toxin is the eukaryotic translocation factor, eEF2. This protein has a modified His residue known as diphthamide. Diphthamide is generated post-translationally on eEF2; the diphthamide moiety of eEF2 is important for maintaining the correct

codon reading frame during translocation. (EF-G of prokaryotes lacks this unusual modification and is not susceptible to diphtheria toxin.) Diphtheria toxin specifically ADP-ribosylates an imidazole-N within the diphthamide moiety of eEF2 (see accompanying figure). ADP-ribosylated eEF2 retains the ability to bind GTP but is unable to function in protein synthesis. Because diphtheria toxin is an enzyme and can act catalytically to modify many molecules of its target protein, just a few micrograms suffice to cause death.

Diphtheria toxin catalyzes the NAD⁺-dependent ADP-ribosylation of selected proteins. ADP-ribosylation of the diphthamide moiety of eukaryotic EF2. (Diphthamide = 2-[3-carboxamido-3-(trimethylammonio)propyl]histidine.)

stabilizes codon-anticodon recognition by interacting directly with the mRNA codon. Further, not only does eEF2 catalyze the GTP-dependent translocation of the ribosome along the mRNA, it ensures the codon-by-codon accuracy of translocation, thereby maintaining the correct reading frame. Elongation continues until a stop codon is reached, signaling termination.

30.6d Eukaryotic Peptide Chain Termination Requires eRF1, eRF3, and GTP

Translation of an mRNA terminates when a stop codon occupies the A site on the ribosome. Termination in eukaryotes is mediated by a ternary complex of release factors eRF1, eRF3, and GTP. The N-terminal domain of eRF1 is able to recognize any of the three stop codons; its C-terminal domain binds eRF3 and another protein called ABCE1. Upon reading a stop codon, eRF1 catalyzes hydrolysis of the nascent polypeptide chain from the P-site peptidyl-tRNA in the following manner: When eRF1 sits on the A-site stop codon, its GGQ sequence motif is positioned adjacent to the peptidyl transferase center (PTC) of the large ribosomal subunit, in proximity to CCA-end of the peptidyl-tRNA. Residue Q¹³⁵ of the eRF1 GGQ motif is close to the ester bond linking the polypeptide to the peptidyl-tRNA. The eRF3 partner of eRF1 is a GTPase whose action drives conformational changes. These changes expose the peptidyl-tRNA ester bond to Q¹³⁵-facilitated nucleophilic attack by water, leading to polypeptide release. Upon termination, the eRF1:eRF3 complex dissociates and the ribosomal subunits are recycled by ATP-driven conformational changes mediated by ABCE1 (ATP-binding cassette protein 1). The action of ABCE1 splits the 80S ribosome into free 40S and 60S subunits, freeing them for recruitment into new translation initiation reactions.

30.7 | Do Protein Synthesis Inhibitors Have Clinical Applications?

Protein synthesis inhibitors serve two major, and perhaps complementary, purposes. First, they have been very useful scientifically in elucidating the biochemical mechanisms of protein synthesis. Second, some of these inhibitors affect prokaryotic but not eukaryotic protein synthesis, and thus, are medically important antibiotics. Table 30.10 is a partial list of these inhibitors and their mode of action. The structures of some of these compounds are given in Figure 30.31.

As indicated in Table 30.10, many antibiotics inhibit protein synthesis by binding to key rRNA components. The two principal sites for antibiotic binding are the 16S rRNA of the decoding center within the small ribosomal subunit and the PTC of the 23S rRNA in the large subunit. More antibiotics are targeted to the PTC than to the decoding center.

Why is rRNA the target for antibiotics? Generally speaking, it is difficult for organisms to defend themselves against agents that bind rRNA rather than protein. First of all, there are many rRNA genes, so mutation of one gene to antibiotic resistance (loss in antibiotic binding, for instance) would affect few rRNA molecules among the many. Further, four bases comprise RNA (as opposed to 20 amino acids in proteins), so there are fewer possibilities for modification of the rRNA so that the RNA retains its function but is no longer able to bind the antibiotic.

30.7a The Decoding Site Is a Target of Aminoglycoside Antibiotics

Aminoglycoside antibiotics are a series of compounds with a 2-deoxy-streptamine (2-DOS) core structure (Figure 30.32a) that is central to their action. These antibiotics bind to an unpaired adenine residue (A¹⁴⁰⁸) within the 16S rRNA decoding site (that part of the 16S rRNA that decodes the mRNA through interactions with the anticodon of the aminoacyl-tRNA in the A site). A¹⁴⁰⁸ lies within a small internal rRNA loop (Figure 30.32b) that is part of the decoding center. The sugar moiety attached to

Figure 30.31 The structures of various antibiotics that act as protein synthesis inhibitors. Puromycin mimics the structure of aminoacyl-tRNA in that it resembles the 3'-terminus of a Tyr-tRNA (shaded box).

the 4-position of the 2-DOS core forms H bonds with A¹⁴⁰⁸ that limit the flexibility of A¹⁴⁹² and A¹⁴⁹³ on the other side of the small RNA loop; A¹⁴⁹² and A¹⁴⁹³ interact with codon nucleotides (see Figure 30.21b). This flexibility loss results in errors in translation fidelity, in which the code is misread, the wrong amino acid is inserted in the growing polypeptide chain, and the protein being made is nonfunctional. Aminoglycoside antibiotics have been useful probes for decoding center properties.

30.7b Many Antibiotics Target the PTC and the Peptide Exit Tunnel

A chemically diverse series of antibiotics targets the PTC and/or the adjacent peptide exit tunnel. Among these, the **macrolide antibiotics** are one of the clinically most important classes; **erythromycin** (see Figure 30.31), a broadly prescribed macrolide, is representative of this class. (The newer, semisynthetic ketolide drugs are analogs of

Table 30.10 Some Protein Synthesis Inhibitors

Inhibitor	Cells Inhibited	Mode of Action
<i>Initiation</i>		
Aurintricarboxylic acid	Prokaryotic	Prevents IF binding to 30S subunit
Kasugamycin	Prokaryotic	Inhibits fMet-tRNA ^{fMet} binding
Streptomycin	Prokaryotic	Prevents formation of initiation complexes
<i>Elongation: Aminoacyl-tRNA Binding</i>		
Tetracycline	Prokaryotic	Inhibits aminoacyl-tRNA binding at A site
Streptomycin	Prokaryotic	Codon misreading, insertion of improper amino acid
Kirromycin	Prokaryotic	Binds to EF-Tu, preventing conformational switch from EF-Tu:GTP to EF-Tu:GDP
<i>Elongation: Peptide Bond Formation</i>		
Sparsomycin	Prokaryotic	Peptidyl transferase inhibitor
Chloramphenicol	Prokaryotic	Binds to 50S subunit, blocks the A site and inhibits peptidyl transferase activity
Clindamycin	Prokaryotic	Binds to 50S subunit, overlapping the A and P sites and blocking peptidyl transferase activity
Erythromycin	Prokaryotic	Blocks the 50S subunit tunnel, causing premature peptidyl-tRNA dissociation
<i>Elongation: Translocation</i>		
Fusidic acid	Both	Inhibits EF-G:GDP dissociation from ribosome
Thiostrepton	Prokaryotic	Inhibits ribosome-dependent EF-Tu and EF-G GTPase activity
Diphtheria toxin	Eukaryotic	Inactivates eEF-2 through ADP-ribosylation
Cycloheximide	Eukaryotic	Binds to the 50S E-site and stalls peptide elongation
<i>Premature Termination</i>		
Puromycin	Both	Aminoacyl-tRNA analog, binds at A site and acts as peptidyl acceptor, aborting peptide elongation
<i>Ribosome Inactivation</i>		
Ricin	Eukaryotic	Catalytic inactivation of 28S rRNA via <i>N</i> -glycosidase action on A ⁴²⁵⁶ within the GAC

Figure 30.32 The antibiotic geneticin and its site of action. **(a)** Structure of geneticin, a representative aminoglycoside antibiotic. Note the characteristic 2-deoxystreptamine (2-DOS) core structure, in red. **(b)** The base sequence of the small RNA loop within the 16S rRNA decoding center. Note that unpaired adenine residues 1408, 1492, and 1493 constitute the internal loop structure. (Adapted from Figure 1 in Hermann, T., 2005. Drugs targeting the ribosome. *Current Opinion in Structural Biology* 15:355–366.)

the macrolide class and act in a similar manner.) X-ray crystallographic analyses of ribosome–macrolide complexes show the macrolide bound within the peptide exit tunnel, 1 to 1.5 nm below the PTC. Macrolide binding plugs the exit tunnel, preventing the movement of the growing peptide chain through the tunnel. Protein synthesis is aborted and the peptidyl-tRNA eventually dissociates from the ribosome. Substituents bound at the 5-position of the macrolide extend outward from the peptide exit tunnel toward the PTC. (The 5-position in macrolides is the position where the $N(\text{CH}_3)_2$ -containing saccharide ring of erythromycin is attached; see Figure 30.31). All direct interactions of macrolide antibiotics with the ribosome involve 23S rRNA, not ribosomal proteins. Both macrolide and ketolide antibiotics adopt a conformation within the ribosome that projects a polar face into the peptide exit tunnel and a

nonpolar face toward the tunnel wall. Hydrophobic interactions between the lactone-ring methyl groups and the tunnel wall contribute significantly to the binding energy of these drugs. Residue A²⁰⁵⁸ of the prokaryotic 23S rRNA lies at the entrance to the peptide exit tunnel and favors macrolide antibiotic binding. The major large-subunit rRNA of ribosomes found in the cytosol and mitochondria of eukaryotic cells have G at the equivalent position and are unaffected by macrolides.

The most common effect of antibiotics that interact with the PTC is to occupy space within this center, such that the amino acid or peptidyl chain linked at the 3'-end of a tRNA cannot be positioned properly for the peptide-bond forming reaction. This mode of inhibition is consistent with the catalytic role of PTC in precisely orienting the substrates so that the peptide bond-forming reaction can occur. This effect is more common for aminoacyl-tRNAs in the A site, although some drugs can bridge the A and P sites and affect both aminoacyl-tRNA and peptidyl-tRNA orientation. Ribosomes with long peptidyl chains attached to the tRNA in the P site are less susceptible to macrolide antibiotics.

30.7c Eukaryotic-Specific Protein Synthesis Inhibitors

Small molecule inhibitors that target the 80S ribosome have use in the treatment of cancer, genetic disorders, or diseases caused by infectious organisms that are eukaryotic. Such compounds include those that target the 60S peptidyl transferase center (PTC), the tRNA E site, the peptide exit tunnel, or the GTPase-activating center (GAC). Others target the 40S decoding center or translation factor-binding sites. Unfortunately, most of these compounds have limited clinical use due to their cytotoxic side effects.

Foundational Biochemistry Things You Should Know after Reading Chapter 30.

- The genetic code allows the information expressed in a base sequence to be translated into the amino acid sequence of a protein.
- tRNAs are adapter molecules that bridge the gap between nucleotide sequence and amino acid sequence.
- The genetic code is a triplet code.
- Codons specify amino acids.
- Of the 64 codons possible from the four bases (A, C, G, U), 61 specify an amino acid (the sense codons) and 3 are termination signals (stop codons or nonsense codons).
- The genetic code is unambiguous, degenerate, and universal.
- An amino acid is matched with its proper tRNA by its specific aminoacyl-tRNA synthetase.
- Cells have 20 different aminoacyl-tRNA synthetases.
- The code by which each aminoacyl-tRNA matches up its amino acid with appropriate tRNAs constitutes a second genetic code.
- Aminoacyl-tRNA synthetases interpret the second genetic code.
- Evolution has provided two distinct classes of aminoacyl-tRNA synthetases.
- Recognition of mRNA codons by tRNA anticodons is through anti-parallel base-pairing.
- The wobble hypothesis points out that the third base of the codon and the first base of the anticodon follow less stringent base-pairing rules.
- Some codons are used more than others.
- Nonsense suppression occurs when suppressor tRNAs read nonsense codons.
- Ribosomes are the agents by which mRNAs are translated into proteins.
- Bacterial ribosomes are composed of 30S and 50S subunits.
- Bacterial ribosomes contain 50 different proteins and three different rRNAs.
- Ribosomes can spontaneously assemble in vitro from a mixture of their component proteins and rRNAs.
- The overall structures of prokaryotic and eukaryotic ribosomes are similar.
- The central domain of the 30S ribosomal subunit is the site of the decoding center.
- The defining reaction of protein synthesis is performed by peptidyl transferase.
- Peptidyl transferase is a catalytic activity of the large rRNA of the large ribosomal subunit.
- Cytosolic ribosomes of eukaryotes are considerably larger and more complex than prokaryotic ribosomes.
- In translation, a ribosome moves along an mRNA in the 5'→3' direction, synthesizing a protein in the N→C direction.
- Initiation of translation involves mRNA binding by the small ribosomal subunit, following by association of the initiator Met-tRNA_i^{Met} that recognizes the first codon, then recruitment of a large ribosomal subunit to form the 70S initiation complex, which is composed of 30 + 50S ribosomal subunits:mRNA:f-Met-tRNA_i^{Met}.
- Elongation is the phase of translation that forms every peptide bond, from the first to the last.
- Elongation is a repetitive series of: codon-directed binding of an aminoacyl-tRNA, peptidyl transfer from the peptidyl-tRNA to the amino group of the aminoacyl-tRNA, and translocation of the ribosome one codon further along the mRNA.
- Three tRNAs may be associated with the ribosome:mRNA complex at any moment: one in the A (or acceptor) site, one in the P (or peptidyl) site, and one in the E (or exit) site.

- Termination is triggered when the ribosome reaches a termination codon on the mRNA.
- Peptide chain initiation requires: mRNA, 30S and 50S ribosomal subunits, initiation factors, GTP, and f-Met-tRNA_i^{Met}.
- In prokaryotes, recognition of the mRNA and proper alignment for translation depends on interaction between the Shine-Dalgarno sequence at the 5'-end of the mRNA and a complementary sequence near the 3'-end of the small ribosomal subunit 16S rRNA.
- Three initiation factors (IF-1, IF-2, and IF-3) participate in initiation of translation.
- IF-2, a G-protein family member, delivers the initiator f-Met-tRNA_i^{Met} to the 30S ribosomal subunit:mRNA complex.
- GTP hydrolysis by IF-2 is triggered when a 50S ribosomal subunit joins the 30S:mRNA:f-Met-tRNA_i^{Met} complex.
- Three elongation factors are required: EF-Tu, EF-Ts, and EF-G.
- The peptide chain elongation cycle has three principal steps:
 1. Codon-directed binding of an incoming aminoacyl-tRNA at the A site.
 2. Peptide bond formation by the 50S subunit peptidyl transferase activity through transfer of the peptidyl chain from the P-site tRNA to the amino group of the aminoacyl-tRNA in the A site.
 3. Translocation of the ribosome one codon further along the mRNA, accompanied by movement of the now longer peptidyl-tRNA from the A site to the P site.
- The decoding center that ensures proper codon:anticodon recognition is a 16S rRNA function.
- EF-Tu is a G-protein family member that mediates delivery of the aminoacyl-tRNA to the A site.
- EF-Ts is a guanine nucleotide exchange factor (GEF) that exchanges GDP for GTP on Ef-Tu.
- 23S rRNA is the peptidyl transferase enzyme.
- Catalysis of peptide bond formation relies on tight binding of the aminoacyl-tRNA and the peptidyl-tRNA by the ribosome.
- The translocation phase of protein synthesis has three principal steps:
 1. The deacylated tRNA must be moved from the P site to the E site.
 2. The newly extended peptidyl-tRNA must be moved from the A site to the P site.
- 3. Concomitant with these events, the ribosome must translocate one codon further along the mRNA.
- EF-G acts as a GTP-driven molecular switch that mediates ribosome movement along the mRNA.
- EF-Tu and EF-G compete for binding at a common site on the ribosome, called the factor-binding center or GTPase-activating center (GAC).
- Peptide chain termination requires yet another G-protein family member, RF-3.
- Molecular mimicry is seen in the structures of EF-TU:tRNA complex, EF-G, and RF-3.
- Termination occurs when release factors recognize a termination codon.
- The ribosomal subunits cycle between 70S complexes and free ribosomal subunits.
- Polysomes are the active structures of protein synthesis.
- Protein synthesis in eukaryotes is more complex than in prokaryotes.
- More than a dozen eukaryotic initiation factors, symbolized as eIFs, are required.
- Eukaryotic initiation proceeds through three stages:
 1. Formation of the 43S preinitiation complex, composed of a set of the eIFs, the 40S ribosomal subunit, and eIF2:GTP:Met-tRNA_i^{Met}.
 2. Formation of the 48S initiation complex, which includes the 43S preinitiation complex, mRNA, and additional eIFs.
 3. Formation of the 80S initiation complex, with the initiator Met-tRNA_i^{Met} atop the initiation codon, through addition of the 60S large ribosomal subunit.
- Control of eukaryotic peptide chain initiation is an important mechanism for post-transcriptional regulation of gene expression.
- Eukaryotic peptide chain elongation resembles the prokaryotic process.
- Eukaryotic peptide chain termination requires release factors eRF1, eRF3, and GTP.
- Because eukaryotic and bacterial protein synthesis is different, some inhibitors of protein synthesis serve as medically important antibiotics.
- The decoding center is a target of aminoglycoside antibiotics.
- Many antibiotics target the peptidyl transferase center and the peptide exit tunnel.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. Translating Nucleotide Sequences into Amino Acid Sequences

(Integrates with Chapter 12.) The following sequence represents part of the nucleotide sequence of a cloned cDNA:

...CAATACGAAGCAATCCCGCGACTAGACCTTAAC...

Can this cDNA be translated into more than one amino acid sequence?

2. Nucleotide Sequences, Possible Codons, and Amino Acid Specification

A random (AG) copolymer was synthesized using a mixture of five parts adenine nucleotide to one part guanine nucleotide as substrate. If this random copolymer is used as an mRNA in a cell-free protein synthesis system, which amino acids will be incorporated into the polypeptide product? What will be the relative abundances of these amino acids in the product?

3. Nucleotide Sequences and Codons If the first nucleotide in a codon is altered due to a mutation, it will almost always lead to a change in the incorporated amino acid. Which two amino acids represent exceptions?

4. The Second Genetic Code Review the evidence establishing that aminoacyl-tRNA synthetases bridge the information gap between amino acids and codons. Indicate the various levels of specificity possessed by aminoacyl-tRNA synthetases that are essential for high-fidelity translation of messenger RNA molecules.

5. Codon–Anticodon Recognition: Base-Pairing Possibilities

(Integrates with Chapter 11.) Draw base-pair structures for (a) a G:C base pair, (b) a C:G base pair, (c) a G:U base pair, and (d) a U:G base pair. Note how these various base pairs differ in the potential hydrogen-bonding patterns they present within the major groove and minor groove of a double-helical nucleic acid.

6. **Consequences of the Wobble Hypothesis** Explain why Crick's wobble hypothesis would allow fewer than 61 anticodons to be used to translate the 61 sense codons. How may wobble accelerate the rate of translation?
7. **Sense-to-Nonsense Codon Mutations** How many codons can mutate to become nonsense codons through a single base change? Which amino acids do they encode?
8. **Tryptophan Substitutions** (Integrates with Chapter 4.) Tryptophan (W) is a unique amino acid in terms of its size, and its physical and chemical properties. List the codons (and the amino acids, if any, that they specify) that could be changed into UGG (the codon for W) by a single point mutation. Describe the effect of each such mutation.
9. **Amino Acid Possibilities in Nonsense Suppression** Nonsense suppression occurs when a suppressor mutant arises that reads a nonsense codon and inserts an amino acid, as if the nonsense codon were actually a sense codon. Which amino acids do you think are most likely to be incorporated by nonsense suppressor mutants?
10. **RNA Editing and Translation** (Integrates with Chapter 29.5i.) Review the discussions about mRNA editing in Section 29.5i. Discuss the effects that RNA editing might have in light of the fact that GUG is sometimes used as a start codon instead of AUG (see Section 30.5a).
11. **Bacterial vs. Eukaryotic Protein Synthesis** Why do you suppose eukaryotic protein synthesis is only 10% as fast as bacterial protein synthesis?
12. **Mutations at a AUG Codon** Compare prokaryotic and eukaryotic translation initiation and explain why a mutation in the first AUG codon from the 5' end of mRNA would not lead to the synthesis of a protein in prokaryotes but may produce a shorter protein in eukaryotes.
13. **Capacity of the Ribosomal Peptide Exit Tunnel** If the tunnel through the large ribosomal subunit is 10 nm long, how many amino acid residues might be contained within it? (Assume that the growing polypeptide chain is in an extended β -sheet-like conformation.)
14. **The Consequences of Ribosome Complexity** Eukaryotic ribosomes are larger and more complex than prokaryotic ribosomes. What advantages and disadvantages might this greater ribosomal complexity bring to a eukaryotic cell?
15. **Ribosomes as Two-Subunit Structures** What ideas can you suggest to explain why ribosomes invariably exist as two-subunit structures, instead of a larger, single-subunit entity?
16. **23S rRNA** Why is 23S rRNA (prokaryotes) classified as a ribozyme?
17. **tRNA^{Met} Recognition and Translation Initiation** How do bacterial cells determine whether a particular methionyl-tRNA^{Met} is intended to initiate protein synthesis or to deliver a Met residue for internal incorporation into a polypeptide chain? How do the Met codons for these two different purposes differ? How do eukaryotic cells handle these problems?
18. **Invariant Nucleotides in tRNA** (Integrates with Chapter 11.) tRNA molecules always have the invariant 3'-AAC sequence of unpaired nucleotides (see Section 11.7a). What is the role of these three nucleotides in the translation process and why are they always unpaired?
19. **The Function of the Shine-Dalgarno Sequence** What is the Shine-Dalgarno sequence? What does it do? The efficiency of protein synthesis initiation may vary by as much as 100-fold for different mRNAs. How might the Shine-Dalgarno sequence be responsible for this difference?
20. **Reconciling Peptide Bond Formation and tRNA Movements** In the protein synthesis elongation events described under the section on translocation, which of the following seems the most apt account of the peptidyl transfer reaction: (a) The peptidyl-tRNA delivers its peptide chain to the newly arrived aminoacyl-tRNA situated in the A site, or (b) the aminoacyl end of the aminoacyl-tRNA moves toward the P site to accept the peptidyl chain? Which of these two scenarios makes more sense to you? Why?
21. **Why Translation Factors Are G Proteins** (Integrates with Chapter 15.) Why might you suspect that the elongation factors EF-Tu and EF-Ts are evolutionarily related to the G proteins of membrane signal transduction pathways described in Chapter 15?
22. **The Energetic Cost of Peptide Elongation** How many ATP equivalents are consumed for each amino acid added to an elongating polypeptide chain during the process of protein synthesis?
23. **Exploring the Structure of the Prokaryotic Ribosome** Go to www.rcsb.org and bring up PDB file 4V42, which shows the structure of the *Thermus thermophilus* 70S ribosome, complete with the three tRNAs and A- and P-site mRNA codons. At the bottom of the box on the left with the image, click on "1D-3D View." A new window opens with an interactive view of the structure. By moving your cursor over the image, you can rotate it to view it from any perspective. Also, a pop-up window at the bottom of the image box reveals the component of the structure that the cursor is resting on.
 - a. Determine which part of the structure is the 30S ribosomal subunit and which is the 50S ribosomal subunit.
 - b. Notice the color-coded tRNAs in the structure. What color is the A-site tRNA, what color is the P-site tRNA, and what color is the E-site tRNA in this image?
 - c. Zoom in and notice the juxtaposition of the 3'-CCA ends of the A-site and P-site tRNAs. What function of the ribosome must lie at this juxtaposition? Which ribosomal subunit is the home of this function?
 - d. Notice the green band of ribbon near the anticodon ends of the A-site and P-site tRNAs. It represents mRNA bearing codons read by the anticodons of these tRNAs. What function of the ribosome must lie near these codons and anticodons? Which ribosomal subunit is the home of this function?
24. **Exploring the Interaction between Elongation Factor eEF2 and the Translating Eukaryotic Ribosome** Go to www.rcsb.org and bring up PDB 6GQB, which shows the structure of yeast eukaryotic ribosome in complex with tRNAs, mRNA, and eEF2, as described in Pellegrino, S., et al., the *Journal of Molecular Biology* **430**:2677–2687. Position 699 in the amino acid sequence of eEF2 is the location of the modified histidine diphthamide moiety. At the bottom of the box on the left with the image, click on "1D-3D View." A new window opens with an interactive view of the structure. By moving your cursor over the image, you can rotate it to view it from any perspective. Also, a pop-up window at the bottom of the image box reveals the component of the structure that the cursor is resting on. eEF2 (designated protein FC in the PDB assignment for 6GQB) shows up in a prominent red color in this image.
 - a. What is the general location of eEF2 relative to the 80S ribosome?
 - b. Zoom in to explore the neighborhood near the residue 690-710 region of eEF2. What key RNA is nearby?
 - c. Interpret the significance of your observations in a. and b. in light of the role of the diphthamide side chain in eEF2 function. (The Human Biochemistry box on page 1120 gives a clue.)
25. **Post-translational Events and Protein Function** The transcription and translation of a particular gene leads to a polypeptide chain but not necessarily to a functional protein. Revisit previous chapters and discuss what post-translational events might be necessary for some proteins to become functional?
26. **Shine-Dalgarno Sequences Base Pair with the 3'-End of 16S rRNA** Review the list of Shine-Dalgarno sequences in Figure 30.18 and select the one that will interact best with the 3'-end of *E. coli* 16S rRNA.
27. **Chloramphenicol Inhibition of Peptidyl Transferase** Chloramphenicol (Figure 30.31) inhibits the peptidyl transferase activity of the 50S ribosomal subunit. The 50S peptidyl transferase active site consists solely of functionalities provided by the 23S rRNA. What sorts of interactions do you think take place when chloramphenicol binds to the peptidyl transferase center? Which groups on chloramphenicol might be involved in these interactions?

Think-Pair-Share Question

Impact of Mutations on Protein Function Consider the DNA sequence shown.

3'-GCATGATACGTGCTAATAGAGTCTTGGACT
TTGCATAA-5'

- Transcribe this DNA sequence into the corresponding mRNA and translate into the corresponding amino acid sequence starting from the appropriate start codon.
- Give at least six reasons why a point mutation in a protein-coding gene may not necessarily lead to a dysfunctional protein.

Completing the Protein Life Cycle: Folding, Processing, and Degradation

31

Life is a process of becoming, a combination of states we have to go through.

Anais Nin (1903–1977)

Courtesy of Reginald H. Garrett (special thanks to Reggie and Ricky Garrett)

◀ Origami cranes. *Origami*—the Asian art of paper folding—arose in China almost 2000 years ago when paper was rare and expensive and the folded shape added special meaning. Protein folding, like origami, takes a functionless form and creates a structure with unique identity and purpose.

Essential Question

Proteins are the agents of biological function. Protein turnover (synthesis and decay) is a fundamental aspect of each protein's natural history. **How are newly synthesized polypeptide chains transformed into mature, active proteins, and how are undesired proteins removed from cells?**

The human genome contains approximately 20,500 genes, but some estimates suggest that the total number of proteins in the human proteome (the entire complement of distinct functional proteins in the human body) may approach 1 million. What processes introduce such dramatically increased variation into the products of protein-encoding genes? We've reviewed many of these processes; a partial list (with examples) includes:

1. Gene rearrangements (immunoglobulin G)
2. Alternative splicing (fast skeletal muscle troponin T)
3. RNA editing (apolipoprotein B)
4. Proteolytic processing (chymotrypsinogen)
5. Isozymes (lactate dehydrogenase)
6. Protein sharing (the glycolytic enzyme enolase is identical to τ -crystallin in the eye)
7. Protein–protein interactions at many levels (oligomerization, supramolecular complexes, assembly of signaling pathway protein complexes upon scaffold proteins)
8. Covalent modifications of many kinds (phosphorylation or glycosylation, with multisite phosphorylation or variable degrees of glycosylation, to name just two of the hundreds of possibilities)

As we will see in this chapter, for each protein variant, its amount and its distribution within the cell is determined not only by gene expression, mRNA stability, and protein synthesis, but also by post-translational modifications, protein–protein interactions, intracellular localization, and, ultimately, protein degradation (Figure 31.1). All of these processes are dynamic and integrated.

Key Questions

- 31.1 How Do Newly Synthesized Proteins Fold?
- 31.2 How Are Proteins Processed Following Translation?
- 31.3 How Do Protein Translocation Pathways Target Proteins to Subcellular Compartments?
- 31.4 How Does Protein Degradation Regulate Cellular Levels of Specific Proteins?

Figure 31.1 Modes of post-transcriptional regulation that control the functional protein pool of the cell. The proper amount of each protein is determined by tightly regulated crosstalk between all of these processes, in response to regulatory signals received by the cell. (Adapted from Figure 1 in Breker, M., and Schuldiner, M., 2014. The emergence of proteome-wide technologies: Systematic analysis of proteins comes of age. *Nature Reviews Molecular and Cell Biology* 15:453–464.)

Figure 31.2 Protein folding pathways. (a) Chaperone-independent folding. The protein folds as it is synthesized on the ribosome (green) (or shortly thereafter). (b) Hsp70/Hsp90-assisted protein folding. Hsp70 (gray) binds to nascent polypeptide chains as they are synthesized and assists their folding. Binding to Hsp90 facilitates further folding. (c) Folding assisted by Hsp70 and chaperonin complexes. The chaperonin complex in *E. coli* is GroES–GroEL.

Thus, the nascent polypeptide emerging from a ribosome is not yet the agent of biological function that is its destiny. First, the polypeptide must fold into its native tertiary structure. This complicated process is made even more so by the crowding of macromolecules inside a typical cell. Even then, seldom is the newly synthesized, folded protein in its final functional state. Proteins often undergo various proteolytic processing reactions and covalent modifications as steps in their maturation to functional molecules. Most proteins are eventually degraded by regulatory processes (after a brief or a long life-span). These regulatory processes carefully control the available amounts of particular proteins. Proteins may also be degraded if they are damaged or unfolded. Proteins that persist for long times in organisms may be untouched by these regulatory processes, but these proteins are at increased risk for damage accumulation that may contribute to cellular aging processes. Damaged or misfolded proteins are a serious hazard; accumulation of protein aggregates can be a cause of human disease, including the prion diseases and diseases of amyloid accumulation, such as Alzheimer's, Parkinson's, or Huntington's disease.

31.1 | How Do Newly Synthesized Proteins Fold?

The information for folding each protein into its unique three-dimensional architecture resides within its amino acid sequence or primary structure (see Chapter 6). Proteins begin to fold even before their synthesis by ribosomes is completed (Figure 31.2a).

Human Biochemistry

Neurodegenerative Disorders are Caused by the Accumulation of Protein Deposits

As noted in Chapter 6, protein misfolding problems can cause disease by a variety of mechanisms. For example, protein aggregates can impair cell function. Most neurodegenerative diseases are caused by aggregation of a particular protein (Table).

Disease	Involved Protein
Alzheimer's disease	β -Amyloid, Tau
Parkinson's disease	α -Synuclein
Diabetes Type 2	Amylin
Amyotrophic lateral sclerosis (Lou Gehrig's disease)	TDP-43
Chronic traumatic encephalopathy	Tau
Huntington's disease	Huntingtin
Creutzfeldt-Jakob disease and kuru	PrP (prion)

All of these proteins except huntingtin (Figure 1) are intrinsically unstructured proteins (IUPs) or contain unstructured domains. Huntingtin in human neurons forms a complex with HAP40 in which both proteins are largely α -helical. Huntingtin plays an important role in neurons in the brain, and mutations in the gene for huntingtin result in disease.

Amyloid plaques (so named because they resemble the intracellular starch, or amyloid, deposits found in plant cells) and **neurofibrillary tangles (NFTs)**, composed of tau (τ) proteins, are proteinaceous deposits found in the brains of individuals suffering from any of several neurodegenerative diseases. In Alzheimer's, disease is caused both by extracellular amyloid deposits composed of proteolytic fragments of the amyloid precursor protein (APP) termed **amyloid- β ($A\beta$)** and intracellular NFTs. $A\beta$ (Figure 2) is a peptide 39 to 43 amino acids long that polymerizes to form long, highly ordered, insoluble fibrils

Figure 2 A model for the $A\beta_{1-40}$ structural unit in β -amyloid fibrils. Fibrils contain β -strands perpendicular to the fibril axis, with interstrand hydrogen bonding parallel to the fiber axis. The top face of the β -sheet is hydrophobic and presumably interacts with neighboring $A\beta$ molecules in fibril formation. (Figure adapted from Figure 1 in Thompson, L. K., 2003. Unraveling the secrets of Alzheimer's β -amyloid fibrils. *Proceedings of the National Academy of Sciences, U.S.A.* **100**:383–385.)

consisting of a hydrogen-bonded parallel β -sheet structure in which identical residues on adjacent chains are aligned directly, in register (see accompanying figure). Why $A\beta$ aggregates in some people but not others is not clear. In Parkinson's, the culprits are NFTs; no amyloid plaques are evident. In Huntington's disease, the protein deposits occur as nuclear inclusions composed of polyglutamine (polyQ) aggregates. PolyQ aggregates arise from mutant forms of **huntingtin**, a protein that characteristically has a stretch of glutamine residues close to its N-terminus.

Many amyloid-forming proteins are secreted and form deposits in the extracellular space of the nervous system and various organs. A few, including α -synuclein, tau and huntingtin are cytosolic and form intracellular inclusions. How do protein aggregates form, and how do they damage neurons in these neurodegenerative diseases? Misfolded and partially folded proteins expose hydrophobic amino acid residues and regions of unstructured polypeptide backbone to the solvent. Spontaneous association of these hydrophobic surfaces results in aggregations that form oligomers and then amyloid fibrils rich in β -sheet structure (Figure 3).

These soluble oligomers are widely considered to be more potent neurotoxins than the fibrils. The oligomers expose sticky surfaces (hydrophobic amino acid residues and unpaired β -strands) that disturb phospholipid bilayers and engage in aberrant interactions with multiple key cellular proteins.

Impairment of cellular function by proteinaceous deposits may be a general phenomenon. In vitro experiments have demonstrated that aggregates of proteins not associated with disease can be cytotoxic, and the ability to form amyloid deposits is a general property of proteins. The evolution of chaperones to assist protein folding and proteasomes to destroy improperly folded proteins may have been driven by the necessity to prevent protein aggregation.

Figure 1 Human huntingtin protein in a complex with HAP40. Huntingtin consists of three domains – N-terminal (N-term, blue), Bridge (yellow) and C-terminal (C-term, green). (PDB id = 6EZ8).

(Continued)

Figure 3 A model for formation of oligomers and amyloid fibrils by proteins involved in neurodegenerative diseases.

However, the cytosolic environment is a very crowded place, with effective protein concentrations as high as 0.3 g/mL. Macromolecular crowding enhances the likelihood of nonspecific protein association and aggregation. The primary driving force for protein folding is the burial of hydrophobic side chains away from the aqueous solvent and reduction in solvent-accessible surface area (see Chapter 6). The folded protein typically has a buried hydrophobic core and a hydrophilic surface. Protein aggregation is driven by hydrophobic interactions, so burial of hydrophobic regions through folding is a crucial factor in preventing aggregation. To evade aggregation, nascent proteins are often assisted in folding by a family of helper proteins known as **molecular chaperones** (see Chapter 6) because, like the chaperones at a prom, their purpose is to prevent inappropriate liaisons. Chaperones also serve to shepherd proteins to their ultimate cellular destinations. Also, mature proteins that have become partially unfolded may be rescued by chaperone-assisted refolding.

31.1a Chaperones Help Some Proteins Fold

Small, single-domain proteins fold efficiently without the aid of chaperones, but larger proteins and multi-domain proteins often require chaperones, especially in the crowded milieu of a cell. A number of chaperone systems are found in all cells. Many of the proteins in these systems are designated by the acronym **Hsp** (for **heat shock protein**) and a number indicating their relative mass in kilodaltons (as in Hsp60). Hsps were originally observed as abundant proteins in cells given brief exposure to high temperature (42°C or so). The principal Hsp chaperones are **Hsp70**, **Hsp60** (the **chaperonins**), and **Hsp90**. In general, proteins whose folding is chaperone-dependent pass down a pathway in which Hsp70 acts first on the newly synthesized protein and then passes the partially folded intermediate to a chaperonin for completion of folding. Protein folding by chaperones is often ATP-dependent, and in many cases, the function of these chaperones is regulated by **cochaperones**, which bind to the chaperone complex and control ATP hydrolysis activity and protein folding.

Nascent polypeptide chains exiting the large ribosomal subunits are met by ribosome-associated chaperones (**TF**, or **Trigger Factor**, in *Escherichia coli*; **NAC** [**nascent chain-associated complex**] in eukaryotes). In *E. coli*, the 50S ribosomal protein L23, which is situated at the peptide exit tunnel, serves as the docking site for TF, directly linking protein synthesis with chaperone-assisted protein folding. TF and NAC mediate transfer of the emerging nascent polypeptide chain to the Hsp70 class of chaperones, although many proteins do not require this step for proper folding.

31.1b Hsp70 Chaperones Bind to Hydrophobic Regions of Extended Polypeptides

In Hsp70-assisted folding, proteins of the Hsp70 class bind to nascent polypeptide chains while they are still on ribosomes (Figure 31.2b). **DnaK** is the principal Hsp70 in

Careers in Chemistry

Dr. Odutayo (Tayo) Odunuga

Dr. Odutayo (Tayo) Odunuga is a Professor of Biochemistry at Stephen F. Austin State University, where he teaches introductory chemistry to science and pre-health majors and non-science majors. He also teaches biochemistry, cell and molecular biology, biochemical techniques, research methods and seminar courses at the undergraduate and graduate levels. He is currently developing accessible biochemistry laboratory experiments that are safe, simple, and inexpensive.

Dr. Odunuga earned a B.S. in Biochemistry at Olabisi Onabanjo University and went on to

his M.S. in Biochemistry from the University of Ibadan in his birthplace of Nigeria. While lecturing in Nigeria he was offered a predoctoral fellowship to pursue a Ph.D. in Biochemistry and Molecular Biology from Rhodes University in South Africa. His thriving research program enjoys collaborations across the United States, South Africa (Rhodes University), and Norway (the Arctic University of Norway). Dr. Odunuga credits his education and career for his many opportunities to travel the world to teach people of all backgrounds the joys of biochemistry.

E. coli. It recognizes exposed, extended regions of polypeptides that are rich in hydrophobic residues. By interacting with these regions, this Hsp70 prevents nonproductive associations and keeps the polypeptide (termed a client protein) in an unfolded (or partially folded) state until productive folding interactions can occur. Completion of folding requires release of the protein from Hsp70; release is energy-dependent and is driven by ATP hydrolysis.

Hsp70 proteins such as DnaK consist of two domains: a 44-kDa N-terminal ATP-binding domain and an 18-kDa central domain that binds polypeptides with exposed hydrophobic regions (Figure 31.3a). The DnaK-ATP complex receives an unfolded (or partially folded) polypeptide chain from **DnaJ** (Figure 31.3b). DnaJ is an **Hsp40** family member. Interaction of DnaK with DnaJ triggers the ATPase activity of DnaK; the DnaK-ADP complex forms a stable complex with the unfolded polypeptide, preventing its aggregation with other proteins. A third protein, **GrpE**, catalyzes nucleotide exchange on DnaK, replacing ADP with ATP, which converts DnaK back to a conformational form having low affinity for its polypeptide substrate. Release of the polypeptide gives it the opportunity to fold. Multiple cycles of interaction with DnaK (or Hsp70) give rise to partially folded intermediates or, in some cases, completely folded proteins. The partially folded intermediates may be passed along either to an Hsp90 (Figure 31.2b) or to the Hsp60/chaperonin system for completion of folding (Figure 31.2c).

The chaperones that mediate protein folding do so in an ATP-dependent manner, as illustrated in Figures 31.3 and 31.5. The affinity of chaperones for their unfolded or misfolded protein substrates is determined by the nature of the nucleotide bound by the ATP binding domain of these proteins, which functions as an ATPase. If ATP is bound, the chaperone adopts a conformation with an open substrate-binding pocket (Figure 31.3c). ATP increases the rate of association of the chaperone Hsp70 (DnaK) with an unfolded peptide or protein client by 100-fold, but it increases the rate of dissociation of the unfolded protein from the chaperone even more, by a factor of 1000. Overall, the chaperone's affinity for an unfolded protein substrate decreases 10-fold (or more) when it binds ATP.

On the other hand, if the substrate-binding site on the peptide binding domain of DnaK is occupied by an unfolded protein client in conjunction with binding of the DnaJ cochaperone (Figure 31.3b), ATP hydrolysis by the ATPase domain is triggered. The presence of ADP in the ATP-binding (ATPase) domain causes a shift in the substrate-binding site of the peptide-binding domain to a closed conformation, high-affinity state (Figure 31.3c). Thus, ATP-dependent chaperones cycle between two stable conformational states, just like allosteric proteins. Bound ATP favors the open conformation for the protein substrate-binding site, and ADP favors the closed conformation. (When ADP is released and no nucleotide occupies the ATP binding site of the ATPase domain, the peptide-binding site remains in the closed, high-affinity conformation; see Figure 31.3b).

- (a) Domain organization and structure of the Hsp70 family member, DnaK

- (b) DnaK mechanism of action

Figure 31.3 Structure and function of DnaK. **(a)** Domain organization and structure of the Hsp70 family member, DnaK. The ribbon diagram on the lower left is the ATP-binding domain of the DnaK analog, bovine Hsc70; bound ADP is shown as a stick diagram (purple). The ribbon diagram on the lower right is the polypeptide-binding domain of DnaK. The small blue ovals highlight the position of the polypeptide substrate; the protein regions that bind the polypeptide substrate are blue-green. **(b)** DnaK mechanism of action: DnaJ binds an unfolded protein (U) or partially folded intermediate (I) and delivers it to the DnaK-ATP complex. The nucleotide exchange protein GrpE replaces ADP with ATP on DnaK and the partially folded intermediate (I) is released. I has several possible fates: It may fold into the native state, N; it may undergo another cycle of interaction with DnaJ and DnaK; or it may become a substrate for folding by the GroEL chaperonin system. (Adapted from Figures 1a and 2a in Frydman, J., 2001. Folding of newly translated proteins in vivo: The role of molecular chaperones. *Annual Review of Biochemistry* 70:603–647.) **(c)** Open and closed structures of DnaK, an Hsp70 from *E. coli*. Left—Open, ATP-bound structure of DnaK (PDB id = 4B9Q). Right—Closed, ADP-bound structure of DnaK (PDB id = 2KHO).

DnaJ in *E. coli* is a *J-domain protein* or simply a *J-protein*. The Hsp70s are likely the most versatile molecular chaperones, and they gain much of this versatility from their multiple J-protein partners (at least 7 in *E. coli* and 45 in humans). These Hsp70/J-protein interactions not only direct Hsp70s to particular substrate proteins, but also integrate Hsp70 functions into cellular developmental and regulatory pathways and also chaperone-mediated protein homeostasis networks.

31.1c Hsp90 Partners With Hsp70 in Hsp70-Hsp90 Folding Cascades

Hsp90 constitutes 1% to 2% of the total cytosolic proteins of eukaryotes, its abundance reflecting its importance. Like other Hsp chaperones, its action depends on cyclic binding and hydrolysis of ATP. Hsp90 is a highly conserved chaperone involved in protein homeostasis. It functions in the remodeling of hundreds of client proteins in eukaryotes and participates in many cellular processes, including signal transduction, protein trafficking, and maturation of receptor proteins. Hsp90 is a homodimer with each monomer consisting of three domains, including an N-terminal domain, a middle-domain (M-domain), and a C-terminal domain. A portion of the M-domain interacts with Hsp70 in *E. coli* and yeast and perhaps also in higher eukaryotes. Hsp90s are highly dynamic proteins that undergo large conformation changes during the chaperone cycle (Figure 31.4).

As Hsp90 moves through its various conformations, client proteins may be bound and released, either in ATP-dependent transitions or in an ATP-independent manner. Following release, the unstructured regions of the client may fold spontaneously into

Figure 31.4 Hsp90 undergoes large conformation changes in the chaperone cycle. **(a)** The peptide sequence of Hsp90 from *E. coli*. **(b)** Two structures of Hsp90 from *E. coli*—the apo state with no substrate or nucleotide bound (PDB id = 2IOQ) and the ADP-bound state (PDB id = 2IOP). One subunit is colored in each image to match the domains indicated in (a).

the native conformation. If the native conformation is not achieved, the client protein may undergo repeated cycles of binding and release by Hsp90 until it finally folds.

Hsp70 and Hsp90 often work together as a protein folding relay team. Hsp70 does not actually fold proteins, but rather is a folding preventer. Its binding pocket accepts stretches of short hydrophobic or aromatic sequences (up to five sequential residues), which would ordinarily end up in the hydrophobic core of folded proteins and late folding intermediates but which are exposed in unfolded proteins. Multiple cycles of binding and release of these hydrophobic segments follow, preventing aggregation but allowing the target protein to fold while not bound. After release, the protein either folds or binds again to Hsp70. Thus, Hsp70 binds early to the core-forming segments of unfolded proteins.

On the other hand, Hsp90 recognizes proteins that are not completely folded by Hsp70 and binds to hydrophobic and charged residues exposed over a large surface area in natively unfolded proteins. An extended binding site on Hsp90 recognizes scattered hydrophobic and charged patches typical of late folding stages. In contrast to Hsp70, Hsp90 does not block folding. Instead, the client can achieve the native state while bound to Hsp90. Hsp70 and Hsp90 thus interact transiently and sequentially, with Hsp90 acting downstream of Hsp70 to improve folding.

Conformational regulation of signal transduction molecules seems to be a major purpose of Hsp90. Receptor tyrosine kinases, soluble tyrosine kinases, and steroid hormone receptors are some of the signal transduction proteins that must associate with Hsp90 in order to become fully competent. CFTR (cystic fibrosis transmembrane regulator), telomerase, and nitric oxide synthase are also Hsp90-dependent.

Association of nascent polypeptide chains with proteins of the various chaperone systems commits them to a folding pathway, redirecting them away from degradation pathways that would otherwise eliminate them from the cell. However, if these protein chains fail to fold, they are recognized as non-native and targeted for destruction.

31.1d The GroES–GroEL Complex of *E. coli* Is an Hsp60 Chaperonin

The Hsp60 class of chaperones, also known as **chaperonins**, assists some partially folded proteins (10% of the cytosolic proteome) to complete folding after their release from ribosomes. Chaperonins sequester partially folded molecules from one another

Chaperone Proteins That Function by Stress-Induced Unfolding

Certain small, ATP-independent chaperones are fully folded and inactive under normal cellular circumstances. These chaperones are activated by stressful conditions that convert them from a fully folded, but inactive, form into a disordered, but active, structure that can bind client proteins, help them to achieve their appropriate folded states, and then undergo a disorder-to-order transition that releases the folded client. For example, HdeA is an acid-activated chaperone in the periplasm of *E. coli* cells. When *E. coli* is ingested by a human subject, the pH of its periplasm rapidly equilibrates with the pH of the stomach (~2). This pH would cause irreversible denaturation and inactivation of most proteins, were it not for HdeA. At pH 7, HdeA is a folded dimer (figure) with no chaperone function. Upon the shift to pH 2, HdeA undergoes partial unfolding and dissociates to form monomers, which are active as chaperones. HdeA monomers bind to a variety of periplasmic protein clients, protecting them against irreversible damage, and thereby shielding *E. coli* from the harmful effects of stomach acid. When the *E. coli* cells move into the small intestine and its near-neutral pH, HdeA releases its client proteins in folded form and reverts to the inactive dimeric state.

In a manner similar to HdeA, Hsp33 is a compactly folded, inactive chaperone protein under nonstressful conditions. Hsp33 is a monomeric, redox-regulated bacterial chaperone composed of an N-terminal domain and a C-terminal domain (figure) with four Cys residues that coordinate a zinc ion. Exposure to oxidizing conditions (bleach, for example, or heat stress) induces partial unfolding of the zinc-binding domain and release of the zinc ion. The four Cys residues are now free to form two disulfide bridges. Partial unfolding and disulfide formation activates Hsp33's chaperone activity. Hsp33 protects hundreds of cytoplasmic proteins against stress-induced protein aggregation and allows bacteria (such as *E. coli* and *Vibrio cholera*) to survive the anti-microbial action of bleach.

Some chaperones, including HdeA and Hsp33, respond to cellular stress. HdeA (left, PDB id = 1DG8) and Hsp33 (right, PDB id = 1VZY). The Zn atom of Hsp33 is green; the coordinating Cys residues are shown as space-filled spheres).

(and from extraneous interactions), allowing folding to proceed in a protected environment. This protected environment is sometimes referred to as an **Anfinsen cage** because it provides an enclosed space where proteins fold spontaneously, free from the possibility of aggregation with other proteins. Chaperonins are large, cylindrical protein complexes formed from two stacked rings of subunits.

The chaperonins have been organized into two groups, I and II, on the basis of their source and structure. Group I chaperonins are found in bacteria and group II in archaea and eukaryotes. The group I chaperonin in *E. coli* is the **GroES–GroEL complex** (Figure 31.2c). GroEL is made of two stacked seven-membered rings of 60 kDa subunits that form a cylindrical α_{14} oligomer 15 nm high and 14 nm wide (Figure 31.5). Each GroEL ring has a 5-nm central cavity where folding can take place. This cavity can accommodate proteins up to 60 kDa in size. GroES, sometimes referred to as a **co-chaperonin**, consists of a single seven-membered ring of 10 kDa subunits that sits like a dome on one end of GroEL (Figure 31.5). The end of GroEL where GroES is sitting is referred to as the *apical end*. Each GroEL subunit has two structural domains: an equatorial domain that binds ATP and interacts with

Figure 31.5 Structure and function of the GroES–GroEL complex. (a) Structure and overall dimensions of GroES–GroEL (top view, left; side view, right; PDB id = 1AON). (b) Section through the center of the complex to reveal the central cavity. (c) Model of the GroEL cylinder (blue) in action. An unfolded (U) or partially folded (I) polypeptide binds to hydrophobic patches on the apical ring of α_7 -subunits, followed by ATP binding, forced protein unfolding, and GroES (red) association. ATP hydrolysis in one ring is required to enable subsequent ATP binding to the opposite ring, but hydrolysis is not required for folding to proceed within the chamber. (d) Depiction of protein folding in the cytoplasm of an *E. coli* cell, emphasizing macromolecular crowding. The cytoplasmic components are present at their known concentrations. Proteins shown include a new protein undergoing folding (orange), chaperone structures (GroEL in green, DnaK in red, and Trigger Factor in yellow), ribosomes (purple), and RNA (salmon). Small Heat Shock Proteins: Nature's Molecular Sponges

The **small heat-shock proteins (sHSP)** are a diverse family of ubiquitous intracellular proteins, with subunit masses of 12 to 43 kDa. sHSPs are important in protein maintenance and cellular responses to stress. They prevent the denaturation and aggregation of a variety of unrelated proteins under stress conditions, such as elevated temperature or reduced or oxidized conditions, at a stoichiometry as low as one subunit of sHSP to one target client protein. The small HSPs have a 100 residue core α -crystallin domain with variable N- and C-terminal extensions. These extensions enable the sHSPs to oligomerize and also mediate recognition of client proteins.

Carol Robinson, Justin Benesch, and their colleagues have studied the behavior of HSP18.1 from *Pisum sativum* (the garden pea) by mass spectrometry and have found that this sHSP exists as a dodecamer at 22°C. However, as the temperature is increased, dimers escape from some of the dodecamers and then add to other dodecamers to form higher-order oligomers of 13 to 20 subunits. In vitro assays conducted at 42°C (the classic heat shock temperature) show that monomers of a model client protein (firefly luciferase) add to sHSP oligomers to form heteromultimeric assemblages that reorganize and enlarge dynamically to yield more than 300 different

sHSP-client combinations! Lila Gierasch has likened this process to a sponge becoming moist and swelling so that it accommodates yet more water. Robinson and Benesch conclude that dynamic equilibrium fluctuations of quaternary structure in such ensembles of sHSP structures underlie the protection of client proteins as they seek their native folded structures.

When native proteins (N) become unstable (U) under heat stress, sHSPs protect cells against deleterious formation of aggregates by dynamic fluctuations of quaternary structure.

neighbors in the other α_7 ring and an apical domain with hydrophobic residues that can interact with hydrophobic regions on partially folded proteins. The hydrophobic patches of the apical domain face the interior of the central cavity. An unfolded (or partially folded) protein binds to the apical patches and is delivered to the central cavity of the upper α_7 ring (Figure 31.5c). ATP binding to the subunits of the upper α_7 ring causes rapid (<100 ms), forced unfolding of the substrate protein, followed by two events that occur on a slower time scale (~1 s): (1) GroES is recruited to GroEL, and (2) the α -subunits undergo a conformational change that buries their hydrophobic patches. The α -subunits now present a hydrophilic surface to the central cavity. This change displaces the bound partially folded polypeptide into the sheltered hydrophilic environment of the central cavity, where it can fold, free from danger of aggregation with other proteins. GroES also promotes ATP hydrolysis (Figure 31.5c).

The GroEL-ADP-GroES complex dissociates when ATP binds to the subunits of the other (lower) α_7 ring. Dissociation of GroES allows the partially folded (or folded) protein to escape from GroEL. If the protein has achieved its native conformation, its hydrophobic residues will be buried in its core and the hydrophobic patches on the α_7 rings will have no affinity for it. On the other hand, if the protein is only partially folded, it may be bound again, gaining access to the Anfinsen cage of the α_7 ring and another cycle of folding. The folding of rhodanese, a 33 kDa protein, requires the hydrolysis of about 130 equivalents of ATP. The extreme crowding of macromolecules in the typical cell, which could interfere with the folding of nascent proteins, justifies the need for elaborate structures like GroES-GroEL, and also the substantial investment of ATP energy in the folding process (Figure 31.5d).

The group II chaperonin and eukaryotic analog of GroEL, **CCT** (also called **TriC**) is also a double-ring structure, but each ring consists of eight different subunits that vary in size from 50 to 60 kDa. Furthermore, group II chaperonins lack a GroES counterpart. **Prefoldin** (also known as **GimC**), a hexameric protein composed of six subunits from two related classes (two α and four β), can serve as a co-chaperone for CCT, much as GroES does for GroEL. However, prefoldin also acts like an Hsp70 protein because it binds unfolded polypeptide chains emerging from ribosomes and delivers them to CCT. Prefoldin resembles a jellyfish, with six tentacle-like coiled coils extending from a barrel-shaped body. The ends of the tentacles have hydrophobic patches for binding unfolded proteins.

Prior to substrate protein binding, CCT exists in a partly open state. ATP binding opens the ring even more, a state in which prefoldin delivers the substrate protein. ATP hydrolysis closes the chamber and drives the folding process. ATP-induced conformation changes that promote protein folding propagate from one subunit to the next around the ring structure.

31.2 | How Are Proteins Processed Following Translation?

The release of the completed polypeptide from the ribosome is not necessarily the final step in the covalent construction of a protein. Many proteins must undergo covalent alterations before they become functional. In the course of these **post-translational modifications**, the primary structure of a protein may be altered, and/or novel derivations may be introduced into its amino acid side chains. Hundreds of different amino acid variations have been described in proteins, virtually all arising post-translationally. The list of such modifications is very large; some are rather commonplace, whereas others are peculiar to a single protein. The diphthamide moiety in elongation factor eEF-2 is one example of an amino acid modification (see the Human Biochemistry box “Diphtheria Toxin ADP-Ribosylates eEF2” in Chapter 30); the fluorescent group of green fluorescent protein (GFP; see Chapter 4) is another. In addition, common chemical groups such as carbohydrates and lipids may be covalently attached to a protein during its maturation. Phosphorylation, acetylation, and methylation of proteins are common mechanisms for regulating protein function. Interestingly, many proteins are modified in multiple ways, and many post-translational modifications act in combinations—a phenomenon termed **cross-talk**. (The majority of proteins in cells can be phosphorylated on one or more residues. A survey of some of the more prominent chemical groups conjugated to proteins is given in Chapter 5.) To put a number on the significance of post-translational modifications, we have seen that the number of human proteins is estimated to exceed the number of human genes (20,500 or so) by several orders of magnitude.

Proteolytic cleavage is the most prevalent form of protein post-translational modification, and it merits special attention. The very occurrence of proteolysis as a processing mechanism seems strange: Why join a number of amino acids in sequence and then eliminate some of them? Three reasons can be cited. First, diversity can be introduced where none exists. For example, a simple form of proteolysis, enzymatic removal of N-terminal Met residues, occurs in many proteins. **Met-aminopeptidase**, by removing

the invariant Met initiating all polypeptide chains, introduces diversity at N-termini. Second, proteolysis serves as an activation mechanism so that expression of the biological activity of a protein can be delayed until appropriate. A number of metabolically active proteins, including digestive enzymes and hormones, are synthesized as larger inactive precursors termed **pro-proteins** that are activated through proteolysis (see zymogens, Chapter 15). The N-terminal pro-sequence on such proteins may act as an intramolecular chaperone to ensure correct folding of the active site. Third, proteolysis is involved in the targeting of proteins to their proper destinations in the cell, a process known as **protein translocation**.

31.3 | How Do Protein Translocation Pathways Target Proteins to Subcellular Compartments?

Approximately 30% of all proteins are translocated across or inserted into lipid membranes. Transporting long polymers with both hydrophilic and hydrophobic residues into or across a bilayer membrane is a challenge for both prokaryotic and eukaryotic cells. Eukaryotic cells must transport many proteins into the ER lumen for processing and must insert others into the ER membrane. Prokaryotic cells transport certain proteins into or across the plasma membrane. Moreover, protein transport must be selective to ensure that the right proteins end up in the right places. Specialized membrane protein complexes called **translocons** have evolved to solve these problems in **protein translocation** pathways. Translocons are selectively permeable protein-conducting channels that catalyze movement of the proteins across the membrane, and metabolic energy in the form of ATP, GTP, or a membrane potential is essential.

31.3a Proteins Are Delivered to the Proper Cellular Compartment by Translocation

Protein translocation occurs in all cells. There are two pathways involved in protein translocation: The **Sec pathway** (where Sec refers to *secretory* functions) transports unfolded proteins. Sec systems are found in every organism. Translocation in the Sec pathway occurs through a hetero-trimeric membrane pore complex: The SecY complex in bacteria, archaea, and chloroplast thylakoid membranes, and the Sec61 complex in eukaryotes. By contrast, the **twin-arginine translocation (Tat) pathway** is a protein export system in the cytoplasmic membrane of prokaryotes that transports proteins that have already folded.

Translocation through Sec channels occurs either co-translationally, by association with translating ribosomes, or post-translationally. The co-translational pathway is used in most species for membrane protein insertion, and also by eukaryotes for protein secretion. The co-translational complex in prokaryotes is SecYEG, composed of subunits SecY, SecE, and SecG, and the analogous complex in eukaryotes is Sec61, composed of Sec61, Sec62, and Sec63 and other accessory proteins. The post-translational pathway is the primary pathway for protein secretion in prokaryotes and involves auxiliary proteins SecD, SecF, and YajC. The Tat pathway is exclusively post-translational.

Proteins that will be translocated carry targeting information at or near their N-terminus that directs the protein to eventual destinations. In both Sec pathways, initiation of translocation depends on delivery to the SecY-Sec61 complex at the plasma membrane or ER membranes of a substrate with a cleavable N-terminal **signal sequence** (for secretory proteins) or the first transmembrane segment (for membrane proteins). In effect, signal sequences serve as zip codes for sorting and dispatching proteins to their proper compartments. Thus, the information specifying the correct cellular localization of a protein is found within its structural gene. Once the protein is routed to its destination, the signal sequence is often, but not always, proteolytically clipped from the protein by a signal sequence-specific endopeptidase called a signal peptidase.

31.3b The SecYEG Translocon Mediates Translocation of Newly Synthesized Prokaryotic Proteins

E. coli, the paradigm of gram-negative bacteria, synthesizes approximately 4400 proteins, including (approximately) 1000 inner membrane proteins, 400 periplasmic proteins, and 160 outer membrane proteins. Non-cleavable signal anchor sequences in inner membrane proteins and N-terminal, cleavable signal sequences in secretory proteins target these proteins for membrane insertion or secretion, respectively. Most of these membrane and periplasmic proteins are translocated into and across the inner membrane by the SecYEG translocon, a complex built on core proteins SecY, SecE, and SecG (Figure 31.6a). This heterotrimeric core is passive by itself. To recognize an enormous variety of different substrate proteins and to be active in protein transport, the SecYEG translocon interacts with multiple additional proteins (SecA, SecD, SecF, and YajC). These partner proteins recognize SecYEG substrates, provide the driving force for transport, mediate substrate release from SecYEG, and communicate with the proteostasis network.

Two protein targeting systems, operate in parallel in bacterial cells to recognize and direct SecYEG substrate proteins to their appropriate destinations. Pre-secretory proteins with cleavable N-terminal signal sequences are targeted by SecA, a dimeric motor ATPase that associates with SecYEG for post-translational secretion (Figure 31.6b). Pre-secretory proteins often associate with a chaperone and the pre-protein-chaperone complex is bound to SecA and then to SecYEG, after which the SecA dimer dissociates.

Figure 31.6 Protein targeting and translocation pathways in bacteria. (a) The structure of the SecYEG-SecA complex from *Tibellus maritimus*. SecA is blue; SecY is dark green; SecG is orange; SecE is light green. The location of the inner membrane is indicated (PDB id = 3DIN.) (b) SecA-dependent transport. Post-translational pathway involves association with chaperones, including trigger factor and SecB, followed by a hand-off to SecA in the SecYEG complex. In the co-translational pathway, SecA associates with the nascent polypeptide at the ribosome and delivers it to the SecYEG complex. (c) SRP-dependent transport. In the co-translational pathway, SRP binds tightly to the nascent polypeptide and delivers it to FtsY and the SecYEG complex. In the post-translational pathway, the SRP-polypeptide complex dissociates from the ribosome and migrates either to the FtsY-SecYEG complex or the FtsY-YidC complex for insertion into the membrane.

In an alternative co-translational pathway, SecA may engage the pre-secretory protein at the ribosome for delivery to SecYEG. In the second targeting system, inner membrane proteins with non-cleavable signal anchor sequences emerging from the ribosome exit tunnel engage a ribosome-bound signal recognition particle (SRP) and interact with SecYEG for co-translational membrane insertion (Figure 31.6c). The SRP is a 325 kDa nucleoprotein assembly that contains six polypeptides and a 300 nucleotide 7S RNA. SRPs typically bind with high affinity to ribosomes and bind the signal anchor sequence of a membrane protein when it emerges from the peptide tunnel of the ribosome. This assemblage is referred to as a **ribosome-associated nascent chain (RNC) complex**. The SRP delivers the RNC complex to FtsY, the SecYEG-bound receptor for nascent membrane proteins. In a parallel pathway, the SRP can deliver membrane proteins to YidC (termed an **insertase**), which can insert membrane proteins independently of SecYEG but which also cooperates with the SecYEG translocon. Finally, the SRP-nascent protein complex may also dissociate from the ribosome and bind to the FtsY-YidC complex for post-translational membrane insertion.

31.3c The Sec61 Translocon Mediates Translocation of Newly Synthesized Eukaryotic Proteins

Eukaryotic cells are characterized by many membrane-bounded compartments. Approximately 30% of all eukaryotic proteins are routed to these membranes and compartments via the Sec61 translocon complexes.

Structure of the Sec61 Translocon Sec61 translocons are dynamic entities, organized around an invariant core, the trimeric Sec61 protein-conducting channel (Figure 31.7). Full maturation of proteins in the ER involves several additional processes, including glycosylation (covalent attachment of sugars), signal peptide cleavage, and membrane protein insertion, orientation and folding. To accomplish these varied functions on a broad range of substrates, the Sec61 channel has different accessory proteins that associate with it, either transiently or in stable complexes.

ER Translocon Pathways The ER translocon complexes use both co-translational and post-translational pathways for protein transport across the ER membrane or insertion into it. These eukaryotic pathways are analogous to those for prokaryotic translocation as described in Figure 31.6. Moreover, the N-terminal signal sequences of eukaryotic secretory proteins are analogous to bacterial signal sequences. Proteins with highly hydrophobic signal sequences are recognized by signal recognition particles (SRPs) as they emerge from the ribosome exit tunnel and then moved through the Sec61 channel co-translationally. Proteins with less hydrophobic signal sequences are transported through the Sec61 channel post-translationally in association with another membrane protein complex comprised of Sec62 and Sec63.

Figure 31.7 Cryo-EM structure of a heterotrimer of Sec61 (open conformation) in complex with a signal peptide. Subunits $\alpha 1$ (green), β (purple), and γ (blue) from *Canis lupus familiaris* are shown with a bovine prolactin signal peptide (yellow) (PDB id = 3JC2).

The Co-Translational Eukaryotic Translocation Pathway In co-translational eukaryotic translocation, the SRP binds to the signal peptide as it emerges from the ribosome (the ribosome-nascent-chain [RNC] complex) and recruits the RNC to the ER membrane via an SRP receptor (SR) (Figure 31.8, Step 2). Ribosome binding to the Sec61 complex enables the nascent unfolded peptide to enter the Sec61 channel (Step 3). A signal peptidase cleaves off the signal sequence from the nascent peptide on the luminal face of the ER membrane (Step 4). The peptide may then be transported entirely across the ER membrane, producing a secretory protein (Step 5). Alternatively, the Sec61 trimer may facilitate insertion of hydrophobic helices of the peptide into the ER membrane, forming a new transmembrane protein.

The ribosome-Sec61 complex at the ER membrane typically includes a number of accessory proteins, including the translocon-associated protein (TRAP) complex and the oligosaccharyl transferase complex (OST). TRAP supports recruitment of specific signal peptides and facilitates membrane insertion and orientation of some peptide

Figure 31.8 Synthesis of a eukaryotic secretory protein and its translocation into the endoplasmic reticulum. **(1)** The signal recognition particle (SRP, red) recognizes the signal sequence emerging from a translating ribosome (ribosome-nascent-chain complex [RNC], gray). **(2)** The RNC-SRP interacts with the SRP receptor (SR, purple) and is transferred to the translocon (pink). **(3)** Release of the SRP and alignment of the peptide exit tunnel of the RNC with the protein-conducting channel of the translocon stimulates the ribosome to resume translation. **(4)** The membrane-associated signal peptidase (purple circle) clips off the N-terminal signal sequence, and BiP (the ER lumen Hsp70 chaperone, blue) binds the nascent chain mediating its folding into its native conformation. **(5)** Following dissociation of the ribosome, BiP plugs the translocon channel. Not shown are subsequent secretory protein maturation events, such as glycosylation. (Adapted from Figures 1a and 2a in Frydman, J., 2001. Folding of newly translated proteins *in vivo*: The role of molecular chaperones. *Annual Review of Biochemistry* 70:603–647.)

substrates, whereas OST is responsible for glycosylation of specific asparagine residues on the translocated peptide substrates. Cryo-EM studies have revealed the details of some of these large and complex structures (Figure 31.9a)

The Post-Translational Eukaryotic Translocation Pathway In the post-translational mode, Sec61 forms a stable complex with Sec62 and Sec63 (Figure 31.9b). This complex is sufficient for post-translational protein translocation in higher eukaryotes (humans,

Human Biochemistry

Autophagy—How Cells Recycle Their Materials

Autophagy is a tightly regulated catabolic process whereby cells use their lysosomes to degrade their own macromolecular and organellar constituents. Autophagy functions to maintain a balance between the synthesis of macromolecules and organelles, their degradation, and recycling of their component materials. More than 30 evolutionarily conserved genes, the **ATG genes**, are involved in autophagy. Their protein products are designated **Atg proteins**. Autophagy is dependent on the hydrolytic capacities of acidic hydrolyases in lysosomes to achieve its ends. Autophagy begins when a volume of cytoplasm or an organelle (such as a mitochondrion) becomes separated from the rest of the cell by a cup-shaped membranous structure called the **phagophore** (Figure a). The phagophore derives from a **pre-autophagosomal structure (PAS)**, a dynamic assembly of Atg proteins with associated lipids that functions as a membrane-forming apparatus. Closure of the phagophore around this sequestered material gives rise to the double-membrane-bounded **autophagosome**. Fusion of the autophagosome membrane with the membrane of a lysosome creates a hybrid vesicle, the **autolysosome** (sometimes called an **autophagolysosome**). Within the autolysosome, the contents delivered by the autophagosome are broken down so that their constituent amino acids, nucleotides, and lipids can be recycled to meet the cell's need for building blocks to create new macromolecules and organelles.

Three forms of autophagy are recognized: **macroautophagy** (just described), **microautophagy** (wherein small blebs of cytoplasm are engulfed directly by a lysosome), and **chaperone-mediated autophagy (CMA)**, in which proteins targeted by Hsc (heat shock cognate)-

containing chaperone/cochaperone complexes are taken up directly by lysosomes. The focus here is on **macroautophagy**, the principal form.

Although autophagy is an ongoing process of homeostasis in normal cells, it becomes crucial when extracellular nutrients become limiting (Figure b). Recycling cellular components through autophagy allows the cell to maintain energy production and macromolecular synthesis despite a paucity of nutrients. As noted in Chapter 27, when mTORC1 (a protein complex that serves as a nutrient and energy sensor) is active, it promotes protein synthesis, cell growth, and cell proliferation. mTORC1 is a negative regulator of autophagy, acting to limit its expression when nutrients are in abundance. When mTORC1 is inactivated upon nutrient depletion (starvation), a particular Atg protein, Atg13, is dephosphorylated, a triggering event that culminates in activation of autophagosome formation.

Autophagy as a source of cellular nutrients can be only a short-term solution. Interestingly, starvation-induced autophagy in cultured mammalian AgRP neurons derived from the hypothalamus causes an intracellular increase in free fatty acids (FFA). In turn, these FFA promote a rise in AgRP levels. Expression of AgRP along with NPY is known to promote eating behavior (see Figure 27.12). Thus, upon starvation, autophagy provides a short-term fix and a long-term solution to nutrient limitation. Autophagy is also implicated in obesity, diabetes, cardiovascular disease, neurodegenerative diseases, and cancer.

Adapted from Xie, Z., and Klionsky, D. J., 2007. Autophagosome formation: Core machinery and adaptations. *Nature Cell Biology* 9:1102–1109.

Adapted from Levine, B., 2005. Eating oneself and uninvited guests: Autophagy-related pathways in cellular defense. *Cell* 120:159–162.

for example). Sec63 interacts with transmembrane segments in the N-terminal half of the Sec61 channel and also with cytosolic loops in the C-terminal half of Sec61. Sec63 causes Sec61 to expand to an open-channel conformation that allows peptide substrates to be transported through the channel. Sec63 also contains a domain that activates the BiP ATPase to bind to the incoming nascent protein. BiP prevents the substrate from sliding back into the cytosol and also drives it through the Sec61 channel. In lower eukaryotes (for example, fungi), the so-called Brl domain of Sec63 blocks ribosome binding to Sec61 and also facilitates binding of Sec71 and Sec72. These latter subunits capture nascent polypeptides associated with Hsp70 and other chaperones and enable post-translational folding.

Retrograde Translocation Prevents Secretion of Damaged Proteins and Recycles Old ER Proteins To prevent secretion of inappropriate proteins, fragmented or misfolded secretory proteins are passed from the ER back into the cytosol via Sec61. Thus, Sec61 also serves as a channel for aberrant secretory proteins to be returned to the cytosol so that they can be destroyed by the proteasome degradation apparatus (see Section 31.4). Among these proteins are ER membrane proteins that are damaged or no longer needed.

31.4 | How Does Protein Degradation Regulate Cellular Levels of Specific Proteins?

Cellular proteins in any organism must be present in the correct amounts, and mutant and damaged proteins must be degraded. As a result, cellular proteins are in a dynamic state of turnover, with the relative rates of protein synthesis and protein degradation ultimately determining the amount of protein present at any point in time. In many instances, transcriptional regulation determines the concentrations of specific proteins expressed within cells, with protein degradation playing a minor role. In other instances, the amounts of key enzymes and regulatory proteins, such as cyclins and transcription factors, are controlled via selective protein degradation. In addition, abnormal proteins arising from biosynthetic errors or post-synthetic damage must be destroyed to prevent the deleterious consequences of their buildup. The elimination of proteins typically follows first-order kinetics, with half-lives ($t_{1/2}$) of different proteins ranging from several minutes to many days. A single, random proteolytic break introduced into the polypeptide backbone of a protein is believed sufficient to trigger its rapid disappearance because no partially degraded proteins are normally observed in cells.

Protein degradation poses a real hazard to cellular processes. To control this hazard, protein degradation is compartmentalized, either in macromolecular structures known as **proteasomes** or in degradative organelles such as lysosomes. Protein degradation within lysosomes is largely nonselective; selection occurs during lysosomal uptake. Proteasomes are found in eukaryotic as well as prokaryotic cells. The proteasome is a functionally and structurally sophisticated counterpart to the ribosome. Regulation of protein levels via degradation is an essential cellular mechanism. Regulation by degradation is both rapid and irreversible.

31.4a Eukaryotic Proteins Are Targeted for Proteasome Destruction by the Ubiquitin Pathway

Ubiquitination is the most common mechanism to label a protein for proteasome degradation in eukaryotes. Ubiquitination has emerged as a major mechanism by which virtually all cellular events can be regulated. **Ubiquitin** is a highly conserved, 76 residue (8.5 kDa) polypeptide widespread in eukaryotes. Proteins are targeted for degradation through ligation to ubiquitin. Three proteins in addition to ubiquitin are involved in the ligation process: **E1**, **E2**, and **E3** (Figure 31.10). The human genome encodes two E1s, at least 40 E2s and more than 600 E3s. E1 is the **ubiquitin-activating enzyme** (105 kDa dimer). It becomes attached via a thioester bond to the

Figure 31.10 Enzymatic reactions in the ligation of ubiquitin to proteins. **Step 1:** ATP drives formation of a ubiquitinyl-acyl-adenylate. **Step 2:** E1, the ubiquitin-activating enzyme, is linked to ubiquitin via a thioester bond to the C-terminal glycine. **Step 3:** Ubiquitin is transferred from E1 to an -SH group on E2, the ubiquitin-carrier protein. **Step 4:** Ubiquitin is attached to selected proteins via isopeptide bonds formed between the ubiquitin carboxy-terminus and free amino groups (α -NH₂ terminus, Lys ϵ -NH₂ side chains) on the protein.

C-terminal Gly residue of ubiquitin through ATP-driven formation of an activated ubiquitin-acyl-adenylate intermediate. Ubiquitin is then transferred from E1 to an SH group on E2, the **ubiquitin-carrier protein**. In protein degradation, E2-S~ubiquitin transfers ubiquitin to free amino groups on proteins selected by E3 (180 kDa), the **ubiquitin-protein ligase**. Upon binding a protein substrate, E3 catalyzes the transfer of ubiquitin from E2-S~ubiquitin to free amino groups (usually Lys ϵ -NH₂) on the protein. Additional regulation of the protein degradation process is provided by the attachment of more than one ubiquitin to a protein substrate, and tandemly linked chains of ubiquitin also occur, either via *isopeptide bonds* between the C-terminal glycine residue of one ubiquitin and the ϵ -amino of Lys residues in another, or via a conventional peptide bond with the N-terminal Met of another ubiquitin. Ubiquitin has seven lysine residues, at positions 6, 11, 27, 29, 33, 48, and 63. Isopeptide linkages to all of these Lys residues have been found, with the K⁴⁸-type being most common as a degradation signal.

E3 plays a central role in recognizing and selecting proteins for degradation. E3 selects proteins by the nature of the N-terminal amino acid. Proteins must have a free α -amino terminus to be susceptible. Proteins having either Met, Ser, Ala, Thr, Val, Gly, or Cys at the amino terminus are resistant to the ubiquitin-mediated degradation pathway. However, proteins having Arg, Lys, His, Phe, Tyr, Trp, Leu, Asn, Gln, Asp, or Glu N-termini have half-lives of only 2 to 30 minutes.

Interestingly, proteins with acidic N-termini (Asp or Glu) show a tRNA requirement for degradation (Figure 31.11). Transfer of Arg from Arg-tRNA to the N-terminus of these proteins alters their N-terminus from acidic to basic, rendering the protein susceptible to E3. It is also interesting that Met is less likely to be cleaved from the N-terminus if the next amino acid in the chain is one particularly susceptible to ubiquitin-mediated degradation.

Most proteins with susceptible N-terminal residues are not normal intracellular proteins but tend to be secreted proteins in which the susceptible residue has been exposed by action of a signal peptidase. Perhaps part of the function of the N-terminal recognition system is to recognize and remove from the cytosol any invading foreign or secreted proteins. Other proteins targeted for ubiquitin ligation and proteasome degradation contain **PEST sequences**—short, highly conserved sequence elements rich in proline (P), glutamate (E), serine (S), and threonine (T) residues.

The broader role that ubiquitination plays in cells is reflected by the large numbers of E2 and E3 that are known. At least 40 E2 ubiquitin-conjugating proteins have been identified, along with more than 600 E3 ubiquitin ligases. The E3 ubiquitin ligases are

Figure 31.11 Proteins with acidic N-termini show a tRNA requirement for degradation. Arginyl-tRNA^{Arg}/protein transferase catalyzes the transfer of Arg to the free α -NH₂ of proteins with Asp or Glu N-terminal residues. Arg-tRNA^{Arg}/protein transferase serves as part of the protein degradation recognition system.

typically complexes of multiple subunits that together recognize a particular target protein and facilitate linkage to ubiquitin or to a **ubiquitin-like** protein (Figure 31.12). Ubiquitination is involved in many biological processes, beyond regulation of protein stability, including gene transcription, DNA repair, cell cycle progression, receptor transport, signal transduction, and immune responses. Given its integral involvement in most cellular events, the ubiquitin system is an important therapeutic target, particularly for treatments of cancer and neurodegenerative disorders.

31.4b Proteins Targeted for Destruction Are Degraded by Proteasomes

Proteasomes are large oligomeric structures enclosing a central cavity where proteolysis takes place. Ubiquitinated proteins are directed to proteasomes for degradation.

The Structures of Proteasomes The 20S proteasome from the archaeon *Thermoplasma acidophilum* is a 700 kDa barrel-shaped structure composed of two different kinds of polypeptide chains, α and β , arranged to form four stacked rings of $\alpha_7\beta_7\beta_7\alpha_7$ -subunit organization. The barrel is about 15 nm in height and 11 nm in diameter, and it contains a three-part central cavity (Figure 31.13a). The proteolytic sites of the 20S proteasome are found within this cavity. Access to the cavity is controlled through a 1.3 nm opening formed by the outer α_7 rings. These rings are believed to unfold proteins destined for degradation and transport them into the central cavity. The β -subunits possess the proteolytic activity. Proteolysis occurs when the β -subunit N-terminal threonine side-chain O atom makes nucleophilic attack on the carbonyl-C of a peptide bond in the target protein. The products of proteasome degradation are oligopeptides seven to nine residues long.

Eukaryotic cells contain two forms of proteasomes: the **20S proteasome**, and its larger counterpart, the **26S proteasome**. The eukaryotic 26S proteasome is a 45 nm-long structure composed of a 20S proteasome plus two additional substructures known as **19S regulators** (also called **19S caps** or **PA700** [for proteasome activator-700 kDa]) (Figure 31.13b). Overall, the 26S proteasome (approximately 2.5 megadaltons) has 2 copies each of 32 to 34 distinct subunits, 14 in the 20S core and 18 to 20 in the cap structures. Unlike the archaeal 20S proteasome, the eukaryotic 20S core structure contains seven different kinds of α -subunits and seven different kinds of β -subunits. Interestingly, only three of the seven different β -subunits have protease active sites. The 26S proteasome forms when the 19S regulators dock to the two outer α_7 rings of the 20S proteasome cylinder.

Regulators of the Proteasome Many of the 19S regulator subunits have ATPase activity. Replacement of certain 19S regulator subunits with others changes the specificity of the proteasome. The 19S regulators cause the proteolytic function of the 20S

Figure 31.12 Structures of representative E1, E2, and E3 complexes. **(a) (Top)** A ubiquitin-E1 heterodimer complex (PDB id = 1R4N; ubiquitin is shown in blue). **(Middle)** A ubiquitin-E2 complex (PDB id = 1FXT; E2 is shown in orange, ubiquitin in blue). **(Bottom)** The clamp-shaped E3 heteromultimer (PDB id = 1LDK and 1FQV). The target protein is bound between the jaws of the clamp. **(b)** CryoEM structure of a cullin-RING-UBE2D ubiquitin ligation assembly. Proteins in the complex include cullin (CUL1, green), S-phase kinase-associated protein 1 (SKP1, blue), a β -transducin repeats-containing protein (β -TrCP, gold), a regulator protein (NEDD8, yellow), ubiquitin (Ub, purple), Ring box 1 (RBX1, dark red), ubiquitin-conjugating enzyme E2 D2 (UBE2D, aqua) and the substrate protein, I κ B α (a protein kinase, gray; PDB id = 6TTU).

Figure 31.13 The structure of the 26S proteasome. **(a)** The yeast (*Saccharomyces cerevisiae*) 20S proteasome core with bortezomib bound (red; PDB id = 2F16). Bortezomib is the first therapeutic proteasome inhibitor used in humans. It is approved in the United States for treatment of relapsed multiple myeloma and mantle cell lymphoma. **(b)** Composite model of the 26S proteasome. The 20S proteasome core is shown in yellow; the 19S regulator (19S cap) structures are in blue. (Adapted from Figure 5 in Voges, D., Zwickl, P., and Baumeister, W., 1999. The 26S proteasome: A molecular machine designed for controlled proteolysis. *Annual Review of Biochemistry* 68:1015–1068.)

Figure 31.14 Diagram of the ubiquitin-proteasome degradation pathway. Pink lollipop structures symbolize ubiquitin molecules. (Adapted from Figure 1 in Hilt, W., and Wolf, D. H., 1996. Proteasomes: Destruction as a program. *Trends in Biochemical Sciences* 21:96–102.)

proteasome to become ATP-dependent and specific for ubiquitinated proteins as substrates. That is, these 19S caps act as regulatory complexes for the recognition and selection of ubiquitinated proteins for degradation by the 20S proteasome core (Figure 31.14). The 26S proteasome shows a preference for proteins having four or more ubiquitin molecules attached to them. The 19S regulators also carry out the unfolding and transport of ubiquitinated protein substrates into the proteolytic central cavity.

The 19S regulators consist of two parts: the base and the lid. The base subcomplex connects to the 20S proteasome and contains the six ATPase subunits that unfold proteasome substrates. These subunits are members of the **AAA+ family of ATPases** (ATPases associated with various cellular activities); AAA+ ATPases are an evolutionarily ancient family of proteins involved in a variety of cellular functions requiring energy-dependent unfolding, disassembly, and remodeling of proteins. The lid subcomplex acts as a cap on the base subcomplex and one of its subunits functions in recognition and ubiquitin-chain processing of proteasome protein substrates.

ATPase Modules Mediate the Unfolding of Proteins in the Proteasome The base of the 19S regulators that cap the 26S proteasome consists of a hexameric ring of AAA+ ATPases that mediate the ATP-dependent unfolding of ubiquitinated proteins targeted for destruction in the proteasome. Structural studies have revealed the presence of loops extending from these AAA+ ATPase subunits; these loops face the central channel of the hexameric ring. The loops are in an up position when an AAA+ ATPase subunit has ATP bound in its active site, but they shift to a down position when ADP occupies the active site. Apparently, these loops bind protein substrates and act like the levers of a machine, using the energy of ATP hydrolysis to tug the protein into an unfolded state and thread it down through the narrow central channel. This channel leads into the cavity of the 20S proteasome, where proteolytic degradation takes place. The AAA+ ATPase cycle of ATP binding, protein substrate binding, ATP hydrolysis, and protein unfolding is reminiscent of the ATP-dependent action of Hsp70 chaperones.

Ubiquitination is a general regulatory protein modification. Protein ubiquitination is a signal for protein degradation, as described in Section 31.4a, but ubiquitin conjugation to proteins is also used for other purposes in cells. Nondegradative functions for ubiquitination include roles in chromatin remodeling, DNA repair, transcription, signal transduction, endocytosis, spliceosome assembly, and sorting of proteins to specific organelles and cell structures. In addition, cells possess a variety of protein modifiers attached to target proteins by processes similar to the ubiquitin pathway, as described in the following section.

31.4c Small Ubiquitin-like Protein Modifiers Are Post-transcriptional Regulators

Small ubiquitin-like protein modifiers (SUMOs) are a highly conserved family of proteins found in all eukaryotic cells. Like ubiquitin, SUMO family members are covalently ligated to lysine residues in target proteins by a three-enzyme conjugating system (Figure 31.15). SUMO proteins share only limited homology to ubiquitin, and sumoylated proteins are not targeted for destruction. Instead, sumoylation alters the ability of the modified protein to interact with other proteins. This ability to change protein–protein interactions is believed to be the biological purpose of SUMO proteins. Post-translational attachment of SUMOs is a key regulatory protein modification in eukaryotic cells. Hundreds of proteins involved in DNA repair, transcription, macromolecular assembly, protein homeostasis and trafficking, and signal transduction are subject to reversible sumoylation.

Sumoylation can have three general consequences for modified proteins (Figure 31.16): (1) it can interfere with the interactions between the target and its partner so that the interaction can occur only in the absence of sumoylation; (2) sumoylation can create a binding site for an interacting partner protein; and (3) sumoylation can induce a conformational change in the modified target protein, altering its interactions with partner proteins. The regulatory opportunities associated with sumoylation are significant for many cellular functions, including transcriptional regulation, chromosome organization, nuclear transport, and signal transduction. Overall, sumoylation represents a protective response.

Figure 31.15 The mechanism of reversible sumoylation. Before conjugation, small ubiquitin-like protein modifiers (SUMOs) need to be proteolytically processed, removing anywhere from 2 to 11 amino acids to reveal the C-terminal Gly–Gly motif. SUMOs are then activated by the E1 enzyme in an ATP-dependent reaction to form a thioester bond between SUMO and E1. SUMO is then transferred to the catalytic Cys residue of the E2 enzyme, Ubc9. Finally, an isopeptide bond is formed, between the C-terminal Gly of SUMO and a Lys residue on the substrate protein, through the action of an E3 enzyme. The SUMO-specific protease SENP can deconjugate SUMO from target proteins.

Figure 31.16 The molecular consequences of sumoylation. The process can affect a modified protein in three ways: **(a)** Sumoylation can interfere with the interaction between a target protein and its binding partner. **(b)** Sumoylation can provide a new binding site for an interacting partner. **(c)** Sumoylation can induce a conformational change in the modified target protein.

Many E2 enzymes participate in ubiquitination processes, but the only known SUMO E2 enzyme is Ubc9 (Figure 31.17a). Ubc9 recognizes a ψ KXD/E consensus sequence in proteins destined for sumoylation. In this sequence, ψ is an aliphatic branched amino acid (such as Leu), K is the lysine to which SUMO is conjugated, and X is any amino acid, with an acidic D or E completing the sequence. Recognition by Ubc9 is possible only if the consensus sequence is in a relatively unstructured part of a target protein or if it is part of an extended loop, as in RanGAP1 (Figure 31.17a). In the Ubc9–RanGAP1 complex, Leu⁵²⁵ of RanGAP1 is in van der Waals contact with several nonpolar Ubc9 residues, whereas RanGAP1 Lys⁵²⁶ lies in a hydrophobic groove of Ubc9, juxtaposed with the catalytic Cys⁹³ (Figure 31.17b). The pK_a of Lys⁵²⁶ is lowered in this complex, activating the lysine amino group for nucleophilic attack to form the SUMO–target protein conjugate.

Figure 31.17 Ubc9 is a SUMO E2 enzyme. **(a)** The complex formed by the E2 enzyme, Ubc9 (yellow), and a target protein, RanGAP1 (blue). The helices of both proteins are labeled alphabetically. **(b)** In the Ubc9–RanGAP1 complex, the exposed loop of RanGAP1 lies in the binding pocket of Ubc9. The exposed loop contains the consensus sequence for sumoylation (ψ KXD/E), including Leu⁵²⁵, which is surrounded by hydrophobic residues from Ubc9; Lys⁵²⁶, which is coordinated by Asp¹²⁷ and Cys⁹³ of Ubc9; and Glu⁵²⁸, which is coordinated by Ubc9 Thr⁸¹. (PDB id = 1KPS)

Sumoylation is reversed by a small number of **isopeptidases** that cleave the target protein-Lys-SUMO linkage. Six proteins in mammals, known as **sentrin-specific proteases (SENPs)** and denoted SENP-1, -2, -3, -5, -6, and -7, possess varying specificities for SUMOylated target proteins, as well as their intracellular locations.

31.4d HtrA Proteases Also Function in Protein Quality Control

The discussion thus far has stressed the importance of protein quality control to cellular health. **HtrA proteases** are a class of proteins involved in quality control that combine the dual functions of chaperones and proteasomes. (The acronym **Htr** comes from “**h**igh **t**emperature **r**equirement” because *E. coli* strains bearing mutations in HtrA genes do not grow at elevated temperatures.) In addition to their novel ability to be either chaperones or proteases, HtrA proteases are the only known protein quality control factor that is not ATP-dependent. Prokaryotic HtrA proteases act as chaperones at low temperatures (20°C) where they have negligible protease activity. However, as the temperature increases, these proteins switch from a chaperone function to a protease function to remove misfolded or unfolded proteins from the cell. With this functional duality, HtrA proteases have the potential to mediate quality control through protein triage (see Section 31.4e: Protein Triage—A Model for Quality Control).

Three HtrA proteases, denoted DegP, DegS, and DegQ, are expressed in *E. coli*. The human counterparts are HtrA1-4. The *E. coli* HtrA protein **DegP** is the best characterized HtrA protease. DegP is localized in the *E. coli* periplasmic space, where it oversees quality control of proteins involved in the cell envelope. It is a 448 residue protein containing a central protease domain with a classic Ser protease Asp-His-Ser catalytic triad (see Chapter 14) and two C-terminal **PDZ domains**. These domains are structural modules involved in protein–protein interactions, and they recognize and bind selectively to the C-terminal three or four residues of target proteins. The PDZ domains act as gatekeepers, determining access of protein substrates to the proteolytic centers. Protease and chaperone activity of all HtrA proteins is dependent on the oligomeric state. The basic building block is a funnel-shaped trimer consisting of protease domains which form the central core and outward-protruding PDZ domains (Figure 31.18a). Binding of unfolded protein targets prompts formation of higher oligomeric states and activates protease function. DegP, for example, can form hexamers (Figure 31.18b) and also 12-, 15-, 18-, 24-, and 30-mers in the presence of substrate proteins that can be refolded

Figure 31.18 Oligomeric states of the HtrA proteases. (a) the HtrA protomer, showing the protease domain and the two PDZ domains (PDB id = 1KY9). (b) the DegP hexamer (PDB id = 1KY9). (c) a DegP 12-mer (PDB id = 2ZLE). (d) a DegP 24-mer (PDB id = 3CS0).

Human Biochemistry

Proteasome Inhibitors in Cancer Chemotherapy

Proteasome inhibition offers a promising approach to treating cancer. The counterintuitive rationale goes like this: The proteasome is responsible for the regulated destruction of proteins involved in cell cycle progression and the control of apoptosis (programmed cell death). Inhibition of proteasome function leads to cell cycle arrest and apoptosis. In clinical trials, proteasome inhibitors have retarded cancer progression by interfering with the programmed degradation of regulatory proteins, causing cancer cells to self-destruct.

Bortezomib, a slowly-reversible proteasome inhibitor developed by Millenium Pharmaceuticals, Inc., has been used since 2003 for

the treatment of multiple myeloma, a cancer of plasma cells that accounts for 10% of all cancers of the blood. Carfilzomib is a tetrapeptide epoxyketone proteasome inhibitor that binds irreversibly and provides prolonged proteasome inhibition. Both bortezomib and carfilzomib must be administered by intravenous infusion. Ixazomib acts similarly to bortezomib but is taken in capsules by mouth.

or degraded. Human HtrA2 is active as a trimer, but human HtrA1 assembles into an active 12-mer complex upon binding of unfolded polypeptides. The multiple oligomeric states of HtrA proteases provide a novel mechanism for substrate specificity and chaperone and protease activity. The different oligomeric states possess different sizes and geometries of central protease cavities, as well as different arrangements of the surrounding PDZ domains. For example, Figure 31.19 shows a 12-mer of *E. coli* DegQ with six lysozyme molecules in the central protease cavity.

Human HtrA proteases are implicated in stress response pathways and also in a wide range of diseases and disorders, including Alzheimer's and Parkinson's diseases and cancer. Human HtrA1 is expressed at higher levels in osteoarthritis and aging and lower levels in ovarian cancer and melanoma. Secreted human Htr1 may be involved in degradation of extracellular matrix proteins involved in arthritis as well as tumor progression and invasion.

31.4e Protein Triage—A Model for Quality Control

Triage is a medical term for the sorting of patients according to their need for (and their likelihood to benefit from) medical treatment. Sue Wickner, Michael Maurizi, and Susan Gottesman have pointed out that cells control the quality of their proteins through a system of triage based on chaperones and the ubiquitination-proteasome degradation pathway. These systems recognize non-native proteins (proteins that are partially folded, misfolded, incorrectly modified, damaged, or in an inappropriate compartment). Depending on the severity of its damage, a non-native protein is directed to chaperones for refolding or targeted for destruction by a proteasome (Figure 31.20).

Figure 31.20 A triage system recognizes non-native proteins, partially folded proteins, and misfolded proteins and directs them to chaperones for refolding or to proteasomes for degradation. (Adapted from Figures 2 and 3 in Wickner, S., Maurizi, M., and Gottesman, S., 1999. Post-translational quality control: Folding, refolding, and degrading proteins. *Science* **286**:1888–1893.)

Foundational Biochemistry Things You Should Know after Reading Chapter 31.

- The functional protein pool of any cell is determined not only by gene expression, mRNA stability, and protein synthesis, but also by post-translational modifications, protein–protein interaction, intracellular localization, and protein degradation.
- Nascent proteins are often assisted in folding by a family of helper proteins known as molecular chaperones, whose actions are often ATP-dependent.
- Hsp70 chaperones bind to hydrophobic regions of extended polypeptides and use the energy of ATP hydrolysis to drive protein folding.
- The GroES-GroEL complex of *E. coli* is an Hsp60 chaperonin. It forms a cylindrical structure with a central cavity where ATP hydrolysis drives the folding of nascent proteins.
- The eukaryotic Hsp90 chaperone system acts on proteins of signal transduction pathways and facilitates the maturation of these proteins.
- Proteolytic cleavage is the most common form of post-translational processing of proteins.
- Proteins are targeted to their proper cellular locations by signal sequences.
- Protein translocation involves interactions of signal recognition particles, signal receptors, translocons, and proteolytic processing.
- Prokaryotic proteins destined for translocation are synthesized as pre-proteins.
- Eukaryotic proteins are routed to their proper destinations by protein sorting and translocation.
- The synthesis of secretory proteins and many membrane proteins is coupled to translocation across the ER membrane.
- The eukaryotic translocon is a complex of proteins that transports nascent polypeptides with targeting signal sequences into the interior of the endoplasmic reticulum.
- Binding of the ribosome-nascent chain/signal recognition particle (RNC-SRP) complex to a signal receptor delivers the RNC to the membrane.
- Retrograde translocation prevents secretion of damaged proteins and recycles old ER proteins.
- Eukaryotic proteins are targeted for proteasome destruction by the ubiquitin pathway.

- Proteasomes are large oligomeric structures enclosing a central cavity where proteolysis takes place.
- The 26S proteasome is a 45 nm-long structure composed of a 20S proteasome plus two 19S regulators. ATPase modules mediate the unfolding of proteins in the 26S proteasome.
- Small ubiquitin-like protein modifiers are post-transcriptional regulators that are covalently ligated to lysine residues on target proteins. SUMOylation alters the ability of the modified proteins to interact with other proteins.
- HtrA proteases are proteins involved in quality control that combine the dual functions of chaperones and proteasomes.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Assessing the ATP Cost of Protein Synthesis** (Integrates with Chapter 30.) Human rhodanese (33 kDa) consists of 296 amino acid residues. Approximately how many ATP equivalents are consumed in the synthesis of the rhodanese polypeptide chain from its constituent amino acids *and* the folding of this chain into an active tertiary structure?
- Understanding the Consequences of Proteolysis** A single proteolytic break in a polypeptide chain of a native protein is often sufficient to initiate its total degradation. What does this fact suggest to you regarding the structural consequences of proteolytic nicks in proteins?
- Understanding the Relevance of Chaperones in Protein Folding** Protein molecules, like all molecules, can be characterized in terms of general properties such as size, shape, charge, and solubility/hydrophobicity. Consider the influence of each of these general features on the likelihood of whether folding of a particular protein will require chaperone assistance or not. Your analysis should distinguish between proteins that interact only with Hsp70 chaperones and those that interact with both Hsp70 chaperones *and* Hsp60 chaperonins.
- Assessing the Chaperone-Assisted Folding of Multidomain Proteins** Many multidomain proteins apparently do not require chaperones to attain the fully folded conformations. Suggest a rational scenario for chaperone-independent folding of such proteins.
- Assessing the Dimensions and Capacity of GroEL** The GroEL ring has a 5 nm central cavity. Calculate the maximum molecular weight for a spherical protein that can just fit in this cavity, assuming the density of the protein is 1.25 g/mL.
- Understanding the Possible Phosphorylated States of Acetyl-CoA Carboxylase** (Integrates with Chapter 24.) Acetyl-CoA carboxylase has at least seven possible phosphorylation sites (residues 23, 25, 29, 76, 77, 95, and 1200) in its 2345 residue polypeptide (see Figure 24.4). How many different covalently modified forms of acetyl-CoA carboxylase protein are possible if there are seven phosphorylation sites?
- Covalent Modifications of Proteins** A protein's primary structure contains two T, one S, and two Y residues. Assume that each residue could be phosphorylated. How many different forms of this protein could exist?
- Comparing the Mechanisms of Action of EF-Tu/EF-Ts and DnaK/GrpE** (Integrates with Chapter 30.) In what ways are the mechanisms of action of EF-Tu/EF-Ts and DnaK/GrpE similar? What mechanistic functions do the ribosome A-site and DnaJ have in common?
- Understanding the Structure and Function of Signal Sequences and Signal Peptidases** The amino acid sequence deduced from the nucleotide sequence of a newly discovered human gene begins: MRSLLILVLCFLPLAALGK... Is this a signal sequence? If so, where does the signal peptidase act on it? What can you surmise about the intended destination of this protein?
- Understanding the Mechanism of Transport of Integral Membrane Proteins** Not only is the Sec61 translocon complex essential for translocation of proteins into the ER lumen, it also mediates the incorporation of integral membrane proteins into the ER membrane. The mechanism for integration is triggered by stop-transfer signals that cause a pause in translocation. The structure of Sec61 is shown in Figure 31.9. Suggest a mechanism for lateral transfer of an integral membrane protein from the protein-conducting channel of the translocon into the hydrophobic phase of the ER membrane.
- Assessing the Dimensions and Capacity of Sec61** The Sec61 core complex of the translocon has a highly dynamic pore whose internal diameter varies from 0.6 to 6 nm. In post-translational translocation, folded proteins can move across the ER membrane through this pore. What is the molecular weight of a spherical protein that would just fit through a 6 nm pore? (Assume a spherical protein with a density of 1.25 g/mL.)
- Assessing the Dimensions and Capacity of the Protein-Conducting Translocon** (Integrates with Chapters 6, 9, and 30.) During co-translational translocation, the peptide tunnel running from the peptidyl transferase center of the large ribosomal subunit and the protein-conducting channel are aligned. If the tunnel through the ribosomal subunit is 10 nm and the translocon channel has the same length as the thickness of a phospholipid bilayer, what is the minimum number of amino acid residues sequestered in this common conduit?
- Understanding the Nature of the Ubiquitin-Ubiquitin Linkage** Draw the structure of the isopeptide bond formed between Gly⁷⁶ of one ubiquitin molecule and Lys⁴⁸ of another ubiquitin molecule.
- Ubiquitination of E1 and E2** Ubiquitin is attached to both E1 and E2 (see Figure 31.10) and yet E1 and E2 are not degraded? Explain why this is the case.
- Understanding the Nature of E3 Ubiquitin Protein Ligation** Assign the 20 amino acids to either of two groups based on their susceptibility to ubiquitin ligation by E3 ubiquitin protein ligase. What are the common attributes among the amino acids in the less susceptible versus the more susceptible group?
- Proteolysis Inside the Proteasome** (Integrates with Chapter 14.) Section 31.4b discusses the mechanism of the proteolytic action inside the proteasome. Draw the sequence of chemical reactions that occur to achieve a complete hydrolysis of the peptide bond. (Hint: Revisit Section 14.6.)
- Assessing the Consequences of Proteasome Inhibition** Lactacystin is a *Streptomyces* natural product that acts as an irreversible inhibitor of 26S proteasome β -subunit catalytic activity by covalent attachment to N-terminal threonine —OH groups. Predict the effects of lactacystin on cell cycle progression.
- Action of Met-Aminopeptidase and Half-Life of Proteins** Explain how the activity of Met-aminopeptidase may affect the longevity of a protein.
- Understanding the Dual Functionality of the HtrA Protease** HtrA proteases are dual-function chaperone-protease protein quality control systems. The protease activity of HtrA proteases depends on a proper spatial relationship for the Asp-His-Ser catalytic triad. Propose a mechanism for the temperature-induced switch of HtrA proteases from chaperone function to protease function.
- Ubc9 Consensus Sequence** In the five peptides shown, circle the sequence of four amino acids recognized by Ubc9 (see Section 31.4c). (Hint: Only two contain the sequence.)

21. **Understanding the Scope and Diversity of Post-Translational Protein Modification** As described in this chapter, the most common post-translational modifications of proteins are proteolysis, phosphorylation, methylation, acetylation, and linkage with ubiquitin and SUMO proteins. Carry out a Web search to identify at least eight other post-translational modifications and the amino acid residues involved in these modifications.
22. **Post-Translational Modifications of Proteins** (Integrates with Chapters 4, 5, 7, 8, 19.) A select range of post-translation modifications of proteins is discussed in this chapter. Review previous chapters regarding protein structure and/or function, and list at least five other typical covalent modifications of proteins that can occur post-translation.
23. **Understanding the Nature and Functional Utility of Fluorescence Resonance Energy Transfer (FRET)** Fluorescence resonance energy transfer (FRET) is a spectroscopic technique that can be used to provide certain details of the conformation of biomolecules. Look up FRET on the Web or in an introductory text on FRET uses in biochemistry, and explain how FRET could be used to observe conformational changes in proteins bound to chaperonins such as GroEL. A good article on FRET in protein folding and dynamics can be found here: Haas, E., 2005. The study of protein folding and dynamics by determination of intramolecular distance distributions and their fluctuations using ensemble and single-molecule FRET measurements. *ChemPhysChem* **6**:858–870. Studies of GroEL using FRET analysis include the following: Sharma, S., et al., 2008. Monitoring protein conformation along the pathway of chaperonin-assisted folding. *Cell* **133**:142–153; and Lin, Z., et al., 2008. GroEL stimulates protein folding through forced unfolding. *Nature Structural and Molecular Biology* **15**:303–311.

24. **Understanding the Nature and Functions of the Phosphodegron** The cross-talk between phosphorylation and ubiquitination in protein degradation processes is encapsulated in the concept of the phosphodegron. What is a phosphodegron, and how does phosphorylation serve as a recognition signal for protein degradation? (A good reference on the phosphodegron and crosstalk between phosphorylation and ubiquitination is Hunter, T., 2007. The age of crosstalk: Phosphorylation, ubiquitination, and beyond. *Molecular Cell* **28**:730–738.)
25. **Assessing the Consequences of a Common Post-Translational Modification** A common post-translational modification is removal of the universal N-terminal methionine in many proteins by Met-aminopeptidase. How might Met removal affect the half-life of the protein?

Think-Pair-Share Question

Proteins as the Primordial Molecules of Life The “Deeper Look” segment in Section 30.5f described the notion of RNAs as the primordial molecules of life. The assumption is that billions of years ago primordial RNA molecules fulfilled the basic functions of biochemistry: carrying information and enabling catalysis. This has led to the hypothesis that life began in a so-called RNA world.

Some of the basic assumptions of any primordial world are:

1. A primordial soup of precursors that could have formed basic carbohydrates, nucleotides, or amino acids;
2. energy for chemical reactions in the forms of UV radiation and geothermal energy; and
3. minerals with microscopic porous surfaces that could have served as catalytic entities to promote chemical reactions.

Review everything you have learned about protein science (particularly chapters 4, 5, 6, and 31) and consider the possibility that protein molecules could serve as the primordial molecules of life. In evaluating this possibility, focus on: information storage, ability to replicate (without error), and ability to function.

The Reception and Transmission of Extracellular Information

32

"Ships that pass in the night, and speak each other in passing, Only a signal shown and a distant voice in the darkness."

by Henry Wadsworth Longfellow

Windsor/SuperStock

◀ Drawing of a human fetus in utero, by Leonardo da Vinci. Human sexuality and embryonic development represent two hormonally regulated processes of universal interest.

Essential Question

Higher life forms must have molecular mechanisms for detecting environmental information as well as mechanisms that allow for communication at the cell and tissue levels. Sensory systems detect and integrate physical and chemical information from the environment and pass this information along to the rest of the organism. Control and coordination of processes at the cell and tissue levels are achieved by chemical signals that are secreted by one set of cells to direct the activity of other cells. **What are the mechanisms of this information transfer and how do excitable membranes transduce the signals of sensory systems?**

Information transfer from cell to cell and between tissues is mediated by **hormones**. Hormones are secreted by certain cells, usually located in glands, and travel, either by simple diffusion or circulation in the bloodstream, to specific target cells (Figure 32.1). As we shall see, some hormones, whether steroid or nonsteroid, bind to specialized receptors on the plasma membrane and induce responses within the cell without themselves entering the target cell (Figure 32.2). Other hormones actually enter the target cell and interact with specific receptors there. By these mechanisms, hormones:

- Regulate the metabolic processes of various organs and tissues.
- Facilitate and control growth, differentiation, reproductive activities, learning, and memory.
- Help the organism cope with changing conditions and stresses in its environment.

All these consequences of hormonal signals are either **metabolic responses** or **gene expression responses** (Figure 32.2).

Key Questions

- 32.1 What Are Hormones?
- 32.2 What Is Signal Transduction?
- 32.3 How Do Signal-Transducing Receptors Respond to the Hormonal Message?
- 32.4 How Are Receptor Signals Transduced?
- 32.5 How Do Effectors Convert the Signals to Actions in the Cell?
- 32.6 How Are Signaling Pathways Organized and Integrated?
- 32.7 How Do Neurotransmission Pathways Control the Function of Sensory Systems?

Figure 32.1 The sites of synthesis and action of a few of the polypeptide and steroid hormones. Hormones typically circulate at low concentrations (1 nM or less) and bind with high affinity to their receptor proteins.

Figure 32.2 Nonsteroid hormones bind exclusively to plasma membrane receptors, which mediate the cellular responses to the hormone. Steroid hormones exert their effects either by binding to plasma membrane receptors or by diffusing to the nucleus, where they modulate transcriptional events. Intracellular responses to hormone binding include metabolic changes and alterations of gene expression.

32.1 | What Are Hormones?

Many different chemical species act as hormones. **Steroid hormones**, all derived from cholesterol, regulate metabolism, salt and water balances, inflammatory processes, and sexual function. Several hormones are **amino acid derivatives**. Among these are *epinephrine* and *norepinephrine* (which regulate smooth muscle contraction and relaxation, blood pressure, cardiac rate, and the processes of lipolysis and glycogenolysis) and the *thyroid hormones* (which stimulate metabolism). **Peptide hormones** are a large group of hormones that regulate processes in all body tissues, including the release of yet other hormones.

Hormones and other signal molecules in biological systems bind with very high affinities to their receptors, displaying K_D values in the range of 10^{-12} to 10^{-6} *M*. The hormones are produced at concentrations equivalent to or slightly above these K_D values. Once hormonal effects have been induced, the hormone is usually rapidly metabolized.

32.1a Steroid Hormones Act in the Nucleus or at the Plasma Membrane

The steroid hormones include the glucocorticoids (cortisol and corticosterone), the mineralocorticoids (aldosterone), and the sex hormones (progesterone and testosterone, for example) (Figure 32.1; see Chapter 24 for the details of their synthesis). The steroid hormones exert their effects in two ways. First, by entering cells and migrating to the nucleus, steroid hormones act as transcription regulators, modulating gene expression. These effects of the steroid hormones occur on time scales of hours and involve synthesis of new proteins. Steroids can also act at the cell membrane, directly regulating ligand-gated ion channels and perhaps other processes. These latter processes take place very rapidly, on time scales of seconds and minutes.

32.1b Polypeptide Hormones Share Similarities of Synthesis and Processing

The largest class of hormones in vertebrate organisms is the **polypeptide hormones** (Figure 32.1). One of the first polypeptide hormones to be discovered, **insulin**, was described by Banting and Best in 1921. Insulin, a secretion of the pancreas, controls glucose utilization and promotes the synthesis of proteins, fatty acids, and glycogen. Insulin, which is typical of the *secreted polypeptide hormones*, is discussed in detail in Chapters 5, 15, and 22.

Many other polypeptide hormones are produced and processed in a manner similar to that of insulin. Three unifying features of their synthesis and cellular processing should be noted. First, all secreted polypeptide hormones are originally synthesized with a signal sequence, which facilitates their eventual routing to secretory granules, and from there to the extracellular milieu. Second, peptide hormones are usually synthesized from mRNA as inactive precursors, termed **preprohormones**, which become activated by proteolysis. Third, a single polypeptide precursor or preprohormone may produce several different peptide hormones by suitable proteolytic processing.

An impressive example of the production of many hormone products from a single precursor is the case of prepro-opiomelanocortin, a 250 residue precursor peptide synthesized in the pituitary gland. A cascade of proteolytic steps produces, as the name implies, a natural opiate substance (endorphin) and several other hormones (Figure 32.3). Endorphins and other opiate-like hormones are produced by the body in response to systemic stress. These substances probably contribute to the runner's high that marathon runners describe, reducing pain and promoting pleasure.

Figure 32.3 The conversion of prepro-opiomelanocortin to a family of peptide hormones, including corticotropin, β - and γ -lipotropin, α - and β -MSH, and endorphin.

Careers in Chemistry

Dr. Shantá D. Hinton

Dr. Shantá D. Hinton is an Associate Professor and Chair of Biology at the College of William and Mary in Williamsburg, Virginia. Dr. Hinton earned her Bachelor's in Biology from the University of North Carolina at Chapel Hill and her Ph.D. in Cell and Developmental Biology from Howard University.

At William and Mary, Dr. Hinton teaches upper-level courses on protein structure and function and corresponding labs on cell signaling. She is also the principal investigator of a signal transduction lab where her undergraduate and Master's students

explore the catalytically inactive members of the protein tyrosine phosphatase family known as pseudophosphatases.

Professor Hinton credits the love and support of her family for nurturing her inquisitive mind and for motivating her to achieve excellence in her studies. Memories of gardening with her grandparents and the self-confidence instilled by her mother taught her how to navigate the unknown with perseverance and determination.

32.2 | What Is Signal Transduction?

Hormonal regulation depends on the transduction of the hormonal signal across the plasma membrane to specific intracellular sites, particularly the nucleus. This **signal transduction** consists of a stepwise progression of signaling stages: receptor → transducers → effectors. The receptor detects the signal, transducers relay the signal, and the effectors convert the signal into an intracellular response.

What are the characteristics of signal transduction systems? Regardless of the organism or the tissue, certain features appear to be universal, or nearly so:

- Transmembrane communication of hormonal signals by *receptor proteins*
- Clustering of membrane receptors and their ligands in large aggregates called **signalsomes**
- Reversible **covalent modifications** that change the function of certain proteins and lipids (including phosphorylation, methylation, acetylation, ubiquitylation, hydroxylation, and cleavage)
- **Protein interaction domains** that selectively recognize specific structural motifs and bind them with high affinity and specificity
- **Second messengers** that bind to specific targets, changing their activity and behavior
- Intracellular **signaling pathways**, often involving a series of enzymes (such as protein kinases), that link receptors to their downstream functional targets
- Cooperativity, in which a structural change in one subunit of a multimeric protein induces similar changes in the other subunits
- Spatial and temporal control of signals and messengers
- Integration of signals
- Converging and diverging networks
- Signal amplification
- Desensitization and adaptation

Each of these phenomena will be discussed and elaborated throughout this chapter.

32.2a Many Signaling Pathways Involve Enzyme Cascades

Signaling pathways must operate with speed and precision, facilitating the accurate relay of intracellular signals to specific targets. This happens via enzyme cascades. Enzymes can produce (or modify) a large number of molecules rapidly and specifically. Many enzymes of signaling cascades are protein kinases and protein phosphatases, and many steps in signaling pathways involve phosphorylation of serine, threonine, and tyrosine residues on target proteins. The complexity of signal transduction is thus manifested in the estimates that the human genome contains over five hundred protein kinase genes and 200 protein phosphatase genes. Enzyme cascades act like a series of amplifiers, dramatically increasing the magnitude of the intracellular response available from a very small amount of hormone (for an example, see the discussion of the phosphorylase cascade in Figure 15.18 and Section 22.5).

32.2b Signaling Pathways Connect Membrane Interactions with Events in the Nucleus

The complete pathway from hormone binding at the plasma membrane to modulation of transcription in the nucleus has been described for many signaling pathways. Figure 32.4 shows a complete signal transduction pathway that connects receptor tyrosine kinases, the Ras GTPase, cytoplasmic Raf, and two other protein kinases with transcription factors that alter gene expression in the nucleus. This pathway represents just one component of a complex signaling network that involves many other proteins and signaling factors. The existence of nearly 4000 human genes devoted to signal transduction portends a complex and interwoven network of signaling interactions in nearly all human cells.

32.2c Signaling Pathways Depend on Multiple Molecular Interactions

Each step in a signaling pathway depends on one or more molecular interactions. For example, a protein along a signaling pathway may bind to a small molecule, a peptide, or even another protein (Figure 32.5). In fact, many signaling proteins are constructed

Figure 32.4 A complete signal transduction pathway that connects a hormone receptor with transcription events in the nucleus. In this pathway, hormone binding causes phosphorylation of the tyrosine kinase domain of the receptor tyrosine kinase protein. Binding of protein GRB2 to the phosphorylated tyrosine of the RTK recruits the SOS protein which binds to the Ras protein, causing dissociation of GDP and binding of GTP. The Ras-GTP complex binds to and activates the Raf protein, catalyzing phosphorylation of the MAPK kinase, which in turn phosphorylates the MAP kinase (MAPK). This leads to stimulation of gene transcription in the nucleus, activating synthesis of cytosolic proteins with a variety of functions. The steps in this signaling cascade are elaborated in more detail later in this chapter. Many similar pathways have been characterized.

Figure 32.5 Five of the protein modules found in cell signaling proteins. The binding specificity of these modules is shown in Figure 32.6a. **(a)** SH3 domains bind to proline-rich peptides; **(b)** SH2 domains bind to phosphorylated tyrosine residues; **(c)** PH domains bind to phosphoinositides (such as IP_3); **(d)** PDZ domains bind to the terminal four or five residues of a target protein; and **(e)** pumilio domains bind to segments of RNA. A given protein may have a number of these protein modules, giving it the ability to interact with multiple partners.

in a cassette-like fashion with several distinct modules, termed **protein interaction domains (PIDs)**, each of which mediates a particular interaction (Figure 32.6a). A protein with multiple modules can interact with several binding targets at once to create a complex, called a **signalsome**, with multiple signaling capabilities (Figure 32.6b). Several signaling systems described in this chapter involve events at a signalsome.

Figure 32.6 Many signaling proteins consist of combinations of protein modules, each with a specific binding or enzymatic function. **(a)** A hypothetical signaling protein consisting of SH3, SH2, PH, WW, and PDZ domains. The binding preferences for each of these domains are described in Figure 32.5. **(b)** Such multiply-interacting proteins can act as scaffolds that direct the assembly of large signaling complexes, termed **signalsomes**.

32.3 How Do Signal-Transducing Receptors Respond to the Hormonal Message?

All receptors that mediate transmembrane signaling processes fit into one of three **receptor superfamilies** (Figure 32.7):

1. The **G-protein-coupled receptors** are integral membrane proteins with an extracellular recognition site for ligands and an intracellular recognition site for a **GTP-binding protein** (see following discussion).
2. The **single-transmembrane segment (1-TMS) catalytic receptors** are proteins with only a single transmembrane segment and substantial globular domains on both the extracellular and the intracellular faces of the membrane. The extracellular domain is the ligand recognition site, and the intracellular catalytic domain is either a **tyrosine kinase** or a **guanylyl cyclase**.
3. **Oligomeric ion channels** consist of associations of protein subunits, each of which contains several transmembrane segments. These oligomeric structures are **ligand-gated ion channels**. Binding of the specific ligand typically opens the ion channel. The ligands for these ion channels are neurotransmitters.

The first two of these receptor superfamilies will be discussed in this section and the third will be discussed in Section 32.7.

32.3a The G-Protein-Coupled Receptors Are 7-TMS Integral Membrane Proteins

The G-protein-coupled receptors (GPCRs) have primary and secondary structure similar to that of bacteriorhodopsin (see Chapter 9), with seven transmembrane

Figure 32.7 The membrane receptor superfamilies. The G-protein-coupled receptors are named for the GTP-binding proteins that mediate some of their effects. The receptor tyrosine kinases and receptor guanylyl cyclases contain intracellular enzymatic domains that respond to extracellular hormone binding. The oligomeric ion channels (some of which were discussed in Chapter 9) open and close in response to ligand binding and/or changes of the transmembrane electrochemical potential.

α -helical segments; they are thus known as *7-transmembrane segment (7-TMS)* proteins. Rhodopsin and the β -adrenergic receptors, for which epinephrine is a ligand, are good examples (Figure 32.8).

The site for binding of cationic catecholamines to the adrenergic receptors is located within the hydrophobic core of the receptor. Binding of hormone to a GPCR induces a conformation change that activates a GTP-binding protein, also known as a G protein. Activated G proteins trigger a variety of cellular effects, including activation of adenylyl and guanylyl cyclases (which produce cAMP and cGMP from ATP and GTP), activation of phospholipases (which produce second messengers from phospholipids), and activation of Ca^{2+} and K^{+} channels (which leads to elevation of intracellular $[\text{Ca}^{2+}]$ and $[\text{K}^{+}]$). (All of these effects are described in Section 32.4.)

(a) β_2 -Adrenergic receptor

(b)

Figure 32.8 GPCRs are 7-transmembrane segment membrane proteins. **(a)** The arrangement of the β_2 -adrenergic receptor in the membrane. Substitution of Asp¹¹³ in the third hydrophobic domain of the β -adrenergic receptor with an Asn or Gln by site-directed mutagenesis results in a dramatic decrease in affinity of the receptor for both agonists and antagonists. Significantly, this Asp residue is conserved in all GPCRs that bind biogenic amines but is absent in receptors whose ligands are not amines. Asp¹¹³ appears to be the counterion of the amine moiety of adrenergic ligands. **(b)** The structure of a β_2 -adrenergic receptor (PDB id = 2RH1). The flexible third intracellular loop and C-terminal segment are not shown. (From Figure 2 from Palczewski, K., et al., 2000. Crystal structure of rhodopsin: A G-protein-coupled receptor. *Science* **289**:739–745.)

There are 600 genes for non-olfactory GPCRs in the human genome, but alternative splicing produces between 1000 and 2000 active GPCRs in human cells. Louis Luttrell and colleagues have shown that synthesis of GPCRs and trafficking to the plasma membrane are regulated by RNA signals. This is one example of the growing awareness that RNA molecules can act as biological signals.

32.3b The Single TMS Receptors Are Guanylyl Cyclases or Tyrosine Kinases

Receptor proteins that span the plasma membrane with a single helical transmembrane segment—either **receptor tyrosine kinase (RTK)** or **receptor guanylyl cyclase (RGC)**—possess an external ligand recognition site and an internal domain with enzyme activity. Each of these enzyme activities is manifested in two different cellular forms. Thus, guanylyl cyclase activity is found in both membrane-bound receptors and in soluble, cytoplasmic proteins. Tyrosine kinase activity, on the other hand, is exhibited by two different types of membrane proteins: The RTKs are integral transmembrane proteins, whereas the non-RTKs are peripheral, lipid-anchored proteins. More than 90 tyrosine kinases have been identified in the human genome; 58 of these are RTKs. Seven receptor guanylyl cyclases have been identified in the human genome. All soluble guanylyl cyclase proteins are dimeric and consist of alpha and beta subunits. Vertebrates possess two alpha forms (α_1 and α_2) and two beta forms (β_1 and β_2). The predominant soluble guanylyl cyclase in animals is the α_1/β_1 dimer.

32.3c RTKs and RGCs Are Membrane-Associated Allosteric Enzymes

The binding of polypeptide hormones and growth factors to RTKs and RGCs activates the intracellular enzyme activity of these proteins. These catalytic receptors are composed of three domains (Figure 32.9): an extracellular receptor-binding domain (which may itself include several subdomains), a transmembrane domain consisting of a single transmembrane α -helix, and an intracellular domain. This intracellular portion includes a tyrosine kinase or guanylyl cyclase domain that mediates the biological response to the hormone or growth factor via its catalytic activity and a regulatory domain that contains multiple phosphorylation sites. The 58 RTKs of the human genome can be grouped into about 20 families on the basis of their kinase domain sequences and the various extracellular subdomains. The **epidermal growth factor (EGF) receptor** and the **insulin receptor** are representative of this class of receptor proteins.

Given that the extracellular and intracellular domains of RTKs and RGCs are joined by only a single transmembrane helical segment, how does extracellular hormone binding activate intracellular enzyme activity? How is the signal transduced? As shown in Figure 32.10, signal transduction occurs by ligand-induced oligomeric association of receptors. Hormone binding triggers a conformational change in the *extracellular* domain, which induces oligomeric association. Oligomeric association allows adjacent *cytoplasmic* domains to interact, leading to phosphorylation of the cytoplasmic domains and stimulation of cytoplasmic enzyme activity. By virtue of these ligand-induced conformation changes and oligomeric interactions, RTKs and RGCs are considered to be **membrane-associated allosteric enzymes**.

32.3d The EGF Receptor Is Activated by Ligand-Induced Dimerization

Prior to EGF binding, the EGF receptors exist as inactive monomers in the plasma membrane, but binding of an activating ligand induces dimerization.

The Structure of the EGF Receptor Human EGF is a 53 amino acid peptide that stimulates proliferation of epithelial cells (cells that cover a surface or line a cavity in biological tissues). The human EGF receptor is a 1186–amino acid RTK. The extracellular domain, where EGF binds, contains 622 amino acids and is divided into four domains (Figure 32.9). Domains I and III are similar β -helical barrels,

Figure 32.9 Four classes of single TMS receptors. The intracellular enzyme domains are tyrosine kinases or guanylyl cyclases. **(a)** The EGF receptor and **(b)** the insulin receptor are receptor tyrosine kinases. EGF receptors are activated by ligand-induced dimerization, whereas the insulin receptor is a glycoprotein composed of two kinds of subunits in an $\alpha_2\beta_2$ tetramer stabilized by disulfide bonds. The extracellular portions of the EGF and insulin receptors consist of multiple modules or domains. Fn refers to a series of fibronectin domains numbered 1, 2a, 2b, and 3. **(c)** The atrial natriuretic peptide receptor is a receptor guanylyl cyclase with a large extracellular hormone-binding domain and two intracellular domains, and activation typically involves ligand-induced dimerization. **(d)** The growth factor receptor Ret is a receptor tyrosine kinase that mediates the effects of neuronal growth factors known as neurotrophins. The Ret receptor domains (yellow) requires a GPI-anchored coreceptor (blue) for binding of ligands (pink).

Figure 32.10 Ligand-induced oligomerization of membrane receptors can occur in several ways. **(a)** EGF receptor dimerization and activation involves binding of hormone to the extracellular domains of two receptor molecules. **(b)** The insulin receptor is a preexisting tetramer. Two insulin-binding sites are created by association of the extracellular domains. **(c)** RGCs bind a single hormone ligand at the dimer interface. (Ligand dimers could presumably act in a similar manner). **(d)** Neurotrophin activation of Ret involves association of two molecules of the Ret kinase and two molecules of a GPI-anchored coreceptor protein.

whereas domains II and IV are long, slender, cysteine-rich domains stabilized by disulfide bonds. Domain II is characterized by a β -hairpin structure that protrudes from the middle of the domain (Figure 32.11a).

In the monomer state, the four domains are folded so that domains II and IV lie parallel, with the β -hairpin of domain II in contact with domain IV (Figure 32.11a). Binding of EGF to domain I induces a conformation change that rotates domains I and II so that the bound EGF is brought into contact with domain III and the β -hairpin is extended away from the rest of the structure. Pairs of such receptor monomers then dimerize by mutual association of the β -hairpin structures (Figure 32.11b). The next event is the critical step in transmembrane signal transduction. Dimerization of the extracellular domains brings the intracellular domains together, activating the tyrosine kinase activity. Thus, EGF-induced dimerization allows an extracellular signal (EGF) to exert an intracellular response.

EGF Receptor Activation Forms an Asymmetric Tyrosine Kinase Dimer The tyrosine kinase domain of the EGF receptor consists of an N-terminal domain built around a twisted β -sheet and a C-terminal domain that is primarily α -helical (Figure 32.12a). In the inactive, monomeric EGF receptor, the active site of the tyrosine kinase

Figure 32.11 Hormonal activation of EGF receptors. (a) In the absence of hormone, the extracellular domain of the EGF receptor is folded with the hairpin loop and dimerization interface on domain II (green) associated with domain IV (orange). Binding of EGF (red) induces a conformation change that exposes the dimerization interface and promotes formation of the activated dimer complex (PDB id = 1NQL). (b) Dimerization involves dove-tailing of the domain II hairpin loops (PDB id = 1IVO).

Figure 32.12 Several structures of the kinase domain of the epidermal growth factor (EGF) receptor. **(a)** The kinase domain of the EGF receptor consists of an N-terminal lobe built around a twisted β -sheet and an α -helical C-terminal lobe. Bound ATP is *pink*, and a portion of the activation loop, shown blocking the active site, is *blue*. **(b)** Hormone-induced receptor dimerization promotes formation of an asymmetric dimer of the intracellular kinase domains (*yellow* and *green*). **(c)** Before hormonal activation (*left*), the kinase active site is blocked by a 30-residue activation loop (*green*). In the activated complex (*right*), the activation loop (*green*) has rotated away from the active site in one of the subunits, making room for binding of a peptide substrate (*blue*). Activation brings Lys⁷²¹ close enough to form an ion pair with Glu⁷³⁸. (a, b, c [*right*]: PDB id = 2GS6; c [*left*]: PDB id = 2GS7.)

domain is blocked by a 30 residue loop of the protein (residues 831–860) that is termed the **activation loop**. Extracellular dimer formation by the EGF receptor appears to promote formation of an asymmetric dimer of the intracellular tyrosine kinase domains (Figure 32.12b), with the C-terminal lobe of one kinase domain juxtaposed with the N-terminal lobe of the other kinase domain. In this asymmetric dimer, one monomer is inactive but acts as an activator of kinase activity in the other monomer. Conversion of the kinase domain from its inactive state to the active conformation involves rotation of the activation loop out of the active site, making room for a peptide substrate to enter the site (Figure 32.12c).

The activated tyrosine kinase domain of the EGF receptor can phosphorylate several tyrosine residues at its own C terminus (Figure 32.13), a process termed **autophosphorylation**. These phosphorylated tyrosines are binding sites for a variety of other signaling proteins that contain phosphotyrosine-binding SH2 domains (see Figures 32.5 and 32.6). Each of these SH2-domain-containing proteins can initiate several signal transduction cascades.

32.3e The Insulin Receptor Mediates Several Signaling Pathways

Insulin, a small heterodimeric peptide (see Figure 5.8), is the most potent anabolic hormone known. It regulates blood glucose levels, and it promotes the synthesis and storage of carbohydrates, proteins, and lipids. Abnormalities of insulin production, action, or both lead to diabetes, as well as other serious health issues. Insulin binding to

Figure 32.13 Hormone-induced dimerization of the EGF receptor promotes autophosphorylation of five tyrosine residues near the C terminus of each EGF receptor subunit. Signaling proteins that contain phosphotyrosine-binding SH2 domains can be activated by binding to these phosphotyrosines.

receptors in liver, muscle, and other tissues triggers multiple signaling pathways, and insulin action is responsible for a variety of cellular effects.

The insulin receptor is an RTK that catalyzes the phosphorylation of tyrosine residues of several intracellular substrates, including the **insulin receptor substrate (IRS)** proteins, and several other proteins known as **Gab-1**, **Shc**, and **APS** (Figure 32.14). Each of these phosphorylated substrates binds a particular family of proteins containing SH2 domains (see Figures 32.5 and 32.6). These SH2 proteins interact specifically with phosphotyrosine-containing IRS sequences. Each of these signaling pathways can be confined to distinct cellular locations and can proceed with a different time course, thus providing spatial and temporal dimensions to insulin action in cells.

The Insulin Receptor Adopts a Folded Dimeric Structure Unlike the majority of RTKs, which are single-chain receptors, the insulin receptor is an $\alpha_2\beta_2$ tetramer. The α -chain contains two leucine-rich domains (L1 and L2) with a cysteine-rich domain (CR) between them, as well as an intact fibronectin domain (Fn1) and a partial fibronectin

Figure 32.14 Substrates of the insulin receptor tyrosine kinase include the insulin receptor substrate (IRS) proteins, as well as Gab-1, Shc, and APS. The phosphorylated substrates in turn bind to several families of SH2 domain-containing proteins, activating several signaling pathways.

domain (Fn2). The β -chain contains the other half of Fn2, followed by a third fibronectin domain (Fn3), a transmembrane α -helix, and (inside the cell) the tyrosine kinase domain (see Figure 32.9). The extracellular domain (the ectodomain) forms a **folded dimer**, with the L1 and L2 domains of one α -chain juxtaposed with the Fn2 domain of the other α/β chain pair, to create the insulin-binding site (Figure 32.15). Thus, each of the two insulin-binding sites of the ectodomain consists of portions of both α -chains.

Autophosphorylation of the Insulin Receptor Kinase Opens the Active Site Binding of insulin to its receptor activates the tyrosine kinase activity of the intracellular domains. Like the EGF receptor kinase, the insulin receptor kinase contains an activation loop that lies across the kinase active site, excluding substrate peptides and thus inhibiting the kinase. Phosphorylation of three tyrosine residues on the activation loop—another case of autophosphorylation—causes the activation loop to move out of and away from the active site (Figure 32.16). This opens the active site so that target proteins are bound and phosphorylated by the kinase, triggering the appropriate signaling pathways (see Figure 32.14).

32.3f Receptor Guanylyl Cyclases Mediate Effects of Natriuretic Hormones

When you eat a salty meal, your body secretes hormones that protect you from the harmful effects of excess salt intake. When your heart senses that blood volume is too great, it sends signals to the kidneys to excrete NaCl and water (processes termed natriuresis and diuresis, respectively). These are just two examples of the action of **natriuretic hormones**, which allow tissues and organs to communicate with one another to regulate the volumes of blood and other body fluids and the osmotic effects of Na⁺, K⁺, Cl⁻, and other ions.

Receptor Guanylyl Cyclases Are Membrane-Associated Allosteric Enzymes Guanylin and uroguanylin are produced in the intestines after ingestion of a salty meal and are secreted into the intestinal lumen. Binding of guanylin and uroguanylin to receptor guanylyl cyclases on cell membranes lining the lumen activates the intracellular guanylyl cyclase (Figure 32.17a). cGMP (see Figure 10.12) produced in this reaction is a second messenger that inhibits Na⁺ uptake from the lumen and activates Cl⁻ export into the lumen. The result is a beneficial enhanced excretion of NaCl and water. (This effect can be carried too far, however. *Heat-stable enterotoxin (ST)* produced by *E. coli*—with a sequence similar to guanylin and uroguanylin—causes violent diarrhea.) **Atrial natriuretic peptide (ANP)** and **brain natriuretic peptide**

Figure 32.15 The ectodomain formed by the insulin receptor is constructed from the two α/β units. These two units are folded so that the L1 domain of one α -chain is juxtaposed with the Fn1 domain of the other α -chain. Each insulin-binding site is created by the L1 and L2 domains of one α -chain and the Fn2 domain of the other α/β chain pair (see Figure 32.9; PDB id = 2DTG).

Figure 32.16 In its inactive state, the insulin receptor tyrosine kinase is inhibited by an activation loop (yellow and red), which prevents substrate access to the active site (left; PDB id = 1IRK). Autophosphorylation of three tyrosine residues on the activation loop induces a conformation change that rotates the loop out of the active site (right; PDB id = 1IR3), permitting access by insulin receptor substrates (blue) and ATP (ATP analog in orange).

Figure 32.17 Ingestion of a salty meal triggers excretion of NaCl and water in the intestines. Binding of guanylin and uroguanylin to RGC on cell membranes lining the lumen activates the intracellular guanylyl cyclase. cGMP produced by the cyclase inhibits Na⁺ uptake from the lumen and activates Cl⁻ export into the lumen. Atrial natriuretic peptide (ANP) protects the heart and circulatory system from the deleterious effects of increased blood volume. When the heart muscle is stressed and stretched, the heart secretes ANP. ANP binding to RGCs in kidney tubules activates intracellular guanylyl cyclase, producing cGMP. Inhibition of Na⁺ uptake in the kidneys stimulates excretion of salt and water, reducing blood volume.

(BNP, so named because it was discovered first in the brain) are both produced primarily in the heart. When the heart muscle is stressed and stretched by increased blood volume, the heart secretes ANP and BNP into the blood. In the kidneys, ANP and BNP bind to RGCs in kidney tubules, activating intracellular guanylyl cyclase and producing cGMP (Figure 32.17b). As in the intestines, cGMP inhibits Na⁺ uptake, once again stimulating excretion of salt and water and reducing blood volume.

A Symmetric Dimer Binds an Asymmetric Peptide Ligand RGC monomers associate as dimers in the membrane, even in the absence of their hormone ligands (Figure 32.18a). A dimeric receptor complex is activated by the binding of a single polypeptide hormone. This raises two important questions about the mechanism of action of these receptors: (1) How does an asymmetric hormone ligand (for example, ANP) bind to a symmetric homodimeric receptor? And (2) how does hormone binding to its extracellular dimeric receptor activate the intracellular guanylyl cyclase domain? Answers to these provocative questions have been provided by Kunio Misono and his colleagues, who determined the structure of the ANP receptor–ANP complex (Figure 32.18b). Remarkably, there is no significant intramolecular conformational change in either of the ANP receptor monomers. However, upon ANP binding, the two ANP receptor molecules undergo a twist motion in the membrane in order to insert the ANP hormone between them (Figure 32.19). The hormone lies like a disc between the two receptor subunits. The hormone-induced twist of the extracellular domains suggests a mechanism for activation of guanylyl cyclase activity across the membrane. Rotation of the transmembrane helices upon hormone binding could reorient the two intracellular domains, giving rise to guanylyl cyclase activity.

Figure 32.18 Activation of the ANP receptor involves binding of an asymmetric ligand at the interface of two identical receptor domains. Comparison of the structures of the receptor domain in the **(a)** absence and **(b)** presence of ANP reveals no significant intramolecular conformational change in either of the receptor monomers. ANP binding induces a twist of the two ANP receptor molecules, allowing the ANP hormone to insert between them. (a, PDB id = 1DP4; b, PDB id = 1T34).

Figure 32.19 The rotation mechanism proposed by Misono and colleagues for transmembrane signaling by the ANP receptor. ANP binding causes a twist of the two extracellular domains, leading to rotation of the two intracellular domains and activation of guanylyl cyclase activity. PKLD is a protein kinase-like domain, and GCD is a guanylyl cyclase domain. (Adapted from Misono, K., Ogawa, H., Qiu, Y., and Ogata, C., 2005. Structural studies of the natriuretic peptide receptor: A novel hormone-induced rotation mechanism for transmembrane signal transduction. *Peptides* 26:957–968.)

32.3g Nonreceptor Tyrosine Kinases Are Typified by pp60^{src}

The first tyrosine kinases to be discovered were associated with *viral transforming proteins*. These proteins, produced by **oncogenic viruses**, enable the virus to *transform* animal cells, that is, to convert them to the cancerous state. A prime example is the tyrosine kinase expressed by the **src gene** of **Rous** or **avian sarcoma virus**. The protein product of this gene is **pp60^{v-src}** (the abbreviation refers to phosphoprotein, 60 kDa, viral origin, sarcoma-causing). The v-src gene was derived from the avian proto-oncogenic gene c-src during the original formation of the virus. The cellular proto-oncogene homolog of pp60^{v-src} is referred to as pp60^{c-src}. pp60^{v-src} is a 526 residue peripheral membrane protein. It undergoes two post-translational modifications: First, the amino group of the NH₂-terminal glycine is modified by the covalent attachment of a *myristoyl* group (this modification is required for membrane association of the kinase; see Figure 32.20). Then Ser¹⁷ and Tyr⁴¹⁶ are phosphorylated.

Figure 32.20 Activation mechanisms for the soluble forms of tyrosine kinases and guanylyl cyclases.

(a) The soluble tyrosine kinase pp60^{src} is activated by anchoring to the plasma membrane via an N-terminal myristoyl group, followed by phosphorylation as shown. (b) The structure of protein tyrosine kinase pp60^{src}, showing AMP-PNP in the active site (blue, green, and red), Tyr⁴¹⁶ (orange), and Tyr⁵²⁷ (yellow). Tyr⁵²⁷ is phosphorylated (purple). (c) Domain structure of the α- and β-subunits of soluble guanylyl cyclase (sGC). Nitric oxide (NO) activates the cyclase by binding to the H-NOX domain. (d) Cryo-EM structure of the inactive form of sGC, showing the bent coiled-coil (PDB id = 6JT0). (e) Cryo-EM structure of the active form of sGC, showing the extended coiled-coil (PDB id = 6JT2).

A Deeper Look

Nitric Oxide, Nitroglycerin, and Alfred Nobel

NO[•] is the active agent released by *nitroglycerin* (see accompanying figure), a powerful drug that ameliorates the symptoms of heart attacks and *angina pectoris* (chest pain due to coronary artery disease) by causing the dilation of coronary arteries. Nitroglycerin is also the active agent in dynamite. Ironically, Alfred Nobel, the inventor of dynamite who also endowed the Nobel prizes, himself suffered from angina pectoris. In a letter to a friend in 1885, Nobel wrote, “It sounds like the irony of fate that I should be ordered by my doctor to take nitroglycerin internally.”

The structure of nitroglycerin, a potent vasodilator.

The phosphorylation at Tyr⁴¹⁶, which increases kinase activity twofold to threefold, appears to be an autophosphorylation. On the other hand, phosphorylation at Tyr⁵²⁷ is inhibitory and is catalyzed by another kinase known as CSK. The significance of nonreceptor tyrosine kinase activity to cell growth and transformation is only partially understood, but 1% of all cellular proteins (many of which are also kinases) are phosphorylated by these kinases.

32.3h Soluble Guanylyl Cyclases Are Receptors for Nitric Oxide

Nitric oxide, or NO[•], a reactive free radical, acts as a neurotransmitter and as a second messenger, activating soluble guanylyl cyclase more than 400-fold. The cGMP thus produced also acts as a second messenger, inducing relaxation of vascular smooth muscle and mediating penile erection. As a dissolved gas, NO[•] is capable of rapid diffusion across membranes in the absence of any apparent carrier mechanism. This property makes NO[•] a particularly attractive second messenger because NO[•] generated in one cell can exert its effects quickly in many neighboring cells. NO[•] has a very short cellular half-life (1 to 5 s) and is rapidly degraded by nonenzymatic pathways.

The α - and β -subunits of sGCs are homologous and each contains four domains (Figure 32.20c): a heme nitric oxide/oxygen (H-NOX) binding domain, a Per/Arnt/Sim (PAS)-like domain, a coiled-coil (CC) domain, and a catalytic cyclase domain (CAT). Binding of NO[•] causes a large-scale conformation change that converts the inactive form to the active guanylyl cyclase (Figure 32.20d and e). The CC domain is bent in the inactive form but is fully extended in the active form. The H-NOX and CAT domains do not contact each other, but both rotate relative to the CC domain in the conversion to the active form. The CC domain is thus the transducer of NO[•] activation of sGCs.

32.4 | How Are Receptor Signals Transduced?

Receptor signals are *transduced* in one of three ways to initiate actions inside the cell:

1. Exchange of GDP for GTP by GTP-binding proteins (G proteins) on the cytoplasmic side of the plasma membrane, which leads to generation of *second messengers*, including cAMP, phospholipid breakdown products, and Ca²⁺.
2. Receptor-mediated activation of phosphorylation cascades that in turn trigger activation of various enzymes. This is the action of the receptor tyrosine kinases described in Section 32.3. Protein kinases and protein phosphatases acting as effectors will be discussed in Section 32.5.
3. Conformation changes that open ion channels or recruit proteins into nuclear transcription complexes. (Ion channels are discussed in Section 32.7, and the formation of nuclear transcription complexes was described in Chapter 29.)

32.4a GPCR Signals Are Transduced by G Proteins

The signals of G-protein-coupled receptors (GPCRs) are transduced by GTP-binding proteins, known more commonly as G proteins. The large G proteins are heterotrimers consisting of α - (45 to 47 kDa), β - (35 kDa), and γ - (7 to 9 kDa) subunits. The α -subunit binds GDP or GTP and has an intrinsic, slow GTPase activity. The $G_{\alpha\beta\gamma}$ complex (Figure 32.21 and see Figure 15.20) in the unactivated state has GDP at the nucleotide site. Binding of hormone to receptor stimulates a rapid exchange of GTP for GDP on G_{α} . The binding of GTP causes G_{α} to dissociate from $G_{\beta\gamma}$ and to associate with an effector protein such as adenylyl cyclase (Figure 32.22). Binding of G_{α} (GTP) activates adenylyl cyclase. The adenylyl cyclase actively synthesizes cAMP as long as G_{α} (GTP) remains bound to it. However, the intrinsic GTPase activity of G_{α} eventually hydrolyzes GTP to GDP, leading to dissociation of G_{α} (GDP) from adenylyl cyclase and reassociation with the $G_{\beta\gamma}$ dimer, regenerating the inactive heterotrimeric $G_{\alpha\beta\gamma}$ complex.

The hormone-activated GPCR is a **guanine-nucleotide exchange factor (GEF)**—promoting the exchange of GDP with GTP on the G protein—in a manner similar to the interaction of EF-Ts with EF-Tu(GDP) (see Section 30.5d). By contrast, the $G_{\beta\gamma}$ complex,

Figure 32.21 A heterotrimeric G protein (α —pink, β —yellow, and γ —blue) docked with a β_2 -adrenergic receptor (green; PDB id = 3SN6).

Figure 32.22 Adenyl cyclase activity is modulated by the interplay of stimulatory (G_s) and inhibitory (G_i) G proteins. Binding of hormones to β_1 - and β_2 -adrenergic receptors activates adenyl cyclase via G_s , whereas hormone binding to α_2 -adrenergic receptors leads to the inhibition of adenyl cyclase. Inhibition may occur by direct inhibition of cyclase activity by $G_{i\alpha}$ or by binding of $G_{i\beta\gamma}$ to $G_{s\alpha}$.

which normally acts to inhibit the spontaneous release of GDP from G_α (in the inactivated state of the GPCR), is termed a **guanine-nucleotide dissociation inhibitor (GDI)**. Other proteins may also behave as GEFs and GDIs; their actions are discussed in Section 32.5.

Two stages of amplification occur in the G-protein-mediated hormone response. First, a single hormone-receptor complex can activate many G proteins before the hormone dissociates from the receptor. Second, the G_α -activated adenyl cyclase synthesizes many cAMP molecules. Thus, the binding of hormone to a very small number of membrane receptors stimulates a large increase in concentration of cAMP within the cell. The hormone receptor, G protein, and cyclase constitute a complete hormone **signal transduction unit**.

Hormone-receptor-mediated processes regulated by G proteins may be stimulatory or inhibitory. Each hormone receptor interacts specifically with either a stimulatory G protein, denoted G_s , or an inhibitory G protein, denoted G_i (Figure 32.22).

32.4b Cyclic AMP Is a Second Messenger

Cyclic AMP (cAMP) was identified in 1956 by Earl Sutherland, who termed cAMP a **second messenger** because it is the intracellular response provoked by binding of hormone (the first messenger) to its receptor. Since Sutherland's discovery of cAMP, many other second messengers have been identified (Table 32.1). The concentrations of second messengers in cells are carefully regulated. Synthesis or release of a second messenger is followed quickly by degradation or removal from the cytosol. Following its synthesis by adenyl cyclase, cAMP is broken down to 5'-AMP by phosphodiesterase (Figure 32.23).

Adenyl cyclase (AC) is an integral membrane enzyme. Its catalytic domain, on the cytoplasmic face of the plasma membrane, includes two subdomains, denoted VC_1 and IIC_2 . Binding of the α -subunit of G_s (denoted $G_{s\alpha}$) activates the AC catalytic domain.

Alfred Gilman, Stephen Sprang, and coworkers have determined the structure of a complex of $G_{s\alpha}$ (with bound GTP) with the cytoplasmic domains (VC_1 and IIC_2) of adenyl cyclase (Figure 32.24). The $G_{s\alpha}$ complex binds to a cleft at one corner of the C_2 domain, and the surface of $G_{s\alpha}$ -GTP that contacts adenyl cyclase is the same surface that binds the $G_{\beta\gamma}$ dimer. The catalytic site, where ATP is converted to cyclic AMP, is far removed from the bound G protein.

Spatial and temporal cAMP concentration gradients modulate the actions of this second messenger. These gradients lie between the sites of cAMP synthesis (by adenyl cyclase) and the sites of degradation (by specific phosphodiesterases).

Table 32.1 Intracellular Second Messengers*

Messenger	Source	Effect
cAMP	Adenylyl cyclase	Activates protein kinases
cGMP	Guanylyl cyclase	Activates protein kinases, regulates ion channels, regulates phosphodiesterases
Ca ²⁺	Ion channels in ER and plasma membrane	Activates protein kinases, activates Ca ²⁺ -modulated proteins
IP ₃	PLC action on PI	Activates Ca ²⁺ channels
DAG	PLC action on PI	Activates protein kinase C
Phosphatidic acid	Membrane component and product of PLD	Activates Ca ²⁺ channels, inhibits adenylyl cyclase
Ceramide	PLC action on sphingomyelin	Activates protein kinases
Anandamide	Action of phospholipases and other enzymes on glycerophospholipids	Activation or inhibition of neuronal circuits
Hydrogen sulfide (H ₂ S)	Action of cystathionine γ lyase on cysteine	Regulation of blood vessels and heart and inflammatory responses
Carbon monoxide (CO)	Action of heme oxygenase in heme catabolism	Cryoprotective and homeostatic functions
Nitric oxide (NO $\cdot$)	NO synthase	Activates guanylyl cyclase, relaxes smooth muscle
Cyclic ADP-ribose	cADP-ribose synthase	Activates Ca ²⁺ channels

*IP₃ = inositol-1,4,5-trisphosphate; PI = phosphatidylinositol; DAG = diacylglycerol; PLC = phospholipase C; PLD = phospholipase D (see Figure 32.26). cCMP and cUMP (not shown) are also cyclic nucleotide second messengers.

Figure 32.23 Cyclic AMP is synthesized by membrane-bound adenylyl cyclase and degraded by soluble phosphodiesterase.

cAMP Activates Protein Kinase A All second messengers exert their cellular effects by binding to one or more target molecules. cAMP produced by adenylyl cyclase activates a protein kinase, which is thus known as *cAMP-dependent protein kinase*. Protein kinase A, as this enzyme is also known, activates many other cellular proteins by phosphorylation. The activation of protein kinase A by cAMP and regulation of the enzyme by intrasteric control was described in detail in Chapter 15. The structure of protein kinase A has served as a paradigm for understanding many related protein kinases (see Figure 15.9).

32.4c Ras and Other Small GTP-Binding Proteins Are Proto-Oncogene Products

GTP-binding proteins are implicated in growth control mechanisms in higher organisms. Certain tumor virus genomes contain genes encoding 21 kDa proteins that bind GTP and show regions of homology with other G proteins. The first of these genes to be identified was found in *rat sarcoma virus* and was dubbed the ***ras* gene**. Genes implicated in tumor formation are known as **oncogenes**; they are often mutated versions of normal, noncancerous genes involved in growth regulation, so-called **proto-oncogenes**. The normal, cellular Ras protein is a GTP-binding protein that functions in a manner similar to that of other G proteins described previously, activating metabolic processes when GTP is bound and becoming inactive when GTP is hydrolyzed to GDP.

Figure 32.24 Structure of a G_{α} complex with the catalytic domain of adenylyl cyclase. **(a)** Two views of the complex of G_{α} with the VC1-IIC2 catalytic domain of adenylyl cyclase (with 2'-deoxy-adenosine 3'-monophosphate shown in *magenta*) and G_{α} (5'-guanosine-diphosphate-monothiophosphate shown in *aqua*). **(b)** Details of the G_{α} complex in the same orientation as the structures in (a). SW-I and SW-II are switch regions, whose conformations differ greatly depending on whether GTP or GDP is bound. (PDB id = 1CS4)

The GTPase activity of the normal Ras p21 is very low, as is appropriate for a G protein that regulates long-term effects like growth and differentiation. A specific **GTPase-activating protein (GAP)** increases the GTPase activity of the Ras protein. Mutant (oncogenic) Ras proteins have severely impaired GTPase activity, locking them in an state that activates cellular growth and metabolism in tumor cells. The conformations of Ras proteins (Figure 32.25) in complexes with GDP are different from the corresponding complexes with GTP analogs such as GMP-PNP (a nonhydrolyzable analog of GTP in which the β -P and γ -P are linked by N rather than by O). Two regions of the Ras structure change conformation upon GTP hydrolysis. These conformation changes mediate the interactions of Ras with other proteins, termed *effectors*.

32.4d G Proteins Are Universal Signal Transducers

A given G protein can be activated by several different hormone-receptor complexes. For example, either glucagon or epinephrine, binding to their distinctive receptor proteins, can activate the same species of G protein in liver cells. The effects are additive, and combined stimulation by glucagon and epinephrine leads to higher cytoplasmic concentrations of cAMP than activation by either hormone alone.

G proteins are a universal means of signal transduction in higher organisms, activating many hormone-receptor-initiated cellular processes in addition to adenylyl cyclase. Such processes include, but are not limited to, activation of phospholipases C and A_2 and the opening or closing of transmembrane channels for K^+ , Na^+ , and Ca^{2+} in brain, muscle, heart, and other organs (Table 32.2). G proteins are integral components of sensory pathways such as vision and olfaction. More than 800 different GPCRs and at least 21 distinct G proteins are known. At least a dozen different G-protein effectors have been identified, including a variety of enzymes and ion channels.

Figure 32.25 The structure of Ras complexed with **(a)** GDP (PDB id = 1LF5) and **(b)** GMP-PNP (PDB id = 1LF0). The Ras p21-GMP-PNP complex is the active conformation of this protein. A Mg^{2+} ion (red) is shown in both structures.

Table 32.2 G Proteins and Their Physiological Effects

G Protein	Location	Stimulus	Effector	Effect
G _s	Liver	Epinephrine, glucagon	Adenylyl cyclase	Glycogen breakdown
G _s	Adipose tissue	Epinephrine, glucagon	Adenylyl cyclase	Fat breakdown
G _s	Kidney	Antidiuretic hormone	Adenylyl cyclase	Conservation of water
G _i	Heart muscle	Acetylcholine	Potassium channel	Decreased heart rate and pumping force
G _i /G _o	Brain neurons	Enkephalins, endorphins, opioids	Adenylyl cyclase, potassium channels, calcium channels	Changes in neuron electrical activity
G _q	Smooth muscle cells in blood vessels	Angiotensin	Phospholipase C	Muscle contraction, blood pressure elevation
G _{olf}	Neuroepithelial cells in the nose	Odorant molecules	Adenylyl cyclase	Odorant detection
Transducin (G _t)	Retinal rod and cone cells of the eye	Light detection	cGMP phosphodiesterase	Light detection (vision)

32.4e Specific Phospholipases Release Second Messengers

A diverse array of second messengers are generated by breakdown of membrane phospholipids. Binding of certain hormones and growth factors to their respective receptors triggers a sequence of events that can lead to the activation of specific phospholipases. The action of these phospholipases on membrane lipids produces the second messengers shown in Figure 32.26.

Inositol Phospholipid Breakdown Yields Inositol-1,4,5-Trisphosphate and Diacylglycerol
Breakdown of **phosphatidylinositol (PI)** and its derivatives by **phospholipase C** produces a family of second messengers. In the best-understood pathway, successive phosphorylations of PI produce **phosphatidylinositol-4-P (PIP)** and **phosphatidylinositol-4,5-bisphosphate (PIP₂)**. Four isozymes of phospholipase C (denoted α , β , γ , and δ) hydrolyze PI, PIP, and PIP₂. Hydrolysis of PIP₂ by phospholipase C yields the second messenger **inositol-1,4,5-trisphosphate (IP₃)** as well as another second messenger, **diacylglycerol (DAG)** (Figure 32.27). IP₃ is water soluble and diffuses to intracellular organelles where release of Ca²⁺ is activated. DAG, on the other hand, is lipophilic and remains in the plasma membrane, where it activates a Ca²⁺-dependent protein kinase known as **protein kinase C**.

Figure 32.26 Lipid second messengers are generated by the action of phospholipases. (a) The general action of phospholipase A₂ (PLA₂), phospholipase C (PLC), and phospholipase D (PLD). (b) The synthesis of second messengers from phospholipids by the action of phospholipases and sphingomyelinase (SMase), which for example cleaves a choline sphingomyelin to yield phosphocholine and ceramide.

Figure 32.27 The family of second messengers produced by phosphorylation and breakdown of phosphatidylinositol. PLC action instigates a bifurcating pathway culminating in two distinct and independent second messengers: DAG and IP₃.

Figure 32.28 Phospholipase C- β is activated specifically by G_q, a GTP-binding protein, and also by Ca²⁺.

Activation of Phospholipase C Is Mediated by G Proteins or by Tyrosine Kinases Phospholipase C- β , C- γ , and C- δ are all Ca²⁺ dependent, but the different phospholipase C isozymes are activated by different intracellular events. Phospholipase C- β is stimulated by G proteins (Figure 32.28). On the other hand, phospholipase C- γ is activated by **receptor tyrosine kinases** (Figure 32.29). The domain organization of phospholipase C- β and C- γ is shown in Figure 32.30. The X and Y domains of phospholipase C- β and C- γ are highly homologous, and both of these domains are required for phospholipase C activity. The other domains of these isozymes confer specificity for G-protein activation or tyrosine kinase activation.

Figure 32.30 The amino acid sequences of phospholipase C isozymes β , γ , and δ share two homologous domains, denoted X and Y. The sequence of γ -isozyme contains src homology domains, denoted SH2 and SH3. SH2 domains (approximately 100 residues in length) interact with phosphotyrosine-containing proteins (such as RTKs), whereas SH3 domains mediate interactions with Pro-rich sequences. (Adapted from Dennis, E., Rhee, S., Gillah, M., and Hannun, E., 1991. Role of phospholipases in generating lipid second messengers in signal transduction. *The FASEB Journal* 5:2068–2077.)

Figure 32.29 Phospholipase C- γ is activated upon phosphorylation by receptor tyrosine kinases and by Ca²⁺.

Human Biochemistry

Cancer, Oncogenes, and Tumor Suppressor Genes

The disease state known as **cancer** is the uncontrolled growth and proliferation of one or more cell types in the body. Control of cell growth and division is an incredibly complex process, involving the signal-transducing proteins (and small molecules) described in this chapter and many others like them. The genes that give rise to these growth-controlling proteins are of two distinct types:

1. **Oncogenes:** These genes code for proteins that are capable of stimulating cell growth and division. In normal tissues and organisms, such growth-stimulating proteins are regulated so that growth is appropriately limited. However, mutations in these genes may result in loss of growth regulation, leading to uncontrolled cell proliferation and tumor development. These mutant genes are known as *oncogenes* because they induce the oncogenic state—cancer. The normal versions of these genes are termed **proto-oncogenes**; proto-oncogenes are essential for normal cell growth and differentiation. Oncogenes are *dominant* because mutation of only one of the cell's two copies of the gene can lead to tumor formation. Table A lists a few of the known oncogenes (more than 60 are now known).

2. **Tumor suppressor genes:** These genes code for proteins whose normal function is to *turn off* cell growth. A mutation in one of these growth-limiting genes may result in a protein product that has lost its growth-limiting ability. Since the normal products suppress tumor growth, the genes are known as *tumor suppressor genes*. Because both cellular copies of a tumor suppressor gene must be mutated to foil its growth-limiting action, these genes are *recessive* in nature. Table B presents several recognized tumor suppressor genes.

Careful molecular analysis of cancerous tissue has shown that tumor development may result from mutations in several proto-oncogenes or tumor suppressor genes. The implication is that *there is redundancy in cellular growth regulation*. Many (if not all) tumors are either the result of interactions of two or more oncogene products or arise from simultaneous mutations in a proto-oncogene and both copies of a tumor suppressor gene. Cells have thus evolved with overlapping growth-control mechanisms. When one is compromised by mutation, others take over.

Table A A Representative List of Proto-Oncogenes Implicated in Human Tumors

Proto-Oncogene	Neoplasm(s)
<i>Abl</i>	Chronic myelogenous leukemia
<i>ErbB-1</i>	Squamous cell carcinoma; astrocytoma
<i>ErbB-2 (Neu)</i>	Adenocarcinoma of breast, ovary, and stomach
<i>Myc</i>	Burkitt's lymphoma; carcinoma of lung, breast, and cervix
<i>H-Ras</i>	Carcinoma of colon, lung, and pancreas; melanoma
<i>N-Ras</i>	Carcinoma of genitourinary tract and thyroid; melanoma
<i>Ros</i>	Astrocytoma
<i>Src</i>	Carcinoma of colon
<i>Jun</i> <i>Fos</i>	} Several

32.4f Lipids Such as Phosphatidylcholine, Sphingomyelin, Glycosphingolipids, and Arachidonic Acid Also Generate Second Messengers

In addition to PI, other phospholipids serve as sources of second messengers. Breakdown of phosphatidylcholine by phospholipases yields a variety of second messengers, including DAG, phosphatidic acid, and prostaglandins. The action of sphingomyelinase on sphingomyelin produces ceramide, which stimulates ceramide-activated protein kinase. Similarly, gangliosides (such as ganglioside G_{M3} ; see Section 8.4) and their break-down products modulate the activity of protein kinases and GPCRs. Anandamide, formed by the action of several phospholipases from PC and PE (Chapter 8 and Table 32.1), is an intracellular messenger in many cells. Anandamide for such purposes is stored in lipid droplets (adiposomes) and other intracellular reservoirs.

Figure 32.31 Cytosolic $[\text{Ca}^{2+}]$ increases occur via the opening of Ca^{2+} channels in the membranes of calciosomes, the endoplasmic reticulum, and the plasma membrane.

32.4g Calcium Is a Second Messenger

Calcium ion is an important intracellular signal. Binding of certain hormones and signal molecules to plasma membrane receptors can cause transient increases in cytoplasmic Ca^{2+} levels, which in turn can activate a wide variety of enzymatic processes, including smooth muscle contraction, exocytosis, and glycogen metabolism. (Most of these activation processes depend on special Ca^{2+} -binding proteins discussed in the following section.) Cytosolic $[\text{Ca}^{2+}]$ can be increased in two ways (Figure 32.31). As mentioned briefly earlier, cAMP can activate the opening of plasma membrane Ca^{2+} channels, allowing extracellular Ca^{2+} to stream in. On the other hand, cells also contain intracellular reservoirs of Ca^{2+} , within the endoplasmic reticulum and **calciosomes**, small membrane vesicles that are similar in some ways to muscle sarcoplasmic reticulum. These special intracellular Ca^{2+} stores are *not* released by cAMP. They respond to IP_3 , a second messenger derived from PI.

Intracellular Calcium-Binding Proteins Mediate the Calcium Signal Given the central importance of Ca^{2+} as an intracellular messenger, it should not be surprising that complex mechanisms exist in cells to manage and control Ca^{2+} . When Ca^{2+} signals are generated by cAMP, IP_3 , and other agents, these signals are translated into the desired intracellular responses by **calcium-binding proteins**, which in turn regulate many cellular processes (Figure 32.32). One of these, protein kinase C, is described in Section 32.5. The other important Ca^{2+} -binding proteins can, for the most part, be divided into two groups on the basis of structure and function: (1) the **calcium-modulated proteins**, including **calmodulin**, **parvalbumin**, **troponin C**, and many others, all of which have in common a structural feature called the **EF hand** (Figure 32.33) and (2) the **annexin proteins**, a family of homologous proteins that interact with membranes and phospholipids in a Ca^{2+} -dependent manner.

More than 170 calcium-modulated proteins are known. All possess a characteristic peptide domain consisting of a short α -helix, a loop of 12 amino acids, and a second α -helix (Figure 32.33). Robert Kretsinger at the University of Virginia initially discovered this pattern in parvalbumin, a protein first identified in the carp fish and later in neurons possessing a high firing rate and a high oxidative metabolism. Kretsinger lettered the six helices of parvalbumin A through F. He noticed that the E and F helices, joined by a loop, resembled the thumb and forefinger of a right hand and named this structure the *EF hand*, a name in common use today to identify the helix-loop-helix motif in calcium-binding proteins. In the EF hand, Ca^{2+} is coordinated by six carboxyl oxygens contributed by a glutamate and three aspartates, by a carbonyl oxygen from a peptide bond, and by the oxygen of a coordinated water molecule. The EF hand was subsequently identified in calmodulin, troponin C, and **calbindin-9K**. Most of the known EF-hand proteins possess two or more (as many as eight) EF-hand domains, usually arranged so that two EF-hand domains may directly contact each other.

32.4h Calmodulin Target Proteins Possess a Basic Amphiphilic Helix

The conformations of EF-hand proteins change dramatically upon binding of Ca^{2+} ions. This change promotes binding of the EF-hand protein with its target protein(s). For example, calmodulin (CaM), a 148 residue protein found in many cell types,

Human Biochemistry

PI Metabolism and the Pharmacology of Li^+

Several steps in the metabolism of phosphatidylinositol and its derivatives are sensitive to lithium ion, Li^+ . Lithium salts have been used in the treatment of *manic-depressive illnesses* for more than 50 years, but the mechanism of lithium's therapeutic effects had been unclear. Recently, however, several reactions in the phosphatidylinositol degradation pathway have been shown to be sensitive to Li^+

ion. For example, Li^+ is an uncompetitive inhibitor of *myo*-inositol monophosphatase (see Section 13.4b). Li^+ levels similar to those used in treatment of manic illness thus lead to the accumulation of several key intermediates. This story is far from complete, and many new insights into phosphoinositide metabolism and the effects of Li^+ can be anticipated.

Figure 32.32 IP_3 -mediated signal transduction pathways. Increased $[\text{Ca}^{2+}]$ activates protein kinases, which phosphorylate target proteins. $\text{Ca}^{2+}/\text{CaM}$ represents calci-calmodulin (Ca^{2+} complexed with the regulatory protein calmodulin).

Figure 32.33 The structure of calmodulin changes dramatically upon binding to a target protein. **(a)** Structure of uncomplexed calmodulin (PDB id = 1LKJ). Calmodulin, with four Ca^{2+} -binding domains, forms a dumbbell-shaped structure with two globular domains joined by an extended, central helix. Each globular domain juxtaposes two Ca^{2+} -binding EF-hand domains. An intriguing feature of these EF-hand domains is their nearly identical three-dimensional structure despite a relatively low degree of sequence homology (only 25% in some cases). **(b, c)** Complex of calmodulin (red) with a peptide from myosin light chain kinase (blue); **(b)** side view; **(c)** top view (PDB id = 1QTX).

Figure 32.34 Helical wheel representations of **(a)** a model calmodulin-binding peptide, Ac-WKKLLKLLKLLKL-CONH₂, and **(b)** the calmodulin-binding domain of spectrin. Positively charged and polar residues are indicated in green, and hydrophobic residues are orange. (Adapted from O'Neil, K., and DeGrado, W., 1990. How calmodulin binds its targets: Sequence independent recognition of amphiphilic α -helices. *Trends in Biochemical Sciences* 15:59–64.)

modulates the activities of a large number of target proteins, including Ca²⁺-ATPases, protein kinases, phosphodiesterases, and NAD⁺ kinase. CaM binds to these and to many other proteins with extremely high affinities (K_D values typically in the high picomolar to low nanomolar range). All CaM target proteins possess a **basic amphiphilic alpha helix** (a **Baa helix**), to which CaM binds specifically and with high affinity. Viewed end-on, in the so-called helical wheel representation (Figure 32.34), a Baa helix has mostly hydrophobic residues on one face; basic residues are collected on the opposite face. However, the Baa helices of CaM target proteins, although conforming to the model, show extreme variability in sequence. How does CaM, itself a highly conserved protein, accommodate such variety of sequence and structure? Each globular domain consists of a large hydrophobic surface flanked by regions of highly negative electrostatic potential—a surface suitable for interacting with a Baa helix. The long central helix joining the two globular regions behaves as a long, flexible tether. When the target protein is bound, the two globular domains fold together (Figure 32.33b). The flexible nature of the tethering helix allows the two globular domains to adjust their orientation synergistically for maximal binding of the target protein or peptide.

32.5 How Do Effectors Convert the Signals to Actions in the Cell?

Transduction of the hormonal signal leads to activation of **effectors**—usually protein kinases and protein phosphatases—that elicit a variety of actions that regulate discrete cellular functions. Of the 518 protein kinases in the human genome, 428 are presumed to phosphorylate serine and threonine residues, whereas the remaining 90 are protein tyrosine kinases. On the other hand, the human genome contains approximately 200 phosphatases. The structures and functions of a few are representative.

32.5a Protein Kinase A Is a Paradigm of Kinases

Most protein kinases share a common catalytic core first characterized in protein kinase A (PKA), the enzyme that phosphorylates phosphorylase kinase (see Figures 15.9 and 15.18). The active site of the catalytic subunit of PKA in a ternary complex with

A Deeper Look

Mitogen-Activated Protein Kinases and Phosphorelay Systems

In multicellular organisms, many physiological processes, including mitosis, gene expression, metabolism, and programmed death of cells, are regulated by a family of **mitogen-activated protein kinases (MAPKs)**. (A mitogen is any agent that induces cell division, that is, mitosis.) MAPKs phosphorylate specific serines and threonines of target protein substrates, and these phosphorylation events function as switches to turn on or off the activity of the substrate proteins. These substrates may be other protein kinases, phospholipases, transcription factors, and cytoskeletal proteins. Protein phosphatases reverse the process, removing the phosphates that were added by MAPKs.

MAPKs are part of a **phosphorelay system** composed of three kinases that are activated in sequence (see accompanying figure). In such systems, the MAPK itself is phosphorylated by a MAPK

kinase (denoted MKK), which is itself phosphorylated by a MAPK kinase kinase (denoted MKKK). MKKKs have distinct domains and motifs that respond to different cellular stimuli, and they have other domains that recognize specific MKKs. The same kinds of specificities regulate the action of MKKs. These specificities are accounted for in the classification of four subfamilies of MAPKs: One group is that of the extracellular signal-regulated kinases, notably ERK1 and ERK2; another is the c-Jun-amino-terminal kinases, including JNK, JNK1, and JNK2; a third group depends on the ERK5 kinase; and the fourth group involves the p38 kinases, including p38 α , p38 β , p38 γ , and p38 δ . There are undoubtedly other MAPK families yet to be discovered. As shown in the figure, these phosphorelay systems link a variety of stimuli to substrates that affect many cellular functions.

MAPK phosphorelay systems. The left column is a general model. The four columns to the right show the four known MAPK phosphorelay families.

From Johnson, G. L., and Lapadat, R., 2002. Mitogen-activated protein kinase pathways mediated by ERK, JNK, and p38 protein kinases. *Science* 298:1911–1912.

MnAMP-PNP and a pseudosubstrate inhibitor peptide, as shown in Figure 32.35, includes a glycine-rich β -strand that acts as a flap over the triphosphate moiety of the bound nucleotide. A conserved residue, Asp¹⁶⁶, is the catalytic base that deprotonates the Ser/Thr-OH during phosphorylation, and Lys¹⁶⁸ stabilizes the transition state of the reaction. Three Glu residues on the enzyme are involved in recognition of the pseudosubstrate inhibitor peptide.

32.5b Protein Kinase C Is a Family of Isozymes

The enzymes called *protein kinase C* are actually a family of 28 similar enzymes—isozymes—that encompass three subclasses. The conventional PKCs, α , β I, β II, and γ , are regulated by Ca²⁺, diacylglycerol (DAG), and phosphatidylserine (PS). Because Ca²⁺ levels increase in the cell in response to IP₃, the activation of conventional

Figure 32.35 The structure of the catalytic subunit of PKA in a ternary complex with MnAMP-PNP and a pseudosubstrate inhibitor peptide (*pink*). A glycine-rich β -strand acts as a flap over the triphosphate moiety of the bound nucleotide. The glycine-rich flap that covers the ATP-binding site is shown in *white*, AMP-PNP is bound in the ATP site, Asp¹⁶⁶ is shown in *beige*, and Lys¹⁶⁸ is shown below in *white* (PDB id = 1ATP).

Figure 32.36 The primary structures of the PKC isozymes. Conserved domains C1–C4 are indicated. Variable regions are shown as simple lines.

PKCs depends on both of the second messengers released by the hydrolysis of PIP₂. The novel PKCs, δ , ϵ , θ , and η , are Ca²⁺ independent but are regulated by DAG and PS. PKCs ζ , ι , and λ are termed atypical and are activated by PS alone. These various cofactor requirements are imparted by subdomains represented in the conventional PKC polypeptide sequence. Conventional PKCs are comprised (Figure 32.36) of four conserved domains (C1–C4) and five variable regions (V1–V5). Domain C1 is a *pseudosubstrate sequence* that regulates the kinase by *intrasteric control* (see Section 15.4b), C2 is a Ca²⁺-binding domain, C3 is the ATP-binding domain, and C4 binds peptide substrates.

PKC phosphorylates serine and threonine residues on a wide range of protein substrates. A role for protein kinase C in cellular growth and division is demonstrated through its strong activation by *phorbol esters* (Figure 32.37). These compounds, from the seeds of *Croton tiglium*, are **tumor promoters**—agents that do not themselves cause tumorigenesis but that potentiate the effects of carcinogens. The phorbol esters mimic DAG, bind to the regulatory pseudosubstrate domain of the enzyme, and activate protein kinase C.

32.5c Protein Tyrosine Kinase pp60^{c-src} Is Regulated by Phosphorylation/Dephosphorylation

Protein tyrosine kinase pp60^{c-src} provides a good example of how phosphorylation converts signals to actions in cells. The structure of protein tyrosine kinase pp60^{c-src} (see Figure 32.20) consists of an N-terminal unique domain, an SH2 domain, an SH3 domain, and a kinase domain that includes a small lobe comprised mainly of a twisted β -sheet and a large lobe that is predominantly α -helical (Figure 32.38; see also Section 32.2). Phosphorylation of Tyr⁵²⁷ in the SH2 domain inhibits tyrosine kinase activity by drawing an activation loop into the active site, blocking ATP, and/or substrate binding. Dephosphorylation of Tyr⁵²⁷ induces a conformation change that removes the activation loop from the active site, permitting autophosphorylation of Tyr⁴¹⁶, which stimulates tyrosine kinase activity.

32.5d Protein Tyrosine Phosphatase SHP-2 Is a Nonreceptor Tyrosine Phosphatase

Protein tyrosine phosphatases reverse the actions of kinases like the protein tyrosine kinase pp60^{c-src} described in the previous section. The human phosphatase SHP-2 is a cytosolic nonreceptor tyrosine phosphatase. It comprises two SH2 domains, a catalytic phosphatase domain, and a C-terminal domain. The SH2 domains enable the enzyme to bind to its target substrates, and they also regulate the phosphatase activity. The catalytic domain of SHP-2 consists of nine α -helices and a ten-stranded mixed β -sheet that wraps around one of the helices (Figure 32.39). The other eight helices pack together on the opposite side of the β -sheet.

The N-terminal SH2 domain regulates phosphatase activity by binding to the phosphatase domain and directly blocking the active site. When a target peptide containing a phos-

Figure 32.37 The structure of a phorbol ester. Long-chain fatty acids predominate at the 12-position, whereas acetate is usually found at the 13-position.

Figure 32.38 A ribbon diagram showing the structure of protein tyrosine kinase pp60^{c-src} with bound AMP-PNP. (Image kindly provided by Stephen C. Harrison.)

phosphotyrosine group binds to the SH2 domain, a conformation change causes this domain to dissociate from the catalytic domain, exposing the active site and allowing peptide substrate to bind. Binding of phosphotyrosine-containing peptide to the second SH2 domain provides additional activation. Target peptides with two phosphotyrosines (one to bind to each SH2 domain) provide maximal activation of the phosphatase activity.

32.6 How Are Signaling Pathways Organized and Integrated?

All signaling pathways are organized in time and space in the cell, they are carefully regulated, and they are integrated with one another. Remarkably, these complex features of signaling depend on the simple concepts already covered in this chapter: PIDs (see Figures 32.5 and 32.6) modulate and control the association of signaling molecules with one another, often in large signalsomes; signaling molecules are switched on and off by covalent modifications such as phosphorylations; and signaling often involves amplification and cooperative effects. The multifaceted behavior of GPCRs serves as a paradigm for the organization and integration of signaling pathways and is the focus of this section.

32.6a GPCRs Can Signal Through G-Protein–Independent Pathways

The classic GPCR signaling pathway involves coupling to heterotrimeric G proteins, but GPCRs can interact with other effector molecules as well. The cellular src kinase (Section 32.3k) can be activated directly by the β_2 -adrenergic receptor (Figure 32.40), leading to activation of a MAPK pathway (see A Deeper Look box, “Mitogen-Activated Protein Kinase and Phosphorelay Systems” in Section 32.5). Activated src phosphorylates Tyr³¹⁷ on the Shc adaptor protein, promoting binding by an SH2 domain of Grb2. Grb2 in turn binds to and activates Sos1, which activates Ras. Ras then activates a kinase cascade (Figure 32.40).

Figure 32.39 A ribbon diagram showing the structure of protein tyrosine phosphatase SHP-2 in its autoinhibited, closed conformation. The N- and C-terminal SH2 domains are orange and purple, respectively. The catalytic domain is blue (PDB id = 2SHP).

Figure 32.40 GPCRs can initiate cellular signaling pathways without involvement of G proteins. Under certain conditions, binding to GPCRs can induce autophosphorylation of the src kinase. Activated src can then bind Shc and phosphorylate Tyr³¹⁷, which promotes binding of Grb2 and initiation of a Ras-dependent kinase cascade.

The **Janus protein kinase (JAK)** and its **associated transducers and activators of transcription (STAT)** constitute the **JAK/STAT** signaling pathway (Figure 32.41). For example, Jana Stankova and her colleagues have shown that binding of the platelet-activating factor (see Figure 8.8b) to the platelet-activating factor receptor (a GPCR) directly stimulates phosphorylation of *tyk2*, a Janus kinase. The activations of src (described earlier) and *tyk2* raise the intriguing possibility that GPCR action may represent an alternate means of activating these signaling pathways (Figures 32.40 and 32.41).

32.6b G-Protein Signaling Is Modulated by RGS/GAPs

The signal-transducing effects of G proteins persist as long as the bound GTP is not hydrolyzed. However, G proteins, such as Ras p21 and G_{sa} , are themselves weak GTPases. For example, Ras p21 hydrolyzes GTP with a rate constant of only 0.02 min^{-1} . If Ras p21 and G_{sa} were efficient enzymes, the GTP-bound state would be short-lived and G-protein-mediated signaling would be ineffective.

How can G proteins be switched off if they are inherently poor GTPases? The answer is provided by **regulators of G-protein signaling (RGS)**, which act as **GTPase-activating proteins (GAPs)**. RGS/GAPs elicit dramatic increases in GTPase activity when bound to G proteins. For example, RGS/GAPs increase the GTPase activity of Ras p21 by a factor of 100,000 and accelerate G_{sa} -catalyzed GTP hydrolysis nearly 100-fold. RGS/GAPs induce conformation changes in the switch domains of their G protein targets and stabilize the transition state of the GTPase reaction (Figure 32.42).

Interestingly, however, RGS proteins are more than GAPs. All RGS proteins contain several other signaling modules in addition to the 120 residue **RGS module** (Figure 32.43). These additional modules enable RGS proteins to bind to a variety of signaling proteins, to behave as effector molecules themselves, and to act as scaffolding proteins in the formation of signalsome complexes. RGS proteins interact directly, for example, with adenylyl cyclase, phospholipase C- β , cGMP phosphodiesterase, guanylyl cyclase, Ca^{2+} channels, and potassium channels (Figure 32.44). These RGS-mediated interactions enable cross-talk between many signaling pathways.

32.6c GPCR Desensitization Leads to New Signaling Pathways

Activation of GPCRs by hormones and other extracellular signals leads to heterotrimeric G protein binding, which triggers a variety of intracellular signals as shown. Importantly, the activated GPCR also binds two other classes of molecules: a family of at least six protein kinases known as **GPCR kinases (GRKs)** and a family of adaptor and

Figure 32.41 Platelet-activating factor receptor (a GPCR) can trigger autophosphorylation of the tyk2 kinase (a Janus protein kinase). Tyk2-induced phosphorylation of STAT essentially mimics the activation of the JAK/STAT signaling pathway by hormones such as erythropoietin (EPO).

scaffolding proteins known as **β -arrestins**. On one level, these two protein families work together to desensitize the GPCRs, arresting the G-protein activation by GPCRs. On another level, the GRKs and β -arrestins act together as a molecular switch, directing GPCRs to a distinctly different role in cell signaling. GRK phosphorylation of various combinations of 13 separate sites on the C-terminal sequence of the GPCR promotes binding of β -arrestin (Figure 32.45) to form a signalsome assembly. Binding of β -arrestin

Figure 32.42 G-Protein signaling is mediated by RGS/GAPs. (a) A fragment of an RGS/GAP (brown) bound to Ras p21 (blue). GAPs increase the GTPase activity of Ras p21 by a factor of 100,000 (PDB id = 1WQ1). (b) An RGS/GAP (pink) bound to $G_{i\alpha}$ (blue). GDP is shown in yellow (PDB id = 2IK8).

Figure 32.43 The RGS proteins (mammalian cells contain more than 30) are classified in subfamilies. Representative members of six of those subfamilies are shown. In addition to the RGS module of 121 residues, each RGS protein contains other motifs and modules that define its functionality. Many of those shown are discussed elsewhere in Chapter 32. (Adapted from Bansal, G., Druey, K. M., and Xie, Z., 2007. R4 RGS proteins: Regulation of G-protein signaling and beyond. *Pharmacology and Therapeutics* 116:473–495.)

Figure 32.44 Several interactions between RGS proteins and G-protein effectors. RGS proteins interact directly with adenylyl cyclase, phospholipase C- β , cGMP phosphodiesterase, and retinyl guanylyl cyclase as well as with the potassium channel known as GIRK and certain calcium channels. (Adapted from Abramow-Newerly, M., Roy, A. A., Nunn, C., and Chidiac, P., 2006. RGS proteins have a signaling complex: Interactions between RGS proteins and GPCRs, effectors, and auxiliary proteins. *Cellular Signaling* 18:579–591.)

has two effects: The GPCR is no longer able to interact with and activate G proteins, and the GPCR is targeted for *clathrin-mediated endocytosis* (Figure 32.45). Following formation of the **endosome**, the GPCR– β -arrestin signalsome enters an **arrestin signaling** mode, recruiting a variety of catalytically active proteins, such as components of the Raf-MEK-ERK signaling cascade. Arrestin-mediated signaling continues until the GPCR returns to the plasma membrane, where it waits for a new extracellular signal. It is important to appreciate that G-protein signaling occurs within seconds of extracellular GPCR activation and typically lasts for 10 min or less, whereas signaling by the GPCR– β -arrestin complex becomes maximal around 10 min and typically persists for 30 min.

Figure 32.45 GPCRs have two signaling modes. **(a)** Signal initiation by ligand binding first activates the G-protein-mediated signaling pathways at the plasma membrane. At the same time, G-protein receptor kinases (GRKs) begin to phosphorylate the receptor, creating high-affinity binding sites for arrestin. Arrestin binding uncouples the receptor from G proteins and targets the receptor either for arrestin-based signaling or for endocytosis. The GPCR–arrestin complex serves as a signalsome scaffold, recruiting catalytically active proteins such as components of the Raf-MEK-ERK cascade. This initiates a distinct set of signals from the endosome-bound signalsome. Endosomes are eventually processed and degraded, returning the GPCRs to the plasma membrane. (Adapted from Figure 1 of Gesty-Palmer, D., and Luttrell, L. M., 2008. Heptahelical terpsichory. Who calls the tune? *Journal of Receptors and Signal Transduction* 28:39–58.) **(b)** Complex of human neurotensin (a GPCR), purple, and β -arrestin1, green. (PDB id = 6UP7).

A Deeper Look

Whimsical Names for Proteins and Genes

The study of cell signaling and the identification of hundreds of new signaling proteins provided an unprecedented creative opportunity for cell biologists and geneticists in the naming of these proteins. In the early days of molecular biology, such names were typically arcane abbreviations and acronyms. One such case is the family of **14-3-3 proteins**, named for the migration patterns of these proteins on DEAE-cellulose chromatography and starch-gel electrophoresis. In the 1970s, a few creative scientists suggested whimsical names for newly discovered genes, such as *sevenless*, named in reference to R7, one of the eight photoreceptor cells in the compound eye of *Drosophila*, the common fruit fly. What began as a trickle became a torrent of whimsical names for proteins and genes. *Sevenless* was followed by *bride of sevenless* (*boss*, a ligand of sevenless), and *son of sevenless* (*sos*, first isolated in a genetic screen of the sevenless receptor tyrosine kinase pathway in *Drosophila*). The *hedgehog* (*hh*) genes, including *sonic hedgehog* (*Shh*), play critical roles in the development and patterning of animal embryonic tissues but were named for a popular video game.

The accompanying table lists a few notable examples of whimsically named genes and gene products, many of which were first identified in *Drosophila*.

Name	Role or Function
Armadillo	Plakoglobin = β -catenin
Bag of marbles	Novel protein involved in oogenesis and spermatogenesis
Bullwinkle	Oocyte protein
Cactus	Signaling protein—I κ B homolog
Cheap date	Alcohol sensitivity
Chickadee	Profilin homolog—regulation of actin cytoskeleton
Corkscrew	A protein tyrosine phosphatase
Dachshund	Nuclear protein required for cell fate determination
Dishevelled	Novel cytoplasmic protein in the wingless pathway
Dunce	A cAMP phosphodiesterase
Hopscotch	A Janus family tyrosine kinase
Naked	A segment polarity gene
Reaper	A death-domain protein functioning in apoptosis
Rutabaga	A Ca ²⁺ /calmodulin-dependent protein kinase
Shark	A tyrosine kinase SH2-nonreceptor
Yak	Literally “yet another kinase”

32.6d Receptor Responses Can Be Coordinated by Transactivation

Hormone and signaling receptors and their pathways do not operate in isolation. Rather, one or more of the second messengers and effectors of a given pathway can often activate (or inhibit) another pathway. For example, binding of *insulin-like growth factor 1* (*IGF-1*) to its own RTK signals enhanced synthesis of a peptide known as *RANTES*. *RANTES* is secreted into the extracellular medium, where it binds to a GPCR known as the *CCR5 receptor* (Figure 32.46a). As an extracellular signal, *RANTES* initiates a signaling pathway that induces cell migration, a part of the cell’s response to inflammation caused by infection. This is an example of transactivation of a GPCR by a RTK.

The reverse can happen as well. GPCRs can transactivate RTKs by a variety of mechanisms. For example, in certain neurons of the hypothalamus, stimulation of α_1 -adrenergic receptors triggers a G-protein–mediated pathway that activates a matrix metalloproteinase. Metalloproteinase action releases heparin-binding EGF-like growth factor (HB-EGF) in the extracellular matrix. Binding of HB-EGF to the EGF receptor initiates a classic RTK-activated signaling pathway (Figure 32.46b).

32.6e Signals from Multiple Pathways Can Be Integrated

A cell can be exposed simultaneously to multiple, potentially contradictory signals in the form of soluble hormones and ligands anchored to adjacent cells or the extracellular matrix. Cells must have mechanisms for sorting these various signals into a defined response. The **Rsk1** protein serine/threonine kinases exhibit such behavior, integrating several signals to achieve full activation. *Rsk1* has two protein kinase

(a) Transcriptional regulation of GPCR ligand synthesis

(b)

Figure 32.46 Examples of transactivation of cell signaling pathways. **(a)** Binding of IGF-1 to RTK (in human breast cancer cells) initiates a signaling pathway that leads to an enhanced synthesis of RANTES (a peptide). RANTES is secreted into the extracellular medium, where it can bind a GPCR known as CCR5. CCR5 activation triggers G-protein-mediated signaling pathways. **(b)** Transactivation that is the reverse of that in (a). Activation of the α₁-adrenergic receptor activates phospholipase C-β, which triggers metalloproteinase (MMP) activation. MPP cleaves a precursor of heparin-binding EGF-like growth factor (HB-EGF). Binding of HB-EGF to the EGF receptor initiates an RTK signaling pathway.

domains (Figure 32.47), of which the N-terminal domain phosphorylates downstream targets. This N-terminal kinase domain is controlled by multiple inputs, including from the C-terminal domain. The ERK MAPK binds to a docking site at the C terminus of Rsk1, phosphorylating sites in the linker region between the two kinase domains and in the C-terminal domain, all of which are essential for activation.

Figure 32.47 Integration of signaling pathways. Activation of a ribosomal serine/threonine kinase known as Rsk1 requires phosphorylation by two protein kinases: a phosphoinositide-dependent kinase (PDK1) and a mitogen-activated protein kinase (ERK; see the Deeper Look box “Mitogen-Activated Protein Kinases and Phosphorelay Systems” in Section 32.5). Thus, both phosphoinositide-mediated and Ras-mediated pathways must be active to activate Rsk1.

Full activation, however, also requires phosphorylation of the N-terminal kinase domain by the PIP_3 -stimulated PDK1 protein kinase. Rsk1 activation thus requires inputs from both the Erk MAPK pathway and the PIP_3 pathway (Figure 32.47).

32.7 | How Do Neurotransmission Pathways Control the Function of Sensory Systems?

The survival of higher organisms is predicated on the ability to respond rapidly to sensory input from physical signals (sights, sounds) and chemical cues (smells). The responses to such stimuli may include muscle movements and many forms of intercellular communication. Hormones (as described earlier in this chapter) can move through an organism only at speeds determined by the circulatory system. In most higher organisms, a faster means of communication is crucial. Nerve impulses, which can be propagated at speeds up to 100 m/s, provide a means of intercellular signaling that is fast enough to facilitate sensory recognition, movement, and other physiological functions and behaviors in higher animals. The generation and transmission of nerve impulses in vertebrates is mediated by an extremely complicated neural network that connects every part of the organism with the brain—itself an interconnected array of as many as 10^{11} nerve cells.

Despite their complexity and diversity, the nervous systems of animals all possess common features and common mechanisms. Physical or chemical stimuli are recognized by specialized **receptor proteins** in the membranes of excitable cells. Conformational changes in the receptor protein result in a change in enzyme activity or a change in the permeability of the membrane. These changes are then propagated throughout the cell or from cell to cell in specific and reversible ways to carry information through the organism. This section describes the characteristics of excitable cells and the mechanisms by which these cells carry information at high speeds through an organism.

32.7a Nerve Impulses Are Carried by Neurons

Neurons and *neuroglia* (or *glial cells*) are cell types unique to nervous systems. The reception and transmission of nerve impulses are carried out by neurons (Figure 32.48), whereas glial cells serve protective and supportive functions. (*Neuroglia* could be translated as “nerve glue.”) Glial cells differ from neurons in several ways. Glial cells do not possess axons or synapses, and they retain the ability to divide throughout their life spans. Glial cells outnumber neurons by at least 10 to 1 in most animals.

Neurons are distinguished from other cell types by their long cytoplasmic extensions or projections, called *processes*. Most neurons consist of three distinct regions (see Figure 32.48): the *cell body* (called the *soma*), the *axon*, and the *dendrites*. The axon ends in small structures called *synaptic terminals*, *synaptic knobs*, or *synaptic bulbs*. Dendrites are short, highly branched structures emanating from the cell body that receive neural impulses and transmit them to the cell body. The space between a synaptic knob on one neuron and a dendrite ending of an adjacent neuron is the *synapse* or *synaptic cleft*.

Three kinds of neurons are found in higher organisms: sensory neurons, interneurons, and motor neurons. *Sensory neurons* acquire sensory signals, either directly or from specific receptor cells, and pass this information along to either *interneurons* or *motor neurons*. Interneurons simply pass signals from one neuron to another, whereas motor neurons pass signals from other neurons to muscle cells, thereby inducing muscle movement (motor activity).

32.7b Ion Gradients Are the Source of Electrical Potentials in Neurons

Propagation of information along a neuron is accomplished by electrical potentials, whereas communication between neurons is chemical in nature. These electrical signals occur as transient changes in the electrical potential differences (voltages) across the membranes of neurons (and other cells). Such potentials are generated by **ion gradients**. Such gradients are used for a variety of purposes in all cells. In neurons, ion gradients are the essence of action potentials that carry the neural messages. The

Figure 32.48 The structure of a mammalian motor neuron. The nucleus and most other organelles are contained in the cell body. One long axon and many shorter dendrites project from the body. The dendrites receive signals from other neurons and conduct them to the cell body. The axon transmits signals from this cell to other cells via the synaptic knobs. Glial cells called Schwann cells envelop the axon in layers of an insulating myelin membrane. Although glial cells lie in proximity to neurons in most cases, no specific connections (such as gap junctions, for example) connect glial cells and neurons. However, gap junctions can exist between adjacent glial cells.

cytoplasm of a neuron at rest is low in Na^+ and Cl^- and high in K^+ , relative to the extracellular fluid (Figure 32.49). These gradients are generated by the Na^+ , K^+ -ATPase (see Section 9.8b). A resting neuron exhibits a potential difference of approximately -60 mV (that is, negative inside).

32.7c Action Potentials Carry the Neural Message

Nerve impulses, also called **action potentials**, are transient changes in the membrane potential that move rapidly along nerve cells. Action potentials are created when the

Figure 32.49 Action potentials are generated by transmembrane flows of ions. (a) The concentrations of Na^+ , K^+ , and Cl^- ions inside and outside of a typical resting mammalian axon are shown. Assuming relative permeabilities for K^+ , Na^+ , and Cl^- are 1, 0.04, and 0.45, respectively, the Goldman equation yields a membrane potential of -60 mV. (See problem 19.) (b) and (c) The time dependence of an action potential, compared with the ionic permeabilities of Na^+ and K^+ . (b) The rapid rise in membrane potential from -60 mV to slightly more than $+30$ mV is referred to as a depolarization. This depolarization is caused (c) by a sudden increase in the permeability of Na^+ . As the Na^+ permeability decreases, K^+ permeability is increased and the membrane potential drops, eventually falling below the resting potential—a state of hyperpolarization—followed by a slow return to the resting potential. (Adapted from Hodgkin, A., and Huxley, A., 1952. A quantitative description of membrane current and its application to conduction and excitation in nerve. *Journal of Physiology* 117:500–544.)

membrane is locally **depolarized** by approximately 20 mV from the resting value of about -60 mV to a new value of approximately -40 mV. This small change is enough to have a dramatic effect on specific proteins in the axon membrane called **voltage-gated ion channels**. These proteins are ion channels that are specific either for Na^+ or K^+ . These ion channels are normally closed at the resting potential of -60 mV. When the potential difference rises to -40 mV, the gates of the Na^+ channels are opened and Na^+ ions begin to flow into the cell. As Na^+ enters the cell, the membrane potential continues to increase and additional Na^+ channels are opened (Figure 32.49). The potential rises to more than $+30$ mV. At this point, Na^+ influx slows and stops. As the Na^+ channels close, K^+ channels begin to open and K^+ ions stream out of the cell, returning the membrane potential to negative values. The potential eventually overshoots its resting value a bit. At this point, K^+ channels close, and the resting potential is eventually restored by action of the Na^+, K^+ -ATPase and the other channels. Alan Hodgkin and Andrew Huxley originally observed these transient increases and decreases, first in Na^+ permeability and then in K^+ permeability. For this and related work, Hodgkin and Huxley, along with J. C. Eccles, won the Nobel Prize in Physiology or Medicine in 1963.

32.7d The Action Potential Is Mediated by the Flow of Na^+ and K^+ Ions

Changes in potential in one part of the axon are rapidly passed along the axonal membrane (Figure 32.50). The sodium ions that rush into the cell in one localized region actually diffuse farther along the axon, raising the Na^+ concentration *and* depolarizing the membrane, causing Na^+ gates to open in that adjacent region of the axon. In this way, the action potential moves down the axon in wavelike fashion. This simple process has several very dramatic properties:

1. Action potentials propagate very rapidly—up to and sometimes exceeding 100 m/s.
2. The action potential is not attenuated (diminished in intensity) as a function of distance transmitted.

The input of energy all the way along an axon—in the form of ion gradients maintained by Na^+, K^+ -ATPase—ensures that the shape and intensity of the action potential are maintained over long distances. The action potential has an all-or-none character.

Figure 32.50 The propagation of action potentials along an axon. Figure 32.49 shows the time dependence of an action potential at a discrete point on the axon. This figure shows how the membrane potential varies along the axon as an action potential is propagated. (For this reason, the shape of the action potential is the apparent reverse of that shown in Figure 32.49.) At the leading edge of the action potential, membrane depolarization causes Na^+ channels to open briefly. As the potential moves along the axon, the Na^+ channels close and K^+ channels open, leading to a drop in potential and the onset of hyperpolarization. When the resting potential is restored, another action potential can be initiated.

Figure 32.51 Some axons are covered by a myelin sheath—a membrane rich in lipids but with very few proteins. The myelin sheath acts as an electrical insulator and speeds the transmission of action potentials. Na⁺ channels are infrequently and randomly distributed in unmyelinated nerve. In myelinated axons, Na⁺ channels are clustered in large numbers in the nodes of Ranvier, between the regions surrounded by myelin sheath structures.

There are no gradations of amplitude; a given neuron is either at rest (with a polarized membrane) or is conducting a nerve impulse (with a reversed polarization). Because nerve impulses display no variation in amplitude, the size of the action potential is not important in processing signals in the nervous system. Instead, it is the number of action potential firings and the frequency of firing that carry specific information.

The action potential is a delicately orchestrated interplay between the Na⁺, K⁺-ATPase and the voltage-gated Na⁺ and K⁺ channels that is initiated by a stimulus at the postsynaptic membrane. The density and distribution of Na⁺ channels along the axon are different for myelinated and unmyelinated axons (Figure 32.51). In unmyelinated axons, Na⁺ channels are uniformly distributed, although they are few in number—approximately 20 channels per μm^2 . On the other hand, in myelinated axons, Na⁺ channels are clustered at the nodes of Ranvier. In these latter regions, they occur with a density of approximately 10,000 per μm^2 . (Ion channel structure and function were discussed in Section 9.7.)

32.7e Neurons Communicate at the Synapse

How are neuronal signals passed from one neuron to the next? Neurons are juxtaposed at the synapse. The space between the two neurons is called the **synaptic cleft**. The number of synapses in which any given neuron is involved varies greatly. There may be as few as one synapse per postsynaptic cell (in the midbrain) to many thousands per cell. Typically, 10,000 synaptic knobs may impinge on a single spinal motor neuron, with 8000 on the dendrites and 2000 on the soma or cell body. The ratio of synapses to neurons in the human forebrain is approximately 40,000 to 1!

Synapses are actually quite specialized structures, and several different types exist. A minority of synapses in mammals, termed **electrical synapses**, are characterized by a very small gap—approximately 2 nm—between the **presynaptic cell** (which delivers the signal) and the **postsynaptic cell** (which receives the signal). At electrical synapses, the arrival of an action potential on the presynaptic membrane leads directly to depolarization of the postsynaptic membrane, initiating a new action potential in the postsynaptic cell. However, most synaptic clefts are much wider—on the order of 20 to 50 nm. In these, an action potential in the presynaptic membrane causes secretion of a chemical substance—called a **neurotransmitter**—by the presynaptic cell. This substance binds to receptors on the postsynaptic cell, initiating a new action potential. Synapses of this type are thus **chemical synapses**.

Different synapses utilize specific neurotransmitters. The **cholinergic synapse**, a paradigm for chemical transmission mechanisms at synapses, employs acetylcholine as a neurotransmitter. Other important neurotransmitters and receptors have been discovered and characterized. These all fall into one of several major classes, including amino acids (and their derivatives), *catecholamines*, *peptides*, and *gaseous neurotransmitters*. Table 32.3 lists some, but not all, of the known neurotransmitters.

Table 32.3 Families of Neurotransmitters

<i>Cholinergic Agents</i>
Acetylcholine
<i>Catecholamines</i>
Norepinephrine (noradrenaline)
Epinephrine (adrenaline)
L-Dopa
Dopamine
Octopamine
<i>Amino Acids (and Derivatives)</i>
γ -Aminobutyric acid (GABA)
Alanine
Aspartate
Cystathionine
Glycine
Glutamate
Histamine
Proline
Serotonin
Taurine
Tyrosine
<i>Peptide Neurotransmitters</i>
Cholecystokinin
Enkephalins and endorphins
Gastrin
Gonadotropin
Neurotensin
Oxytocin
Secretin
Somatostatin
Substance P
Thyrotropin releasing factor
Vasopressin
Vasoactive intestinal peptide (VIP)
<i>Gaseous Neurotransmitters</i>
Carbon monoxide (CO)
Nitric oxide (NO)

Figure 32.52 Cell–cell communication at the (a) synapse is mediated by neurotransmitters such as acetylcholine, produced from choline by choline acetyltransferase. (b) The arrival of an action potential at the synaptic knob opens Ca^{2+} channels in the presynaptic membrane. (c) Influx of Ca^{2+} induces the fusion of acetylcholine-containing vesicles with the plasma membrane and release of acetylcholine into the synaptic cleft. (d) Binding of acetylcholine to receptors in the postsynaptic membrane opens Na^{+} channels. The influx of Na^{+} depolarizes the postsynaptic membrane, generating a new action potential.

32.7f Communication at Cholinergic Synapses Depends upon Acetylcholine

In cholinergic synapses, small **synaptic vesicles** inside the synaptic knobs contain large amounts of acetylcholine (approximately 10,000 molecules per vesicle; Figure 32.52). When the membrane of the synaptic knob is stimulated by an arriving action potential, special **voltage-gated Ca^{2+} channels** open and Ca^{2+} ions stream into the synaptic knob, causing the acetylcholine-containing vesicles to attach to and fuse with the knob membrane. The vesicles open, spilling acetylcholine into the synaptic cleft. Binding of acetylcholine to specific **acetylcholine receptors** in the postsynaptic membrane causes opening of ion channels and the creation of a new action potential in the postsynaptic neuron.

A variety of toxins can alter or affect this process. The anaerobic bacterium *Clostridium botulinum*, which causes botulism poisoning, produces several toxic proteins that strongly inhibit acetylcholine release. The black widow spider, *Latrodectus mactans*, produces a venom protein, **α -latrotoxin**, that stimulates abnormal release of acetylcholine at the neuromuscular junction. The bite of the black widow causes pain, nausea, and mild paralysis of the diaphragm but is rarely fatal.

32.7g There Are Two Classes of Acetylcholine Receptors

Two different acetylcholine receptors are found in postsynaptic membranes. They were originally distinguished by their responses to **muscarine**, a toxic alkaloid in toadstools, and **nicotine** (Figure 32.53). The **nicotinic receptors** are cation channels in postsynaptic membranes, and the **muscarinic receptors** are transmembrane proteins that interact with G proteins. The receptors in sympathetic ganglia and those in motor endplates of skeletal muscle are nicotinic receptors. Nicotine locks the ion channels of these receptors in their open conformation. Muscarinic receptors are found in smooth muscle and in glands. Muscarine mimics the effect of acetylcholine on these latter receptors.

The nicotinic acetylcholine receptor is a 290 kDa transmembrane glycoprotein consisting of a ring of four homologous subunits (α , β , γ , and δ) in the order $\alpha\gamma\alpha\beta\delta$.

Figure 32.53 Two types of acetylcholine receptors are known. Nicotinic acetylcholine receptors are locked in their open conformation by nicotine. Obtained from tobacco plants, nicotine is named for Jean Nicot, French ambassador to Portugal, who sent tobacco seeds to France in 1550 for cultivation. Muscarinic acetylcholine receptors are stimulated by muscarine, obtained from the intensely poisonous mushroom, *Amanita muscaria*.

Figure 32.54 The nicotinic acetylcholine receptor is an elongated funnel constructed from homologous subunits named α , β , γ , and δ . The pentameric channel includes two copies of the α -subunit. The extracellular domain of each subunit is a β -barrel, whereas the transmembrane and intracellular domains are α -helical. **(a)** Top view; **(b)** side view (PDB id = 2BG9).

(Figure 32.54a). The receptor is shaped like an elongated (160 Å) funnel, with a large extracellular ligand-binding domain, a membrane-spanning pore, and a smaller intracellular domain. Acetylcholine binds to the two α -subunits at sites that lie 40 Å from the membrane surface.

The Nicotinic Acetylcholine Receptor Is a Ligand-Gated Ion Channel The nicotinic acetylcholine receptor functions as a **ligand-gated ion channel**, and on the basis of its structure, it is also an **oligomeric ion channel**. When acetylcholine (the ligand) binds to this receptor, a conformational change opens the channel, which is equally permeable to Na^+ and K^+ . Na^+ rushes in while K^+ streams out, but because the Na^+ gradient across this membrane is steeper than that of K^+ , the Na^+ influx greatly exceeds the K^+ efflux. The influx of Na^+ depolarizes the postsynaptic membrane, initiating an action potential in the adjacent membrane. After a few milliseconds, the channel closes, even though acetylcholine remains bound to the receptor. At this point, the channel will remain closed until the concentration of acetylcholine in the synaptic cleft drops to about 10 nM.

Figure 32.57 Plants and reptiles are rich sources of neurotoxic agents. **(a)** Tubocurarine, obtained from the plant *Chondrodendron tomentosum*, is the active agent in tube curare, named for the bamboo tubes in which it is kept by South American indigenous hunters. **(b)** Atropine is produced by *Atropa belladonna*, the poisonous deadly nightshade. The species name, which means “beautiful woman,” derives from the use of atropine in years past by Italian women to dilate their pupils. Atropine is still used for pupil dilation in eye exams by ophthalmologists. **(c)** Cobratoxin and **(d)** α -bungarotoxin are proteins produced by the cobra (*Naja naja*) and the banded krait snake (*Bungarus multicinctus*), respectively.

Covalent Organophosphorus Inhibitors

Figure 32.58 Covalent inhibitors of acetylcholinesterase include DIPF, (also known as diisopropylfluorophosphate, or DIFP), the nerve gases tabun and sarin, and the insecticide malathion.

others are **inhibitory** and prevent the postsynaptic neuron from carrying other signals. Just as acetylcholine acts on both nicotinic and muscarinic receptors, so most of the known neurotransmitters act on several (and in some cases, many) different kinds of receptors. Biochemists are just beginning to understand the sophistication and complexity of neuronal signal transmission.

32.7i Glutamate and Aspartate Are Excitatory Amino Acid Neurotransmitters

The common amino acids glutamate and aspartate act as neurotransmitters. Like acetylcholine, glutamate and aspartate are excitatory and stimulate receptors on the postsynaptic membrane to transmit a nerve impulse. No enzymes that degrade glutamate exist in the extracellular space, so glutamate must be cleared by the high-affinity presynaptic and glial transporters—a process called **reuptake**.

A Deeper Look

Tetrodotoxin and Saxitoxin Are Na^+ Channel Toxins

Tetrodotoxin and **saxitoxin** are highly specific blockers of Na^+ channels and bind with very high affinity ($K_D < 1 \text{ nM}$). This unique specificity and affinity have made it possible to use radioactive forms of these toxins to purify Na^+ channels and map their distribution on axons. Tetrodotoxin is found in the skin and several internal organs of puffer fish, also known as blowfish or swellfish, members of the family *Tetraodontidae*, which react to danger by inflating themselves with water or air to nearly spherical (and often comical) shapes (see accompanying figure).

Although tetrodotoxin poisoning can easily be fatal, puffer fish are delicacies in Japan, where they are served in a dish called fugu. For this purpose, the puffer fish must be cleaned and prepared by specially trained chefs. Saxitoxin is made by *Gonyaulax catenella* and *G. tamarensis*, two species of marine dinoflagellates or plankton that are responsible for red tides that cause massive fish kills. Saxitoxin is concentrated by certain species of mussels, scallops, and other shellfish that are exposed to red tides. Consumption of these shellfish by animals, including humans, can be fatal.

Human Biochemistry

Neurexins and Neuroligins—the Scaffolding of Learning and Memory

How do we learn, remember, and forget? And how do our brains change in response to new experiences? Answers to these questions are being revealed by new research at the crossroads of cell biology and biochemistry. The human brain contains about 100 billion neurons that are interconnected by more than 100 trillion synapses—a total of approximately 100,000 miles of biological wiring. Synapses are the fundamental unit of neural circuits. Each of the 20 billion neurons of the neocortex have, on average, 7000 synaptic connections to other neurons, with some neurons making up to 100,000 synaptic connections to other neurons. Remarkably, it is estimated that each neuron is able to contact any other neuron with no more than six interneuronal connections. Thus, any two neurons are no more than six connections from one another.

Learning and the acquisition of long-term memory involve **plasticity**—in other words, the ability to change the structures and functions of synaptic connections. Plasticity may include the remodeling and strengthening of existing synapses as well as the formation of new synapses. In all cases, synaptic function requires that postsynaptic neurotransmitter receptors on the dendrite be precisely aligned opposite chemically matched presynaptic vesicles in the axon. This alignment is achieved with a complex scaffolding network composed of presynaptic and postsynaptic partner proteins that associate across the cleft. The best understood of such partners are presynaptic **neurexins** and postsynaptic **neuroligins** (figure). Neurexins were first identified as the receptors for α -latrotoxin, the venom protein of the black widow spider. The mammalian genome contains only three

Trans-synaptic complexes of scaffolding proteins anchor and stabilize the synapse and, by virtue of their associated intracellular functional domains, also activate a variety of signaling processes that regulate synaptic function in both neurons. (Adapted with permission from Südhof, T., 2008. Neuroligins and neurexins link synaptic function to cognitive function. *Nature* 455:903–911.)

(Continued)

neurexin genes, but extensive alternative splicing at five positions generates thousands of neurexin isoforms. Neurexins partner with a variety of postsynaptic scaffolding proteins besides the neuroligins, and some neurexin-partner associations involve soluble secreted bridge proteins such as the 35 kDa **cerebellin precursor protein, Cbln1**. Emerging research also is identifying other presynapse-postsynapse scaffolding protein pairs, including the presynaptic LAR protein tyrosine phosphatase receptor and its partner the postsynaptic netrin G ligand-3.

The involvement of trans-synaptic scaffold protein interactions such as these in learning and memory is becoming increasingly apparent. For example, Nobelist Eric Kandel and his colleagues

have shown recently that expression of an autism-linked variant of neuroligin in *Aplysia* (large, shell-less gastropod molluscs commonly known as sea slugs) blocks both intermediate and long-term memory formation while having no effect on basal synaptic transmission. In other words, neuroligin defects can lead to sluggish learning.

At least five subclasses of glutamate receptors are known. The best understood of these excitatory receptors is the *N*-methyl-D-aspartate (NMDA) receptor, a ligand-gated channel that, when open, allows Ca^{2+} and Na^+ to flow into the cell and K^+ to flow out of the cell. **Phencyclidine (PCP)** is a specific antagonist of the NMDA receptor (Figure 32.59). Phencyclidine was once used as an anesthetic agent, but legitimate human use was quickly discontinued when it was found to be responsible for bizarre psychotic reactions and behavior in its users. Since this time, PCP has been used illegally as a hallucinogenic drug, under the street name of angel dust. Sadly, it has caused many serious, long-term psychological problems in its users.

32.7j γ -Aminobutyric Acid and Glycine Are Inhibitory Neurotransmitters

Certain neurotransmitters, acting through their conjugate postsynaptic receptors, inhibit the postsynaptic neuron from propagating nerve impulses from other neurons. Two such inhibitory neurotransmitters are **γ -aminobutyric acid (GABA)** and

Figure 32.59 NMDA receptors assemble as heterotetramers, with two (glycine-binding) GluN1 and two (glutamate-binding) GluN2 subunits. The architecture of the receptor consists of amino-terminal domains (ATDs) and ligand-binding domains (LBDs) on the extracellular side of the membrane, a transmembrane domain (TMD) and a carboxy-terminal domain (not shown). NMDA receptors are Na^+ and Ca^{2+} channels. They are stimulated by NMDA, inhibited by phencyclidine, and regulated by Zn^{2+} and glycine (PDB id = 4TLM).

Figure 32.60 GABA (γ -aminobutyric acid) and glycine are inhibitory neurotransmitters that activate chloride channels. Influx of Cl^- causes a hyperpolarization of the postsynaptic membrane. GABA receptors are similar in many respects to nicotinic acetylcholine receptors, with $\alpha_2\beta\gamma\delta$ stoichiometry. A pentamer of $\beta 3$ subunits is shown here (PDB id = 4COF). (a) Side view; (b) top view; (c) the pentameric transmembrane domain.

glycine. These agents make postsynaptic membranes permeable to chloride ions and cause a net influx of Cl^- , which in turn causes **hyperpolarization** of the postsynaptic membrane (making the membrane potential more negative). Hyperpolarization of a neuron effectively raises the threshold for the onset of action potentials in that neuron, making the neuron resistant to stimulation by excitatory neurotransmitters. These effects are mediated by the GABA and glycine receptors, which are ligand-gated chloride channels (Figure 32.60). GABA is derived by a decarboxylation of glutamate (Figure 32.61) and appears to operate mainly in the brain, whereas glycine

Figure 32.61 Glutamate is converted to GABA by glutamate decarboxylase. GABA is degraded by the action of GABA–glutamate transaminase and succinate semialdehyde dehydrogenase to produce succinate.

Human Biochemistry

The Biochemistry of Neurological Disorders

Defects in catecholamine processing are responsible for the symptoms of many neurological disorders, including clinical depression (which involves norepinephrine [NE]) and parkinsonism (involving dopamine [DA]). Once these neurotransmitters have bound to and elicited responses from postsynaptic membranes, they must be efficiently cleared from the synaptic cleft (Figure 1). Clearing can occur by several mechanisms. NE and DA transport or reuptake proteins exist both in the presynaptic membrane and in nearby glial cell membranes. On the other hand, catecholamine neurotransmitters can be metabolized and inactivated by two enzymes: **catechol-O-methyl-transferase** in the synaptic cleft and **monoamine oxidase** in the mitochondria (Figure 2). Catecholamines transported back into the presynaptic neuron are accumulated in synaptic vesicles by the same H^+ -ATPase/ H^+ -ligand exchange mechanism described for glutamate. Clinical depression has been treated by two different strategies. **Monoamine oxidase inhibitors** act as antidepressants by increasing levels of catecholamines in the brain. Another class of antidepressants, the **tricyclics**, such as desipramine (Figure 3a), act on several classes of neurotransmitter reuptake transporters and facilitate

more prolonged stimulation of postsynaptic receptors. **Prozac** is a more specific reuptake inhibitor and acts only on serotonin reuptake transporters.

Parkinsonism is characterized by degeneration of dopaminergic neurons, as well as consequent overproduction of postsynaptic dopamine receptors. In recent years, Parkinson's patients have been treated with dopamine agonists such as **bromocriptine** (Figure 3b) to counter the degeneration of dopamine neurons.

Catecholaminergic neurons are involved in many other interesting pharmacological phenomena. For example, **reserpine** (Figure 3c), an alkaloid from a climbing shrub of India, is a powerful sedative that depletes the level of brain monoamines by inhibiting the H^+ -monoamine exchange protein in the membranes of synaptic vesicles.

Cocaine (Figure 3d), a highly addictive drug, binds with high affinity and specificity to reuptake transporters for the monoamine neurotransmitters in presynaptic membranes. Thus, at least one of the pharmacological effects of cocaine is to prolong the synaptic effects of these neurotransmitters.

(g) The structure of propofol, a widely used anesthetic.

Figure 32.63 The pathway for the synthesis of catecholamine neurotransmitters. Dopa, dopamine, noradrenaline, and adrenaline are synthesized sequentially from tyrosine.

Figure 32.62 Strychnine binds strongly to glycine receptors.

acts primarily in the spinal cord. The glycine receptor has a specific affinity for the convulsive alkaloid **strychnine** (Figure 32.62). The effects of ethanol on the brain arise in part from the opening of GABA receptor Cl^- channels.

GABA receptors assemble as pentamers from a family of homologous subunits encoded by 19 different genes: $\alpha 1$ to 6, $\beta 1$ to 3, $\gamma 1$ to 3, δ , ϵ , θ , π , and $\rho 1$ to 3. The physiologically active heteromers usually contain two α subunits, two β subunits, and a γ subunit. Interestingly, $\beta 3$ subunits can assemble into functional homomeric channels (Figure 32.60). Each subunit includes an extracellular domain of 200 to 250 residues, a transmembrane domain of four α -helices, and an intracellular domain of 85 to 255 residues. Neurotransmitters bind in extracellular pockets between the subunits. GABA receptors are the targets of a wide range of drugs, including benzodiazapines (for example, Valium and Xanax) used in the treatment of epilepsy, insomnia, anxiety and panic disorder, and the intravenous general anesthetic propofol.

32.7k The Catecholamine Neurotransmitters Are Derived from Tyrosine

Epinephrine, **norepinephrine**, **dopamine**, and **L-dopa** (3,4-dihydroxyphenylalanine) are collectively known as **catecholamine** neurotransmitters. These compounds are synthesized from tyrosine (Figure 32.63), both in sympathetic neurons and in the adrenal glands. They function as neurotransmitters in the brain and as hormones in the circulatory system. However, these two pools operate independently, thanks to the **blood–brain barrier**, which permits only very hydrophobic species in the circulatory system to cross over into the brain. Hydroxylation of tyrosine (by **tyrosine hydroxylase**) to form L-dopa is the rate-limiting step in this pathway. Dopamine, a crucial catecholamine involved in several neurological diseases, is synthesized from L-dopa by a pyridoxal phosphate-dependent enzyme, **dopa decarboxylase**. Subsequent hydroxylation and methylation produce norepinephrine and epinephrine (Figure 32.63). The methyl group in the final reaction is supplied by *S*-adenosylmethionine.

Each of these catecholamine neurotransmitters is known to play a unique role in synaptic transmission. The neurotransmitter in junctions between sympathetic nerves and smooth muscle is norepinephrine. On the other hand, dopamine is involved in other processes. Either excessive brain production of dopamine or hypersensitivity of dopamine receptors is responsible for psychotic symptoms and schizophrenia, whereas lowered production of dopamine and the loss of dopamine neurons are important factors in Parkinson's disease.

32.7l Various Peptides Also Act as Neurotransmitters

Many relatively small peptides have been shown to possess neurotransmitter activity (see Table 32.3). One of the challenges of this field is that the known neuropeptides may represent a very small subset of the neuropeptides that exist. Another challenge arises from the small in vivo concentrations of these agents and the small number of receptors that are present in neural tissue. Physiological roles for most of these peptides are complex. For example, the **endorphins** and **enkephalins** are natural opioid substances and potent pain relievers. The **endothelins** are a family of homologous regulatory peptides, synthesized by certain endothelial and epithelial cells that act on nearby smooth muscle and connective tissue cells. They induce or affect smooth muscle contraction; vasoconstriction; heart, lung, and kidney function; and mitogenesis

and tissue remodeling. **Vasoactive intestinal peptide (VIP)** produces a G protein–adenylyl cyclase–mediated increase in cAMP, which in turn triggers a variety of protein phosphorylation cascades, one of which leads to conversion of phosphorylase *b* to phosphorylase *a*, stimulating glycogenolysis. Moreover, VIP has synergistic effects with other neurotransmitters, such as norepinephrine. In addition to increasing cAMP levels through β -adrenergic receptors, norepinephrine acting at α_1 -adrenergic receptors markedly stimulates the increases in cAMP elicited by VIP. Many other effects have also been observed. For example, injection of VIP increases rapid eye movement (REM) sleep and decreases waking time in rats. VIP receptors exist in regions of the central nervous system involved in sleep modulation.

32.7m Some Ion Channels Respond to Physical Stimuli Rather Than Chemicals

There are other ion channels involved in neurotransmission that are not chemical receptors but rather are sensors of physical stimuli, including temperature, voltage, pH, redox status, and mechanical phenomena. These include the transient receptor potential (TRP) channels and the mechano-sensing Piezo channels.

Piezo channels are mechanically activated proteins that enable a cell to sense force by allowing ions to pass through the cell membrane in response to mechanical stimuli. Piezo channels are found in many vertebrates, invertebrates, and plants. Piezo proteins have key roles in many physiological and developmental processes that involve mechanosensitivity, including breathing, touch, and vascular development. The best-characterized of the mammalian Piezo proteins is Piezo1 (Figure 32.64). Piezo1 is found in the lungs, bladder, and skin of mammals as well as in red blood cells. A homologous protein, Piezo2, is found in sensory neurons. Piezo1 has been implicated in extrusion of epidermal cells and skin homeostasis, preventing excess proliferation of skin tissue. It is also involved in cancer biology and plays a role in metastases.

TRP receptors are found in mammals, amphibians, birds, and reptiles. The TRP superfamily in mammals is composed of 28 members divided into six subfamilies. TRP channels consist of four subunits, each containing six transmembrane helical segments, and virtually all conduct Ca^{2+} . TRPM8 (Figure 32.64) is the cold- and menthol-sensing receptor in animals and plays a role in migraine pain sensing. Animals feel cold when a decrease in temperature triggers the opening of TRPM8 channels and Ca^{2+} conduction. Variation of protein sequence in TRPM8 results in different triggering temperatures for the channel and enables animals such as penguins and elephants to adapt to low temperatures. Wild giant pandas in the Qinling mountains of China roll in fresh horse droppings when the temperature decreases. The horse manure contains caryophyllenes, sesquiterpenes that bind to TRPM8 and prevent channel opening, presumably contributing to cold tolerance by the pandas.

Figure 32.64 Structures of ion channels that respond to physical stimuli. **(a)** Cryo-EM structure of Piezo1. This protein is unusually large compared with most proteins, consisting of 2547 amino-acid residues. It is unrelated structurally to most other proteins, and forms a homotrimer in the membrane with three propeller blades around a central core. Remarkably, each subunit of the trimer possesses 38 transmembrane helices (PDB id = 5Z10). **(b)** Cryo-EM structure of TRPM8, which exists as a homotetramer in the membrane, each subunit having six transmembrane α -helices (PDB id = 6BPQ). Images in parts (a) and (b) are looking through the central transport channel.

Foundational Biochemistry Things You Should Know after Reading Chapter 32.

- Hormones regulate metabolic processes of tissues and organs as well as facilitate and control growth and differentiation, reproductive activities, learning, and memory.
- Hormones help the organism cope with changing conditions and stresses in the environment.
- The effects of hormonal signals are either metabolic responses or gene expression responses.
- Steroid hormones act either at the plasma membrane or in the nucleus of eukaryotic cells.
- Peptide hormones are often synthesized as inactive precursors that are activated by proteolysis.
- Signal transduction systems typically involve receptor proteins and signalsomes, covalent modifications of proteins and lipids, protein interaction domains, second messengers, and intracellular signaling pathways.
- Signal transduction systems are modulated by cooperativity, spatial and temporal control, signal integration, converging and diverging networks, signal amplification, and desensitization and adaptation.
- Many signaling pathways involve enzyme cascades.
- Signaling pathways connect membrane interactions with events in the nucleus.
- Signaling pathways depend on multiple molecular interactions.
- All receptors that mediate transmembrane signaling belong to one of three receptor superfamilies—the G-protein-coupled receptors, the single-transmembrane segment catalytic receptors, and the oligomeric ion channels.
- The G-protein-coupled receptors are 7-TMS integral membrane proteins.
- The single TMS receptors are guanylyl cyclases or tyrosine kinases.
- RTKs and RGCs are membrane-associated allosteric enzymes.
- The EGF receptor is activated by ligand-induced dimerization.
- The insulin receptor mediates several signaling pathways that regulate blood glucose levels and promote the synthesis and storage of carbohydrates, proteins and lipids.
- Receptor guanylyl cyclases mediate effects of natriuretic hormones.
- Soluble (non-receptor) tyrosine kinases and guanylyl cyclases, analogous to their receptor counterparts, also participate in signaling pathways.
- Soluble guanylyl cyclases are receptors for nitric oxide, a gaseous second messenger.
- GPCR signals are transduced by GTP-binding proteins (G proteins).
- Second messengers involved in signaling pathways include cyclic AMP, cyclic GMP, Ca^{2+} , IP_3 , NO, and a variety of lipid breakdown products.
- Ras and other small GTP-binding proteins are proto-oncogene products.
- Specific phospholipases release second messengers including DAG, the inositol phosphates, ceramide, and unsaturated fatty acids such as arachidonic acid.
- Activation of phospholipase C is mediated by G proteins or by tyrosine kinases.
- Intracellular calcium-binding proteins mediate the calcium signal.
- Transduction of hormonal signals activates effectors—protein kinases and protein phosphatases—that elicit a variety of intracellular actions that regulate cellular functions.
- Most protein kinases share a common catalytic core first characterized in protein kinase A.
- The protein kinase C isozymes are regulated by Ca^{2+} , diacylglycerol, and phosphatidylserine.
- Protein tyrosine kinase pp60^{c-src} is regulated by phosphorylation/dephosphorylation.
- G-Protein signaling is modulated by RGS/GAPs.
- GPCR desensitization by arrestin leads to new signal pathways.
- Nerve impulses are carried by action potentials—changes in ion gradients mediated by the flows of Na^+ and K^+ —that are propagated in neurons.
- Neurotransmitters enable neuron communication at synapses by binding to receptor proteins such as the nicotinic- and muscarinic-acetylcholine receptors.
- Glutamate and aspartate are excitatory amino acid neurotransmitters.
- γ -Aminobutyric acid and glycine are inhibitory neurotransmitters.
- Catecholamine neurotransmitters are derived from tyrosine.
- Peptides such as endorphins, enkephalins, endothelins, and the vasoactive intestinal peptide also function as neurotransmitters.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Assessing the Features and Physiology of Hormones** Compare and contrast the features and physiological advantages of each of the major classes of hormones, including the steroid hormones, polypeptide hormones, and the amino acid-derived hormones.
- Understanding the Features and Physiology of the Second Messengers** Compare and contrast the features and physiological advantages of each of the known classes of second messengers.
- Are There Gaseous Second Messengers Besides NO?** Nitric oxide may be merely the first of a new class of gaseous second messenger/neurotransmitter molecules. Based on your knowledge of the molecular action of nitric oxide, suggest another gaseous molecule that might act as a second messenger, and propose a molecular function for it.
- Assessing the Action of an Antibiotic** Herbimycin A is an antibiotic that inhibits tyrosine kinase activity by binding to SH groups of cysteine in the *src* gene tyrosine kinase and other similar tyrosine kinases. What effect might it have on normal rat kidney cells that have been transformed by Rous sarcoma virus? What other effects might this interesting antibiotic have?
- Proposing Uses for Monoclonal Antibodies Against Phosphotyrosine** Monoclonal antibodies that recognize phosphotyrosine are commercially available. How could such an antibody be used in studies of cell signaling pathways and mechanisms?

6. **Studying Phosphorylated Proteins** ATP [γ - ^{32}P] is a commercially available compound. (a) Describe the structure of this compound. (b) Design an experiment to measure kinase activity using this compound.
7. **Are there Functions of Hormone Receptors Other Than Signal Amplification?** Explain and comment on this statement: The main function of hormone receptors is that of signal amplification.
8. **Determining the Concentration of a Neurotransmitter in a Synaptic Vesicle** Synaptic vesicles are approximately 40 nm in outside diameter, and each vesicle contains about 10,000 acetylcholine molecules. Calculate the concentration of acetylcholine in a synaptic vesicle.
9. **Imagining a Model for Neurotransmitter Release** GTP γ S is a nonhydrolyzable analog of GTP. Experiments with squid giant axon synapses reveal that injection of GTP γ S into the presynaptic end (terminal) of the neuron inhibits neurotransmitter release (slowly and irreversibly). The calcium signals produced by presynaptic action potentials and the number of synaptic vesicles docking on the presynaptic membrane are unchanged by GTP γ S. Propose a model for neurotransmitter release that accounts for all of these observations.
10. **Assessing the Binding of a Hormone to Its Receptor** A typical hormone binds to its receptor with an affinity (K_D) of approximately 1×10^{-9} M. Consider an in vitro (test-tube) system in which the total hormone concentration is approximately 1 nM and the total concentration of receptor sites is 0.1 nM. What fraction of the receptor sites is bound with hormone? If the concentration of receptors is decreased to 0.033 nM, what fraction of receptor is bound with the hormone?
11. **Epinephrine and Glucagon** Glucagon and epinephrine signaling activates the same G protein type in liver cells. What signal is transmitted by glucagon? By epinephrine? How do these signals lead to similar effects inside a cell?
12. **Assessing the Effects of Statins on Steroid Hormones** (Integrates with Chapter 24.) All steroid hormones are synthesized in the human body from cholesterol. What is the consequence for steroid hormones and their action from taking a statin drug, such as Zocor, which blocks the synthesis of cholesterol in the body? Are steroid hormone functions compromised by statin action?
13. **Reconciling the Apparent Preference for Helices in Transmembrane Proteins** Given that β -strands provide a more genetically economical way for a polypeptide to cross a membrane, why has nature chosen α -helices as the membrane-spanning motif for G-protein-coupled receptors? That is, what other reasons can you imagine to justify the use of α -helices?
14. **α -Helices vs β -Sheets in Transmembrane Receptors** What is the functional benefit of α -helix structural elements compared to β -sheet structural elements in the transmembrane portion of a transmembrane receptor?
15. **Understanding Reaction Mechanisms for Adenylyl Cyclase and Phosphodiesterases** Write simple reaction mechanisms for the formation of cAMP from ATP by adenylyl cyclase and for the breakdown of cAMP to 5'-AMP by phosphodiesterases.
16. **Receptors and ATP** Kinases in signaling pathways depend on ATP. Which other signaling pathway components depend (indirectly) on the presence of ATP?
17. **Intervention in Cell Signaling** You have been tasked with developing an enzyme inhibitor to decrease the production of cAMP (see Figures 32.22 and 32.23). List at least three potential targets. For each target, evaluate whether the inhibition (and the subsequent reduction in cAMP levels) would be selective or affect multiple cell signaling pathways.
18. **Determining the Equilibrium Transmembrane Potential for K^+ and Na^+** (Integrates with Chapter 9.) Consider the data in Figure 32.49a. Recast Equation 9.2 to derive a form from which you could calculate the equilibrium electrochemical potential at which no net flow of potassium would occur. This is the Nernst equation. Calculate the equilibrium potential for K^+ and also for Na^+ , assuming $T = 37^\circ\text{C}$.
19. **Calculating Transmembrane Potential Using the Goldman Equation** The calculation of the actual transmembrane potential difference for a neuron is accomplished with the Goldman equation:

$$\Delta\psi = \frac{RT}{\mathcal{F}} \ln \left(\frac{\sum P_C [C]_{\text{outside}} + \sum P_A [A]_{\text{inside}}}{\sum P_C [C]_{\text{inside}} + \sum P_A [A]_{\text{outside}}} \right)$$
 where $[C]$ and $[A]$ are the cation and anion concentrations, respectively, and P_C and P_A are the respective permeability coefficients of cations and anions.
 Assume relative permeabilities for K^+ , Na^+ , and Cl^- of 1, 0.04, and 0.45, respectively, and use this equation to calculate the actual transmembrane potential difference for the neuron whose ionic concentrations are those given in Figure 32.49a.
20. **Understanding the Movement of K^+ , Na^+ , and Cl^- During an Action Potential** Use the information in problems 18 and 19, together with Figure 32.50, to discuss the behavior of potassium, sodium, and chloride ions as an action potential propagates along an axon.
21. **Action Potential Trigger** The action potential in a neuron is an all-or-nothing phenomenon: Once the membrane is depolarized by 20 mV, the action potential can commence. What triggers this initial small depolarization?
22. **Assessing Signal Amplification in a Signaling Pathway** Review the cell signaling pathway shown in Figure 32.4. With the rest of the chapter as context, discuss all the steps of this pathway that involve signal amplification.
23. **Understanding the Consequences of a Ras Mutation on a Signaling Pathway** In the cell signaling pathway shown in Figure 32.4, what would be the effect if Ras were mutated so that it had no GTPase activity?
24. **Understanding the Action of GPCRs in G-Protein – Independent Pathways** One of the topics discussed in this chapter is the ability of GPCRs to exert signaling effects without the involvement of G proteins. Using the pathway shown in Figure 32.40, and considering everything you have learned in this chapter, suggest some reasons that would explain why this G-protein-independent signaling was difficult to verify experimentally.
25. **Pharmacology and GABA Receptors** Why does it make pharmacological sense that agonists (activators) of GABA receptors are used to treat conditions like epilepsy, insomnia, and anxiety? (Hint: See Section 32.7j.)
26. **Assessing the Action of a Popular Pesticide** Malathion (Figure 32.58) is one of the secrets behind the near-complete eradication of the boll weevil from cotton fields in the United States. For most of the twentieth century, boll weevils wreaked havoc on the economy of states from Texas to the Carolinas. When boll weevils attacked cotton fields in a farming community, the destruction of cotton plants meant loss of jobs for farm workers, bankruptcies for farm owners, and resulting hardship for the entire community. Relentless application of malathion to cotton crops and fields has turned the tide, however, and agriculture experts expect that boll weevils will be completely gone from cotton fields within a few years. Remarkably, malathion-resistant boll weevils have not emerged despite years of this pesticide's use. Consider the structure and chemistry of malathion, and suggest what you would expect to be the ecological consequences of chronic malathion application to cotton fields.

27. **Assessing the Structural Requirements for a Regulatory Protein in a Signaling Network** Consult the excellent review article “Assembly of Cell Regulatory Systems Through Protein Interaction Domains” (*Science* **300**:445–452, 2003, by Pawson and Nash), and discuss the structural requirements for a regulatory protein operating in a signaling network.

PSAFE Problems

(PSAFE models, listed by chapter or protein name, can be found at <http://www.psafeonline.net/>.)

28. Using the PSAFE Model for Brca2 (the protein encoded by the BRCA2 gene associated with breast cancer susceptibility), discuss how a mutation in a BRC motif could cause breast cancer.

29. Using the PSAFE Model for c-Abl kinase, explain how Gleevec functions as a therapy for chronic myelogenous leukemia patients.

Think-Pair-Share Question

Binding of Hormones to Receptors A cell receives two hormonal signals simultaneously: (1) insulin signaling to promote glycogen synthesis and (2) epinephrine signaling to promote glycogen breakdown. What would be the ultimate effect inside the cell? List at least six factors that could determine the overall balance between these two opposing signals.

Abbreviated Answers to Problems

Detailed answers to the end-of-chapter problems and additional problems to solve are available in the *Student Solutions Manual, Study Guide and Problems Book*.

Chapter 1

1. a. The amino acid side chains of proteins provide a range of shapes, polarity, and chemical features that allow a protein to be tailored to fit almost any possible molecular surface in a complementary way.
- b. Immunoglobulin is hundreds of times bigger than alanine. It would take only a very small fraction of the surface area of IgG to accommodate alanine.
2. Biopolymers may be informational molecules because they are constructed of different monomeric units (“letters”) joined head to tail in a particular order (“words, sentences”). Polysaccharides are often linear polymers composed of only one (or two repeating) monosaccharide unit(s) and thus display little information content. Polysaccharides with a variety of monosaccharide units may convey information through specific recognition by other biomolecules. Also, most monosaccharide units are typically capable of forming branched polysaccharide structures that are potentially very rich in information content (as in cell surface molecules that act as the unique labels displayed by different cell types in multicellular organisms).

9. The long-chain alkanes that make up the structure of calcium stearate do not contain any functional groups that could interact favorably with water. This inability to interact with water will lead to a decreased solubility and increased tendency to separate from water (the hydrophobic effect).
10. Two carbon atoms interacting through van der Waals forces are 0.34 nm apart; two carbon atoms joined in a covalent bond are 0.154 nm apart.
11. Slight changes in temperature, pH, ionic concentrations, and so forth may be sufficient to disrupt weak forces (H bonds, ionic bonds, van der Waals interactions, hydrophobic interactions).
12. Living systems are maintained by a continuous flow of matter and energy through them. Despite the ongoing transformations of matter and energy by these highly organized, dynamic systems, no overt changes seem to occur in them: They are in a *steady* state.

3. Informational polymers must have “sense” or direction, and they must be composed of more than one kind of monomer unit.
4. DNA molecules essentially have only one function: “store information on how to make RNA and protein molecules.” Proteins are the “workhorses” of our biochemistry; the multitude of biochemical events happening in our cells are mediated by a multitude of different proteins; requiring them to adopt a multitude of different shapes.
5. Molecular recognition is based on structural complementarity. If complementary interactions involved covalent bonds (strong forces), stable structures would be formed that would be less responsive to the continually changing dynamic interactions that characterize living processes.
6. a. Raise the temperature.
b. The kinetic energy may overwhelm the energy of the weak forces and disrupt interactions between molecules.
c. Generally speaking, the opposite of b.
7. 1,000 kg of monomer would correspond to 5,000 mol monomer. (5,000–1) mol linkages would have been made with release of (5,000–1) mol of water. 4,999 mol water corresponds to 89,982 g water. 89,982 g water would correspond to 89.982 L water.
8. As this compound has both an amine and a carboxylic acid functional group, it can make repeated amide bonds (as shown in Figure 1.9) with other molecules of its kind.

13. Because bacteria (compared with humans) have simple nutritional requirements, their cells obviously contain enzyme systems that allow them to convert rudimentary precursors (even inorganic substances such as NH_4^+ , NO_3^- , N_2 , and CO_2) into complex biomolecules—proteins, nucleic acids, polysaccharides, and complex lipids. On the other hand, animals have an assortment of different cell types designed for specific physiological functions; these cells possess a correspondingly greater repertoire of complex biomolecules to accomplish their intricate physiology.
14. Consult Figures 1.19 to 1.21 to confirm your answer.
15.
 - a. Laid end to end, 250 *E. coli* cells would span the head of a pin.
 - b. The volume of an *E. coli* cell is about 10^{-15} L.
 - c. The surface area of an *E. coli* cell is about 6.3×10^{-12} m². Its surface-to-volume ratio is 6.3×10^6 m⁻¹.
 - d. 600,000 molecules.

- e. 1.7 nM .
- f. Because we can calculate the volume of one ribosome to be $4.2 \times 10^{-24} \text{ m}^3$ (or $4.2 \times 10^{-21} \text{ L}$), 15,000 ribosomes would occupy $6.3 \times 10^{-17} \text{ L}$, or 6.3% of the total cell volume.
- g. Because the *E. coli* chromosome contains 4600 kilobase pairs ($4.6 \times 10^6 \text{ bp}$) of DNA, its total length would be 1.6 mm—approximately 800 times the length of an *E. coli* cell.
- h. This DNA would encode 4300 different proteins, each 360 amino acids long.
16. a. The volume of a single mitochondrion is about $4.2 \times 10^{-16} \text{ L}$ (about 40% the volume calculated for an *E. coli* cell in problem 3).
- b. A mitochondrion would contain on average fewer than eight molecules of oxaloacetate.
17. a. Laid end to end, 25 liver cells would span the head of a pin.
- b. The volume of a liver cell is about $8 \times 10^{-12} \text{ L}$ (8000 times the volume of an *E. coli* cell).
- c. The surface area of a liver cell is $2.4 \times 10^{-9} \text{ m}^2$.
- d. Its surface-to-volume ratio is $3 \times 10^5 \text{ m}^{-1}$, or about 0.05 (1/20) that of an *E. coli* cell.
- Cells with lower surface-to-volume ratios are limited in their exchange of materials with the environment.
- e. The number of base pairs in the DNA of a liver cell is $6.06 \times 10^9 \text{ bp}$.
- f. The total length of the DNA in liver cell is 2.06 m (or more than 6 feet of DNA!) contained within a cell that is only $20 \text{ }\mu\text{m}$ on a side.
- g. Maximal information content of liver cell DNA = $3.03 \times 10^9 \text{ bp}$, which, expressed in proteins 400 amino acids in length, could encode 2.5×10^6 proteins.
18. a. The fraction of the *M. genitalium* genes encoding proteins = 0.925.
- b. Genes not encoding proteins encode RNA molecules.
- c. $(0.925)(580,074 \text{ base pairs}) = 536,820 \text{ base pairs}$ devoted to protein-coding genes.
- d. Since three base pairs specify an amino acid in a protein, 369 amino acids are found in the average *M. genitalium* protein.
- e. If each amino acid contributes on average 120 D to the mass of a protein, the mass of an average *M. genitalium* protein is 44,280 D.
19. $(0.925)(206) = 191$ proteins. Assuming its genes are the same size as *M. genitalium*, the minimal genome would be 228,480 base pairs.
20. Given 1109 nucleotides (or base pairs) per gene, the minimal virus, with a 3500-nucleotide genome, would have only three genes; the maximal virus, with a 280,000-bp genome, would have 252 genes.
21. Fate of proteins synthesized by the rough ER:
- a. Membrane proteins would enter the ER membrane, and, as part of the membrane, be passed to the Golgi, from which vesicles depart and fuse with the plasma membrane.
- b. A secreted protein would enter the ER lumen and be transferred as a luminal protein to the Golgi, from which vesicles depart. When the vesicle fuses with the plasma membrane, the protein would be deposited outside the cell.

Think-Pair-Share Question:

Chapter 2

1. a. 3.3; b. 9.85; c. 5.7; d. 12.5; e. 4.4; f. 6.97.
2. a. 1.26 mM ; b. $0.25 \text{ }\mu\text{M}$; c. $4 \times 10^{-12} \text{ M}$; d. $2 \times 10^{-4} \text{ M}$; e. $3.16 \times 10^{-10} \text{ M}$; f. $1.26 \times 10^{-7} \text{ M}$ ($0.126 \text{ }\mu\text{M}$).
3. The scientist is incorrect. Given the values of pH and pK_a and using the Henderson–Hasselbalch equation one can determine that the ratio of uncharged species to charged species is 1/100. Thus about 1% would be in the uncharged form and about 99% would be in the charged form.
4. Structure C, containing the carboxylic acid functional group —COOH is the acidic compound.
5. When acids dissociate in water, water molecules bind the released protons ($\text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+$). Water is acting as a base. An organic molecule like liquid hexane does not have basic properties and cannot pick up any released protons. Thus, in this type of environment the pK_a values of acids would be much higher (the acids would be much less acidic).
6. a. $[\text{H}^+] = 2.51 \times 10^{-5} \text{ M}$; b. $K_a = 3.13 \times 10^{-8} \text{ M}$; $\text{pK}_a = 7.5$.
7. a. $\text{pH} = 2.38$; b. $\text{pH} = 4.23$.
8. Combine 187 mL of 0.1 M acetic acid with 813 mL of 0.1 M sodium acetate.
9. $[\text{HPO}_4^{2-}]/[\text{H}_2\text{PO}_4^-] = 0.398$.
10. Combine 555.7 mL of 0.1 M Na_3PO_4 with 444.3 mL of 0.1 M H_3PO_4 . Final concentrations of ions will be $[\text{H}_2\text{PO}_4^-] = 0.0333 \text{ M}$; $[\text{HPO}_4^{2-}] = 0.0667 \text{ M}$; $[\text{Na}^+] = 0.1667 \text{ M}$; $[\text{H}^+] = 3.16 \times 10^{-8} \text{ M}$.
11. a. Fraction of H_3PO_4 : @pH 0 = 0.993; @pH 2 = 0.58; @pH 4 = 0.01; negligible @pH 6.
- b. Fraction of H_2PO_4^- : @pH 0 = 0.007; @pH 2 = 0.41; @pH 4 = 0.986; @pH 6 = 0.94; @pH 8 = 0.14; negligible @pH 10.
- c. Fraction of HPO_4^{2-} : negligible @pH 0, 2, and 4; @pH 6 = 0.06; @pH 8 = 0.86; @pH 10 $\approx$ 1.0; @pH 12 = 0.72.
- d. Fraction of PO_4^{3-} : negligible at any pH < 10; @pH 12 = 0.28.
12. At pH 5.2, $[\text{H}_3\text{A}] = 4.33 \times 10^{-5} \text{ M}$; $[\text{H}_2\text{A}^-] = 0.0051 \text{ M}$; $[\text{HA}^{2-}] = 0.014 \text{ M}$; $[\text{A}^{3-}] = 0.0009 \text{ M}$.
13. a. $\text{pH} = 7.02$; $[\text{H}_2\text{PO}_4^-] = 0.0200 \text{ M}$; $[\text{HPO}_4^{2-}] = 0.0133 \text{ M}$.
- b. $\text{pH} = 7.38$; $[\text{H}_2\text{PO}_4^-] = 0.0133 \text{ M}$; $[\text{HPO}_4^{2-}] = 0.0200 \text{ M}$.
14. The increase in CO_2 levels in the circulation creates acidosis. The kidneys try to counteract this situation by reabsorbing bicarbonate as a base to keep the pH balanced.

15. $[\text{H}_2\text{CO}_3] = 2.2 \mu\text{M}$; $[\text{CO}_{2(\text{d})}] = 0.75 \text{ mM}$. When $[\text{HCO}_3^-] = 15 \text{ mM}$ and $[\text{CO}_{2(\text{d})}] = 3 \text{ mM}$, $\text{pH} = 6.8$.
16. Titration of the fully protonated form of anserine will require the addition of three equivalents of OH^- . The pK_a values lie at 2.64 (COOH); 7.04 (imidazole- N^+H); and 9.49 (NH_3^+). Its isoelectric point lies midway between pK_2 and pK_3 , so $\text{pH}_i = 8.265$. To prepare 1 L of 0.04 M anserine buffer, add 164 mL of 0.1 M HCl to 400 mL of 0.1 M anserine at its isoelectric point and make up to 1 L final volume.
17. c
18. 166.7 g/mole.
19. Add 193 mL of water and 307 mL of 0.1 M HCl to 500 mL of 0.1 M triethanolamine.
20. Combine 200 mL of 0.1 M Tris- H^+ with 732 mL water and 68 mL of 0.1 M NaOH.

- c. The relevant pK_a for this calculation is 8.3. Combine 400 mL of 0.1 M bicine at its pH_i ($\text{pH} 5.3$) with 55 mL of 0.1 M NaOH and 545 mL of water.
- d. The relevant pK_a for this calculation is 2.3. The concentration of fully protonated form of bicine at $\text{pH} 7.5$ is $2.18 \times 10^{-7} \text{ M}$.
22. 0.063 M
23. 5.2 mM
- 24.

25. 1.53 nmol/mL · sec

26. a. 3.55 μM
- b. Theoretically, 4 μM OH^- would neutralize all of the H_2CO_3 , swamping the buffer system, and leading to a dangerous rise in pH.
- c. 1.2 mM.
- d. $K_{\text{overall}} = 8.07 \times 10^{-7}$.
- e. $\text{pK}_{\text{overall}} = 6.1$.
27. a. As $[\text{CO}_2]$ drops due to excessive exhalation, $[\text{H}_2\text{CO}_3]$ in the blood plasma falls, followed by a decline in $[\text{H}^+]$ and $[\text{HCO}_3^-]$ in the blood plasma. Blood pH rises within 20 sec of the onset of hyperventilation, becoming maximal within 15 minutes pH can change from its normal value of 7.4 to $\text{pH} = 7.74$. This rise in plasma pH (increase in alkalinity) is termed respiratory alkalosis.
- b. $[\text{H}^+]$ drops from its normal value of 40 nM ($\text{pH} = 7.4$) to 18 nM ($\text{pH} = 7.74$).
28. Hypoventilation results in respiratory acidosis, as CO_2 accumulates, giving rise to H_2CO_3 , which dissociates to form H^+ and HCO_3^- .

Think-Pair-Share Question:

- a. Two inflection points can be observed in the titration curve: after the addition of 10 and 20 mL 0.2 M NaOH. This implies that, $0.01 \text{ L} \times 0.2 \text{ mol/L} = 0.002 \text{ mol}$, corresponds to the molar equivalents of acid that was present. Thus, the concentration of acid was $0.002 \text{ mol} / 0.02 \text{ L} = 0.1 \text{ M}$.
- b. Given that 10 mL 0.2 M NaOH corresponds to the inflection points, 5 mL and 15 mL 0.2 M NaOH added, corresponds to the half-way points. Thus, one can estimate that the pK_a values are about 2.0 and 7.0.

Chapter 3

- In the human body, the temperature is 37°C (310 K). Assuming the values of ΔH and ΔS are the same in the human body as in the laboratory, and applying $\Delta G = \Delta H - T \Delta S$ one calculates $\Delta G = -20 \text{ kJ/mol}$; making the reaction spontaneous.
- $K_{\text{eq}} = 613 \text{ M}$; $\Delta G^\circ = -15.9 \text{ kJ/mol}$.
- $\Delta G^\circ = 1.69 \text{ kJ/mol}$ at 20°C ; $\Delta G^\circ = -5.80 \text{ kJ/mol}$ at 30°C . $\Delta S^\circ = 0.75 \text{ kJ/mol} \cdot \text{K}$.
- $\Delta G = -24.8 \text{ kJ/mol}$.
- State functions are quantities that depend on the state of the system and not on the path or process taken to reach that state. Volume, pressure, and temperature are state functions. Heat and all forms of work, such as mechanical work and electrical work, are not state functions.
- The dispersion of a set of molecules confined to a small volume (concentrated solution) into a much larger volume (diluted solution) significantly increases the entropy of the system; making it a spontaneous process.
- $\Delta G^\circ = \Delta G^\circ - 39.5 n$ (in kJ/mol), where n is the number of H^+ produced in any process. So $\Delta G^\circ = \Delta G^\circ + 39.5 n = -30.5 \text{ kJ/mol} + 39.5(1) \text{ kJ/mol}$. $\Delta G^\circ = 9.0 \text{ kJ/mol}$ at 1 M $[\text{H}^+]$.
- a. $K_{\text{eq}}(\text{AC}) = (0.02 \times 1000) = 20$.
- b. $\Delta G^\circ(\text{AB}) = 10.1 \text{ kJ/mol}$.
 $\Delta G^\circ(\text{BC}) = -17.8 \text{ kJ/mol}$.
 $\Delta G^\circ(\text{AC}) = -7.7 \text{ kJ/mol}$.
 $K_{\text{eq}} = 20$.

9. a. The ΔG of the first reaction would not change.
 b. The addition of the second enzyme catalyzing the hydrolysis of ATP (typically with $\Delta G < 0$) would make this an example of “coupled reactions” and the ΔG of the combined reactions would be < 0 .

10. See *The Student Solutions Manual, Study Guide and Problems Book* for resonance structures.

11. $K_{\text{eq}} = [\text{Cr}][\text{P}_i]/[\text{CrP}][\text{H}_2\text{O}]$.

$$K_{\text{eq}} = 3.89 \times 10^7.$$

12. CrP in the amount of 135.3 moles would be required per day to provide 5860 kJ energy. This corresponds to 28,548 g of CrP per day. With a body content of 20 g CrP, each molecule would recycle 1,427 times per day.

Similarly, 637 moles of glycerol-3-P, or 108,300 g of glycerol-3-P, would be required. Each molecule would recycle 5410 times/day.

13. $\Delta G = -46.1 \text{ kJ/mol}$.

14. The hexokinase reaction is a sum of the reactions for hydrolysis of ATP and phosphorylation of glucose:

The free energy change for the hexokinase reaction thus can be obtained by summing the free energy changes for the first two reactions listed here.

$$\Delta G^{\circ'} \text{ for hexokinase} = -30.5 \text{ kJ/mol} + 13.9 \text{ kJ/mol} = -16.6 \text{ kJ/mol}$$

15. The oxidation reaction may require the input of activation energy to initiate the oxidation reactions. Enzymes typically lower the required activation energy and as such promote reactivity. An excellent related article: Borden, W. T. et al., 2020. Dioxxygen: What Makes This Triplet Diradical Kinetically Persistent? *Journal of the American Chemical Society* **139**:9010–9018.

16. Comparing the acetyl group of acetoacetyl-CoA and the methyl group of acetyl-CoA, it is reasonable to suggest that the acetyl group is more electron-withdrawing in nature. For this reason, it tends to destabilize the thiol ester of acetoacetyl-CoA, and the free energy of hydrolysis of acetoacetyl-CoA should be somewhat larger than that of acetyl-CoA. In fact, $\Delta G^{\circ'} = -43.9 \text{ kJ/mol}$, compared with -31.5 kJ/mol for acetyl-CoA.

17. Carbamoyl phosphate should have a somewhat larger free energy of hydrolysis than acetyl phosphate, at least in part because of greater opportunities for resonance stabilization in the products. In fact, the free energy of hydrolysis of carbamoyl phosphate is -51.5 kJ/mol , compared with -43.3 kJ/mol for acetyl phosphate.

18. a. $K_{\text{eq}, 298} = 0.0204$. $K_{\text{eq}, 320} = 9$.

b. $\Delta H = 219.44 \text{ kJ/mol}$. $\Delta S = 704 \text{ J/mol}$. $\Delta G^{\circ} = 9.642 \text{ kJ/mole}$.

19. The value of ΔG° is determined at standard state, which includes $1 \text{ M} [\text{H}^+]$. Using Equation 3.17, a value for ΔG° of -3.36 kJ/mol can be calculated. This value applies at pH 2, 7, and 12 because, of course, ΔG° is pH independent. However, Equation 3.17 can also be used to determine that $\Delta G^{\circ'}$ is -14.77 kJ/mol at pH 2 and -71.82 kJ/mol at pH 12. Finally, $\Delta G^{\circ'}$ for enolase is not pH-dependent because the enolase reaction (see Figure 3.8) neither consumes nor produces protons. $\Delta G^{\circ} = \Delta G^{\circ'} = 1.8 \text{ kJ/mol}$.

20. The magnitude of $\Delta G^{\circ'}$ for ATP hydrolysis is sufficiently great that it provides ample energy to drive the conversion of A to B, even though the reaction is unfavorable. The result is that the equilibrium ratio of B to A is more than 10^8 greater when the reaction is coupled to ATP hydrolysis. If $\text{A} \rightarrow \text{B}$ were coupled instead to 1,3-bisphosphoglycerate hydrolysis, the ratio of B to A would be even greater, since the $\Delta G^{\circ'}$ for hydrolysis of 1,3-bisphosphoglycerate is substantially greater than that of ATP. Using the concentrations for 1,3-BPG and 3-PG in Table 18.2, and repeating the calculations in the A Deeper Look box “ATP Changes the K_{eq} by a Factor of 10^8 in Section 3.8” yields a ratio of $[B_{\text{eq}}]/[A_{\text{eq}}] = 4.14 \times 10^9$, an even greater ratio than that calculated in the A Deeper Look box “ATP Changes the K_{eq} by a Factor of 10^8 ” in Section 3.8.

21. a. $\Delta G^{\circ'} = -31.5 \text{ kJ/mol}$

b. $K_{\text{eq}} = 1.38$

c. The concentration of fatty-acyl CoA is not specified in this problem, since it varies in a typical cell. Assuming [fatty-acyl CoA] = 1 mM , $\Delta G = 15.63 \text{ kJ/mol}$

22. a. Temperature is not specified.

Assuming $T = 298 \text{ K}$, $\Delta G = -58.8 \text{ kJ/mol}$

b. $K_{\text{eq}} = 1.24 \times 10^7$

c. $\Delta G^{\circ'} = -9.97 \text{ kJ/mol}$

d. $K_{\text{eq}} = 55.7$

23. This exercise is left to the student. Use Figure 3.5 as a guide.

24. Without pyrophosphate cleavage, the acyl-CoA synthetase reaction is only slightly favorable, with a $\Delta G^{\circ'}$ of 0.8 kJ/mol . With pyrophosphate cleavage included, the net $\Delta G^{\circ'}$ for the reaction is -33.6 kJ/mol , a far more favorable value.

25. Use data in Table 3.1 to determine $\Delta G^{\circ'}$ for creatine kinase reaction: $\text{Cr} + \text{ATP} \rightarrow \text{CrP} + \text{ADP}$
 $\Delta G^{\circ'} = +12.8 \text{ kJ/mol}$.
 Use ΔG in muscle of 8.04 kJ/mol with Equation 3.8 to calculate $[\text{Cr}] = 0.012 \text{ M} = 12 \text{ mM}$.

Think-Pair-Share Question:

- a. The various reagents should be organized with increasing values of $\mathcal{E}_0'$. Beaker B should contain FMN, beaker C should contain cytochrome b_L (Fe^{3+}), beaker D should contain UQ and beaker E should contain cytochrome c (Fe^{3+}).

- b. Beakers A and B:

$$\Delta \mathcal{E}_0' = -0.219 \text{ V} - (-0.32 \text{ V}) = 0.101 \text{ V}$$

Beakers B and C:

$$\Delta \mathcal{E}_0' = -0.100 \text{ V} - (-0.219 \text{ V}) = 0.119 \text{ V}$$

Beakers C and D:

$$\Delta \mathcal{E}_0' = 0.060 \text{ V} - (-0.100 \text{ V}) = 0.16 \text{ V}$$

Beakers D and E:

$$\Delta \mathcal{E}_0' = 0.254 \text{ V} - (0.060 \text{ V}) = 0.194 \text{ V}$$

Beakers E and F:

$$\Delta \mathcal{E}_0' = 0.816\text{V} - (0.254\text{V}) = 0.562\text{V}$$

c. Overall reaction

$$\Delta \mathcal{E}_0' = 0.816\text{V} - (-0.32\text{V}) = 1.136\text{V}$$

Chapter 4

1. Structures for glycine, aspartate, leucine, isoleucine, methionine, and threonine are presented in Figure 4.3.

2. Asparagine = Asn = N.

Arginine = Arg = R.

Cysteine = Cys = C.

Lysine = Lys = K.

Proline = Pro = P.

Tyrosine = Tyr = Y.

Tryptophan = Trp = W.

3. LDPTY and MHQAT

4. a. The structure is not a zwitterion as it has a surplus of positive charges.

b. Increasing the pH could remove a proton from one of the N-containing functional groups and balance the positive and negative charges within the structure.

5. Alanine dissociation:

Glutamate dissociation:

Histidine dissociation:

Lysine dissociation:

Phenylalanine dissociation:

6. The proximity of the α -carboxyl group lowers the pK_a of the α -amino group.

b. Ratio = 25.1

9. Denoting the four histidine species as His^{2+} , His^+ , His^0 , and His^- , the concentrations are:

pH 2: $[\text{His}^{2+}] = 0.097\text{ M}$, $[\text{His}^+] = 0.153\text{ M}$,
 $[\text{His}^0] = 1.53 \times 10^{-5}\text{ M}$, $[\text{His}^-] = 9.6 \times 10^{-13}\text{ M}$.

pH 6.4: $[\text{His}^{2+}] = 1.78 \times 10^{-4}\text{ M}$, $[\text{His}^+] = 0.071\text{ M}$,
 $[\text{His}^0] = 0.179\text{ M}$, $[\text{His}^-] = 2.8 \times 10^{-4}\text{ M}$.

pH 9.3: $[\text{His}^{2+}] = 1.75 \times 10^{-12}\text{ M}$, $[\text{His}^+] = 5.5 \times 10^{-5}\text{ M}$,
 $[\text{His}^0] = 0.111\text{ M}$, $[\text{His}^-] = 0.139\text{ M}$.

10. $\text{pH} = \text{pK}_a + \log(2/1) = 4.3 + 0.3 = 4.6$.

The γ -carboxyl group of glutamic acid is two-thirds dissociated at $\text{pH} = 4.6$.

11. $\text{pH} = \text{pK}_a + \log(1/4) = 10.5 + (-0.6) = 9.9$.

12. a. The pH of a 0.3 M leucine hydrochloride solution is approximately 1.46.

b. The pH of a 0.3 M sodium leucinate solution is approximately 11.5.

c. The pH of a 0.3 M solution of isoelectric leucine is approximately 6.05.

13. The sequence of reactions shown would demonstrate that L(-)-serine is related stereochemically to L(-)-glyceraldehyde:

Straight arrows indicate reactions that occur with retention of configuration. Looped arrows indicate inversion of configuration. (From Kopple, K. D., 1966. Peptides and Amino Acids. New York: Benjamin Co.)

14. Cystine (disulfide-linked cysteine) has two chiral carbons, the two α -carbons of the cysteine moieties. Each chiral center can exist in two forms, so there are four stereoisomers of cystine. However, it is impossible to distinguish the difference between L-cysteine/D-cysteine and D-cysteine/L-cysteine conjugates. So three distinct isomers are formed:

15. 43

16.

17. There are eight Tyr residues in the protein.

18. A water is removed from each amino acid when it is incorporated into a protein, so the “molecular weight” of a residue is lower by 18 units. Also, most proteins have relatively more small side chains (Gly, Ala) and fewer Trp side chains than a statistical average would predict.

19. Aspartame is composed of aspartic acid and phenylalanine, with a carboxymethyl cap. These amino acids are linked by a peptide (amide) bond in aspartame. Heating can cleave amide linkages. For this reason, drinks such as coffee and hot chocolate must be consumed relatively quickly after preparation. Aspartame kept hot for several hours is quite bitter tasting (based on the experience of one of the authors).

20. Phenylketonuria is an autosomal-recessive genetic disease caused by a deficiency or absence of the enzyme phenylalanine hydroxylase (PAH), an essential enzyme that converts phenylalanine to tyrosine. Without sufficient PAH activity, phenylalanine accumulates and is converted to phenylpyruvate (which can be detected in the urine). Without treatment, phenylketonurics eventually experience progressive mental retardation and seizures. Phenylketonuria can be controlled by eliminating phenylalanine from the diet, and phenylketonurics should be advised not to use aspartame.

21. The process for distinguishing R- and S-configurations of chiral molecules is described in the Critical Developments in Biochemistry box “Rules for Description of Chiral Centers in the (R,S) System” in Section 4.4. Enzymes discriminate between isomers of chiral molecules thanks to the asymmetric arrangement of amino acid residues in the enzyme active site.

22. Appropriate ranges for buffering:

Alanine—1.4–3.4, 8.7–10.7

Histidine—0.8–2.8, 5.0–7.0, 8.2–10.2

Aspartic acid—1.1–4.9, 8.8–10.8

Lysine—1.2–3.2, 8–11.5

23. This exercise is left to the student and will presumably be different for every student.

24. M. A. Rosanoff, an instructor at New York University, proposed the D,L-nomenclature system for chiral molecules.

25. See “A Deeper Look - Why Nature Chose Selenium” on page 82 for a full explanation.

26. This exercise is left to the student and will presumably be different for every student.

27. With pK_a of 8.3, cysteine would make a useful buffer except that cystine, the disulfide of cysteine, can form readily in this pH range. For every cystine formed, two cysteine-SH groups are eliminated, making the buffering capacity of cysteine of limited usefulness. Also, the cysteine sulfhydryl group is the most potent nucleophile among the side chains of the 20 common amino acids.

28. L-threonine is (2S, 3R)-threonine.

D-threonine is (2R, 3S)-threonine.

L-allothreonine is (2S, 3S)-threonine.

D-allothreonine is (2R, 3R)-threonine.

Think-Pair-Share Question:

PHE	3.82	3.83
ASP	1.08	1.11
PRO	2.78	2.79
MET	3.46	3.47
LYS	4.46	4.47
SER	2.29	2.31
ALA	2.89	2.91
VAL	3.33	3.35
LEU	3.67	3.68

hydrophobic interactions. The relatively large size of the tyrosine side chain will permit substantial van der Waals interactions.

His: The imidazole side chain of histidine can act as both an acceptor and donor of hydrogen bonds and, when protonated, can participate in ionic bonds. Van der Waals interactions are expected, but hydrophobic interactions are less likely in most cases.

4. All proteins, independent of their primary structure, are polyamides containing regularly spaced amide functionalities. As α helices and β sheets are created through hydrogen bonds between amide groups, α helices or β sheets can be created in many different proteins.
5. The presence of the hydroxyl groups on the proline or lysine residues provide additional hydrogen-bonding capabilities that help stabilize the triple helical conformation of collagen.
6. Protein A appears to have the most appropriate amino acid balance with 31.4% hydrophobic (A, G, I, L, F, P, V), 29.1% hydrophilic (R, N, D, C, E, Q, H, S, T) and 33.5% amphipathic (K, M, W, Y) amino acids. Protein B has excess hydrophobic amino acids (55%), while protein C has excess hydrophilic amino acids (48.1%).
7. There would be much more steric hindrance in the peptide or protein chain, limiting the possibilities to form secondary or tertiary structures.
8. As an imino acid, proline has a secondary nitrogen with only one hydrogen. In a peptide bond, this nitrogen possesses no hydrogens and, thus, cannot function as a hydrogen-bond donor in α -helices. More importantly, ϕ , the angle of rotation around the C_α -N bond, is fixed in Pro. On the other hand, proline stabilizes the *cis*-configuration of a peptide bond and thus, is well suited to β -turns, which require the *cis*-configuration.
9. For a right-handed cross-over, moving in the N-terminal to C-terminal direction, the cross-over moves in a clockwise direction when viewed from the C-terminal side toward the N-terminal side. The reverse is true for a left-handed cross-over; that is, movement from N-terminus to C-terminus is accompanied by counterclockwise rotation.
10. The Ramachandran plot reveals allowable values of ϕ and ψ for α -helix and β -sheet formation. The plots consider steric hindrance and will be somewhat specific for individual amino acids. For example, peptide bonds containing glycine can adopt a much wider range of ϕ and ψ angles than can peptide bonds containing tryptophan.
11. The protein appears to be a tetramer of four 60-kD subunits. Each of the 60-kD subunits in turn is a heterodimer of two peptides, one of 34 kD and one of 26 kD, joined by at least one disulfide bond.
12. Hydrophobic interactions frequently play a major role in subunit-subunit interactions. The surfaces that participate in subunit-subunit interactions in the B_4 tetramer are likely to possess larger numbers of hydrophobic residues than the corresponding surfaces of protein A.
13. The length is given by $(53 \text{ residues}) \times (0.15 \text{ nm run/residue}) = 7.95 \text{ nm}$. The number of turns in the helix is given by $(53 \text{ residues})/(3.6 \text{ residues/turn}) = 14.7 \text{ turns}$. There are 49 hydrogen bonds in this helix.
14. Glycines are essential components of tight turns (β -turns) and, thus, are often essential for maintenance of protein structure.
15. Asp, Glu, Ser, Thr, His, and perhaps also Asn, Gln, Cys, Arg, Lys.
16. The ability of poly-Glu to form α -helices requires that the glutamate carboxyls be protonated. Deprotonation produces a poly-anionic peptide that is not amenable to helix formation.
17. A coiled-coil formed from α -helices with 3.5 residues per turn would form a symmetrical seven-residue-repeating structure that would place the first and fourth residues of the seven-residue repeat at the same positions about the helix axis in every seven-residue repeat. This would allow the two helices of a coiled-coil structure to lie side by side with no twist about the coiled-coil axis. Such a structure would probably not be as stable as the twisted structure of coiled coils formed from α -helices with 3.6 residues per turn.
18. Linear motifs are peptide sequences that are short and conserved. These blocks occur within a larger protein and act as recognition modules. A sequence containing a phosphorylatable tyrosine and a proline-rich sequence are two examples. Linear motifs are different from domains in the sense that the linear sequence rather than a folded domain is the recognizable unit. Consult the references provided in this question for additional information.
19. The student should consult the references provided to answer this question.
20. The work of Dorothee Kern has provided evidence that conformational transitions in proteins may be assisted by transient interactions resulting from internal protein motions. Consult the reference provided for more information on this interesting phenomenon.
21. Born in Pocahontas, Virginia, Herman Branson received a B.S. from Virginia State University in 1936 and a Ph.D. in Physics from the University of Cincinnati in 1939. He became a professor of physics and chemistry at Howard University in 1941 and spent 27 years on that faculty. In 1948, he took a sabbatical leave in the laboratory of Linus Pauling at the California Institute of Technology. Pauling asked him to do a mathematical analysis of all helical structures for peptide chains that would fit the structural constraints determined previously by Pauling and Robert Corey. The first (and most revolutionary) paper on the α -helix was submitted to *Proceedings of the National Academy of Sciences* on Pauling's 50th birthday (2/28/1951) by Pauling, Corey, and Branson. An excellent account of this story is provided by David Eisenberg (*Proceedings of the National Academy of Sciences* **100**:11207–11210 [2003]).
22.
 - a. The third sequence would place hydrophobic residues on both sides of a β -strand and thus could be found in a parallel β -sheet.
 - b. The second sequence would place hydrophobic residues on just one side of a β -strand and thus could be found in an anti-parallel β -sheet.
 - c. The sixth sequence consists of GPX repeats (where X is any amino acid) and thus could be part of a tropocollagen molecule.
 - d. The first sequence consists of seven-residue repeats, with first and fourth residues hydrophobic, and thus could be part of a coiled coil structure.
23. The solution to this exercise is to be completed by the student.
24. $\Delta G^\circ = -34.23 \text{ kJ/mol}$, a number that corresponds to one to two H bonds.
25. For the folded state (F) to unfolded state (U) reaction,

$$F \rightleftharpoons U$$

the equilibrium constant is given by $K_{eq} = u/f = u/(1 - u)$, where u and f are the unfolded and folded fractions; $u + f = 1$. Given $\Delta G^\circ = -RT \ln K_{eq}$, if $u = 0.8$, $K_{eq} = 0.8/0.2 = 4$ and $\Delta G^\circ = 3.4 \text{ kJ/mole}$. If $u = 0.2$, then $K_{eq} = 0.2/0.8 = 0.25$ and $\Delta G^\circ = -3.4 \text{ kJ/mole}$. So the transition from 80% unfolded to 80% folded is given by $\Delta G = 3.4 \text{ kJ/mol} - (-3.4 \text{ kJ/mole}) = 6.8 \text{ kJ/mol} \approx 7 \text{ kJ/mol}$.

26. a. 28
 b. about 8
 c. Assuming an antiparallel pair of β -strands, about 12.
 d. 2×12 (β -strands) + 28 (α -helix) + 2×4 (each β -bend) = approximately 60.
 e. 2 for the β -bends, $n - 4 = 24$ for α -helix, and about 12 for the pair of β -strands = approximately 38 total.
27. Charge will be approximately -1 , although the tyrosine will begin to deprotonate at pH 9.8.
28. Charge will be approximately $+2.5$. (The histidine will be half-protonated at pH 6.)
29. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

Chapter 7

- See structures in *The Student Solutions Manual, Study Guide and Problems Book*.
- See structures and titration curve in *The Student Solutions Manual, Study Guide and Problems Book*.

13.

enantiomer

anomer

C3-epimer

- Structure A: Hexose, L, aldose
 Structure B: Hexose, L, aldose, α , pyranose
 Structure C: Hexose, D, ketose, β , furanose
- A sample that is 0.69 g α -D-glucose/mL and 0.31 g β -D-glucose/mL will produce a specific rotation of 83° .
- See structures in *The Student Solutions Manual, Study Guide and Problems Book*.
- A 0.2 g sample of amylopectin corresponds to 0.2 g/162 g/mole or 1.23×10^{-3} mole glucose residues; 50 μ mole is 0.04 of the total sample or 4% of the residues. Methylation of such a sample should yield 1,2,3,6-tetramethylglucose for the glucose residues on the reducing ends of the sample. The amylopectin sample contains 1.2×10^{18} reducing ends.
- There are several target sites for trypsin and chymotrypsin in the extracellular sequence of glycoporphin, and it would be reasonable to expect that access to these sites by trypsin and chymotrypsin would be restricted by the presence of oligosaccharides in the extracellular domain of glycoporphin.
- Energy yield upon combustion (whether by metabolic pathways or other reactions) depends on the oxidation level. Carbohydrate

3.

- See Figure 7.2. All of the structures in the same row as D-xylose are D-diastereomers of it.

5. L-Gulose

- a. Converting D-galactose to D-talose would require breaking of bonds, so they represent different configurations.

b. Chair structures of β -D-allose differ by conformation.

7. D-2-Deoxyarabinose

- D-Fructose can tautomerize to D-glucose or D-mannose, both of which are reducing sugars.

- The systematic name for trehalose is α -D-glucopyranosyl-(1 $\rightarrow$ 1)- α -D-glucopyranoside.

Trehalose is not a reducing sugar. Both anomeric carbons are occupied in the disaccharide linkage.

- See structures in *The Student Solutions Manual, Study Guide and Problems Book*.

11. α -1,4

12.

and protein are at approximately the same oxidation level, and both of these are significantly less than that of fat.

- This mechanism could involve either an S_N1 or S_N2 mechanism. In the former, protonation of the bridging oxygen would result in dissociation to produce a carbo-cation intermediate, which could be attacked by the phosphate nucleophile. The observation of retention of configuration at the anomeric carbon favors this mechanism. An S_N2 mechanism would presumably involve water attack at the anomeric carbon, with dissociation of the oxygen of the carbohydrate chain. This would be followed by S_N2 attack by phosphate. Two S_N2 attacks would result in retention of configuration at the anomeric carbon atom.
- Laetrile contains a cyanide group. Breakdown of laetrile and release of this cyanide function in the body would be highly toxic.
- Chondroitin and glucosamine are amino sugar components of cartilage and connective tissue. Dietary supplement with these substances could help replenish the cartilage matrix proteoglycan, relieving pain and restoring the proper function of connective tissue structures.
- Two of the sugar units in stachyose are glucose and fructose, and the bond joining them is easily cleaved by stomach enzymes. However, the other two sugar units in stachyose are galactoses

in $\alpha(1 \rightarrow 6)$ -linkages, which are not broken down by human enzymes. The result is that stachyose loses a fructose in the stomach but the resulting trisaccharide passes into the intestines, where bacterial enzymes degrade it, producing intestinal gas in the process. Beano contains an enzyme that hydrolyzes $\alpha(1 \rightarrow 6)$ -galactose linkages. Taking several Beano tablets before a meal of beans or legumes facilitates complete breakdown of stachyose and other related oligosaccharides in the stomach, avoiding the production of intestinal gas. The active enzyme in Beano is referred to as a $\alpha(1 \rightarrow 6)$ -galactosidase.

24. β -D-Fructofuranosyl-*O*- α -D-galactopyranosyl-(1 $\rightarrow$ 6)-*O*- α -D-galactopyranosyl-(1 $\rightarrow$ 6)- α -D-glucopyranoside
25. Starch phosphorylase cleaves glucose units, one at a time, from starch chains until a (1 $\rightarrow$ 6)-branch is encountered. Thus, limit dextrins are amylopectin fragments with a glucose in (1 $\rightarrow$ 6)-linkage at each nonreducing end. The mechanism of the reaction that cleaves these glucose units is essentially the same as that for starch phosphorylase, except that it occurs at a glucose unit that is (1 $\rightarrow$ 6)-linked.
26. In the beer-making process, the mash fermented by yeast contains starch, which is partially broken down by the amylase from the malt to produce limit dextrins (see problem 16). These limit dextrins add significant caloric content to regular beers. Joseph Owades used the enzyme amyloglucosidase, which hydrolyzes both (1 $\rightarrow$ 4) and (1 $\rightarrow$ 6) linkages in starch, thus breaking down the limit dextrins to simple glucose, which is fermented normally. (This raises the alcohol content of the beer above what normally would be produced, and water typically is added to adjust the alcohol content.)
27. As described in problem 14, Beano is a $\alpha(1 \rightarrow 6)$ -galactosidase. Thus, Beano can slowly convert the limit dextrins produced in the beer-brewing process into simple glucose units, much like the enzyme used by Joseph Owades (see problem 17). Amateur brewers have learned to use Beano to make their own light beer, often referred to as Beano beer.
28. Assuming each glucose unit contributes 0.55 nm to the growing cellulose polymer (and the plant length), a growth rate of 1 foot per day corresponds to a rate for cellulose synthase of 6400 glucose units per second.
29. Lactaid contains a natural lactase enzyme derived from *Aspergillus oryzae*. It converts lactose into glucose and galactose.
30. Lactose-free milk is prepared by treating regular milk with a lactase enzyme, which converts lactose to glucose and galactose. One could make lactose-free milk at home by treating regular milk with Lactaid tablets. Suitable references would reveal the lactose concentration in regular milk and the activity of the lactase enzyme in Lactaid tablets. One could then calculate how many Lactaid tablets and how much time (at a given temperature) would be required to consume all of the lactose in a given quantity of regular milk.
31. This exercise is left to the student and will presumably be different for every student.
32. This exercise is left to the student and should be based on the reference provided.

34. This exercise is left to the student and should be based on the reference provided.
35. Basic amino acid side chains (Arg, His, Lys) in antithrombin III present positively charged side chains for ionic interactions with sulfate functions on heparin; H-bond donating amino acid side chains could form H bonds with O atoms in —OH groups on the heparin carbohydrate residues; H-bond accepting amino acid side chains could form H bonds with H atoms in —OH groups of heparin.
36. Because these glycosaminoglycans are rich in hydroxyl groups, amine groups, and anionic functions (carboxylates, sulfates), they interact strongly with water. The heavily hydrated proteoglycans formed from these glycosaminoglycans are reversibly dehydrated in response to the pressure imposed on a joint during normal body movements. This dehydration has a cushioning effect on the joint; when the pressure is relieved, the glycosaminoglycans are spontaneously rehydrated due to their affinity for water.
37. This exercise is left to the student and will presumably be different for every student.
38. This exercise is left to the student and will presumably be different for every student.

Chapter 8

1. Because the question specifically asks for triacylglycerols that contain stearic acid *and* arachidonic acid, we can discount the triacylglycerols that contain only stearic or only arachidonic acid. In this case, there are six possibilities:

2. See *The Student Solutions Manual, Study Guide and Problems Book* for a discussion.
3.
 - a. Phosphatidylethanolamine and phosphatidylserine have a net positive charge at low pH.
 - b. Phosphatidic acid, phosphatidylglycerol, phosphatidylinositol, phosphatidylserine, and diphosphatidylglycerol normally carry a net negative charge.
 - c. Phosphatidylethanolamine and phosphatidylcholine carry a net zero charge at neutral pH.
4. Unlike the phosphate group, the sulfate group in a diester bond is uncharged. This lack of the negative charge would give the “glycosulfolipids” different physicochemical properties.

5. Diets high in cholesterol contribute to heart disease and stroke. On the other hand, plant sterols bind to cholesterol receptors in the intestines but are not taken up by the cells containing these receptors. There is substantial evidence that a diet that includes plant sterols can reduce serum cholesterol levels significantly.
6. Former Interior Secretary James Watt was well known during the Reagan administration for his comments on several occasions that trees caused and produced air pollution. As noted in this chapter, it is, of course, true that trees emit isoprenes that are the cause of the blue-gray haze that is common in still air in mid-to late-summer in the eastern United States. However, these isoprene compounds are not significantly toxic to living things, and it would be misleading to call them pollutants.
7. Louis L'Amour clearly knew his biochemistry. His protagonist knew that fat carries a higher energy content than protein or carbohydrate. If meals are going to be scarce (as for a person living in the wild and on the run), it is wise to consume fat rather than protein or carbohydrate. The same reasoning applies for migratory birds in the weeks preceding their long flights.
8. Phospholipase A₂ from snake bites operates without regulation or control, progressively breaking down cell membranes. Phospholipase A₂ action is under precise control and is carefully regulated to produce just the right amounts of required cell signals.
9. The lethal dose for 50% of animals is referred to as the LD₅₀. The LD₅₀ for dogs is approximately 3 mg/kg of body weight. Thus, for a 40-lb dog (18.2 kg), consumption of approximately 55 mg of warfarin would be lethal for 50% of animals.
10. See the *Student Solution Guide* and www.cengage.com/login for the solutions to this problem.
11. Humans require approximately 2000 kcal per day. Seal blubber is predominantly triglycerides, which yield approximately 9 kcal per gram. This means that a typical human would need to consume 222 grams of seal blubber per day (about half a pound) in order to obtain all of his or her calories from this energy source.
12. α -linolenic acid
13. Results for this problem will depend on the particular cookies chosen by the student.
14. The only structural differences between cholesterol and stigmasterol are the double bond of stigmasterol at C₂₂–C₂₃, and the ethyl group at C₂₄.
15. Androgens mediate the development of sexual characteristics and sexual function in animals. Glucocorticoids participate in the control of carbohydrate, protein, and lipid metabolism. Mineralocorticoids regulate salt (Na⁺, K⁺, and Cl[–]) balances in tissues.
16. The answers to this question will depend on the household products chosen and the isoprene substances identified.
17. 6
18. Hydroxide ions (in lye) catalyze the breakdown of triglycerides to produce fatty acid salts such as sodium stearate and sodium palmitate and leaving glycerol as a by-product. Micelle formation by these “soaps” leads to emulsification of fats and other nonpolar substances.
19. Amphipathic phosphatidylcholine from egg yolk exerts a detergentlike action on mixtures of vegetable oil and water. Micelles made primarily of egg phosphatidylcholine emulsify the vegetable oil, forming a stable suspension that persists indefinitely. (Thus, mayonnaise does not need to be mixed or shaken before use, whereas oil and vinegar mixtures do.) The micellar particles of mayonnaise are large enough to scatter visible light, so mayonnaise appears milky white, whereas the separated layers of oil and water in containers of oil and vinegar appear clear.
20. In general, esters are more readily hydrolyzed compared to ethers. Phospholipases specifically act upon ester bonds; not ether bonds. This makes ether linkages more stable from a chemical or biochemical point of view.
21. Stanol esters function in cholesterol reduction by binding to cholesterol receptors in the intestines. However, each serving of stanol esters consumed only blocks a fraction of all intestinal receptors. Regular consumption of stanol esters eventually blocks all or most available receptors. Binding of stanol esters is tight and long lasting, but not indefinite, so stanol ester consumption must be continued to maintain the beneficial results. The graph in the Human Biochemistry box “Plant Sterols and Stanols—Natural Cholesterol Fighters” in Section 8.7 shows that reductions of serum cholesterol levels can approach 15%; given that the typical diet accounts for about 15% of total serum cholesterol, it may be concluded that stanol esters are highly effective in preventing uptake of dietary cholesterol.
22. Serum cholesterol is partly derived from diet and partly from synthesis in the liver. Stanol esters prevent uptake of dietary cholesterol but do not affect synthesis in the liver. Cholesterol-lowering drugs, on the other hand, block cholesterol synthesis but have no effect on uptake from diet. Thus, the effects of these two classes of cholesterol-lowering agents are additive.
23. Research has shown that consumption of substantial quantities of plant fats can lead to significant reduction of serum cholesterol. The content of so-called phytosterols varies depending on the source. However, a sterol- or stanol-fortified spread like Benecol probably provides the highest concentration of dietary agents for cholesterol lowering.
24. Tetrahydrogestrinone (THG) is synthesized by the catalytic hydrogenation of gestrinone (which has an acetylene group in place of the ethyl group on the D-ring of tetrahydrogestrinone). Patrick Arnold, known as the “father of prohormones,” is credited with the synthesis of THG from gestrinone and the promotion of THG as an anabolic steroid in preparations such as The Clear and The Cream. These substances were marketed aggressively to top athletes in several sports by Arnold and Victor Conte of the Bay Area Laboratory Co-Operative. THG (at that time) was undetectable by existing laboratory analyses, and its use was not specifically prohibited in athletic competitions by the World Anti-Doping Code. Use of THG has since been prohibited by nearly all sports regulatory agencies, and effective methods for its detection have been developed. Numerous athletes have by now admitted to use of THG or have been convicted for perjury in denial of its use, and many have been stripped of medals and awards for athletic accomplishments aided by THG.
25. Most obviously, a diet of triglycerides (from the blubber of seals, the polar bears’ favorite food) provides high energy and material that can be reprocessed into other triglycerides and used as insulation under the skin. Less obvious is the need of the polar bear to stay warm and conserve water. (Polar bears cannot afford to eat snow or ice [they are too cold], and they cannot drink seawater [it is too salty].) The polar bear is adapted to conserve body water and stay warm, and thus it does not urinate for months at a time. (Urination would give up both water and heat.) To achieve this, it must consume little or no nitrogen because a diet rich in nitrogen would require urination and defecation. Triglycerides contain no nitrogen and are thus ideal food for the

adult polar bear. Juvenile polar bears, which have not yet reached their full adult body size, must consume protein in order to make their own proteins. Once the bear reaches its full size, it changes its diet and consumes much less protein!

26. Snake venom phospholipase A₂ cleaves fatty acids from phospholipids at the C-2 position. The fatty acids behave as detergents and form micelles (see Chapter 9) that can remove lipids and proteins from the membrane and disrupt membrane structure, causing pores and eventually rupturing the cell itself.
27. This exercise is left to the student and will presumably be different for every student.
28. This exercise is left to the student and will presumably be different for every student.
29. a. Phospholipase D
b. Phospholipase D
c. Phospholipase A₂
d. A lyso-phosphatidic acid.
30. The starting phospholipid is 1-linoleoyl-2- α -linolenoyl-phosphatidylcholine. The first enzyme is phospholipase A₁, which produces linoleic acid and a lysophosphatidylcholine. The second enzyme is phospholipase D, which cleaves the latter molecule to produce a lysophosphatidic acid and choline.
31. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

energy bar 1: 1.19 ATP; energy bar 2: 1.19 ATP

Chapter 9

1. Glycerophospholipids with an unsaturated chain at the C-1 position and a saturated chain at the C-2 position are rare to nonexistent. Glycerophospholipids with two unsaturated chains, or with a saturated chain at C-1 and an unsaturated chain at C-2, are commonly found in biomembranes.
2. The phospholipid/protein molar ratio in purple patches of *H. halobium* is 10.8.
3. Apart from the basic nutritional value provided by the fat and protein content, eggs are rich in cholesterol. During embryonic growth and development, the process of cell replication requires the making of new membranes which creates an increased requirement for cholesterol in pregnant women.
4. See *The Student Solutions Manual, Study Guide and Problems Book* for plots of sucrose solution density versus percent by weight and by volume. The plot in terms of percent by weight exhibits a greater curve because less water is required to form a solution that is, for example, 10% by weight (10 g sucrose/100 g total) than to form a solution that is 10% by volume (10 g sucrose/100 mL solution).
5. $r = (4Dt)^{1/2}$.
According to this equation, a phospholipid with $D = 1 \times 10^{-8} \text{ cm}^2$ will move approximately 200 nm in 10 milliseconds.
6. Fibronectin: For $t = 10 \text{ msec}$, $r = 1.67 \times 10^{-7} \text{ cm} = 1.67 \text{ nm}$.
Rhodopsin: $r = 110 \text{ nm}$.
All else being equal, the value of D is roughly proportional to $(M_r)^{-1/3}$. Molecular weights of rhodopsin and fibronectin are 40,000 and 460,000, respectively. The ratio of diffusion coefficients is thus expected to be $(40,000)^{-1/3}/(460,000)^{-1/3} = 2.3$.

On the other hand, the values given for rhodopsin and fibronectin give an actual ratio of 4286. The explanation is that fibronectin is anchored in the membrane via interactions with cytoskeletal proteins, and its diffusion is severely restricted compared with that of rhodopsin.

7. a. Divalent cations increase T_m .
b. Cholesterol broadens the phase transition without significantly changing T_m .
c. Distearoylphosphatidylserine should increase T_m , due to increased chain length and also to the favorable interactions between the more negative PS head group and the more positive PC head groups.
d. Dioleoylphosphatidylcholine, with unsaturated fatty acid chains, will decrease T_m .
e. Integral proteins will broaden the transition and could raise or lower T_m , depending on the nature of the protein.
8. $\Delta G = RT \ln([C_2]/[C_1])$.
 $\Delta G = +4.0 \text{ kJ/mol}$.
9. $\Delta G = RT \ln([C_{\text{out}}]/[C_{\text{in}}]) + ZF\Delta\psi$.
 $\Delta G = +4.08 \text{ kJ/mol} - 2.89 \text{ kJ/mol}$.
 $\Delta G = +1.19 \text{ kJ/mol}$.
The unfavorable concentration gradient thus overcomes the favorable electrical potential, and the outward movement of Na^+ is not thermodynamically favored.
10. The student should note the structural similarities between digoxin and the cardiotonic steroids shown in Figure 9.50. Based upon the discussions within Section 9.8b one could assume that digoxin is used to treat cardiovascular issues like hypertension and that it is an inhibitor of the Na^+ , K^+ -ATPase transport protein.
11. One could solve this problem by going to the trouble of plotting the data in v vs. $[S]$, $1/v$ vs. $1/[S]$, or $[S]/v$ vs. $[S]$ plots, but it is simpler to examine the value of $[S]/v$ at each value of $[S]$. The Hanes–Woelf plot makes clear that $[S]/v$ should be constant for all $[S]$ for the case of passive diffusion. In the present case, $[S]/v$ is a constant value of $0.0588 \text{ (L/min)}^{-1}$. It is thus easy to recognize that this problem describes a system that permits passive diffusion of histidine.
12. This is a two-part problem. First calculate the energy available from ATP hydrolysis under the stated conditions; then use the answer to calculate the maximal internal fructose concentration against which fructose can be transported by coupling to ATP hydrolysis. Using a value of -30.5 kJ/mol for the ΔG° of ATP and the indicated concentrations of ATP, ADP, and P_i , one finds that the ΔG for ATP hydrolysis under these conditions (and at 298 K) is -52.0 kJ/mol . Putting the value of $+52.0 \text{ kJ/mol}$ into Equation 9.1 and solving for C_2 yields a value for the maximum possible internal fructose concentration of 1300 M! Thus, ATP hydrolysis could (theoretically) drive fructose transport against internal fructose concentrations up to this value. (In fact, this value is vastly in excess of the limit of fructose solubility.)
13. Each of the transport systems described can be inhibited (with varying degrees of specificity). Inhibition of the rhamnose transport system by one or more of these agents would be consistent with involvement of one of these transport systems with rhamnose transport. Thus, nonhydrolyzable ATP analogs should inhibit ATP-dependent transport systems, ouabain should specifically block Na^+ (and K^+) transport, uncouplers should inhibit

- proton gradient-dependent systems, and fluoride should inhibit the PTS system (via inhibition of enolase).
14. *N*-myristoyl lipid anchors are found linked only to N-terminal Gly residues. Only the peptide in (e) of this problem contains an N-terminal Gly residue.
 15. Only the peptide in (a) possesses a CAAX sequence (where C = Cys, A = aliphatic (Ala, Val, Leu, Ile), and X = any amino acid).
 16. The hydropathy plot of a soluble protein should show no substantial stretches of hydrophobic residues, except for the signal sequence.
 17. Amino acids with side chains that can be positively or negatively charged are most likely to be found in the interior of ion channels. This would include amino acids like aspartic acid, glutamic acid, histidine, arginine or lysine.
 18. The hydration of ions by water molecules would result in the masking of the ions' charges. Transmembrane channels that allow for the transport of hydrated ions would allow the transport of negatively and positively charged ions.
 19. Prolines are destabilizing to α -helices, and a short helix with a proline would not be likely to be stable. Where a proline occurs in an α -helix, the helix is bent or kinked. Helices with a proline kink tend to be longer than average, presumably because longer helices are more stable and more able to tolerate the loss of H bonds in the kink region.
 20. The structural consequences of a proline-induced kink in an α -helix are described in detail in the references provided in this problem.
 21. Porin proteins typically consist of 18-stranded β -barrels. With 9 to 11 residues per strand, about 180 to 200 residues would be required to form the barrel, with a roughly equivalent number required to form the loops between strands. (The maltoporin chains from *E. coli* consists of about 420 residues.) The transmembrane domain of Wza consists of eight α -helical segments with about 25 residues per helix, about 200 residues in all. Thus, the number of residues needed to create the transmembrane pore in these two proteins is about the same, even though the number of residues per membrane spanning segment is less for a β -strand (9 to 11) than for an α -helix (21 to 25).
 22. From Figure 9.30, the area within a typical "fenced" area is about $0.3 \mu\text{m} \times 0.3 \mu\text{m}$, or $9 \times 10^6 \text{ \AA}^2$. Dividing by $60 \text{ \AA}^2$, it appears that there are about 150,000 phospholipids in a monolayer-fenced area in the membrane (assuming a membrane of pure phospholipid, with no cholesterol, etc.).
 23. The lysine side chain N is about $5.5 \text{ \AA}$ from the α -carbon (about $1.1 \text{ \AA}$ per bond). If a Lys side chain was reoriented toward the membrane center, the maximum change in position relative to the membrane center would be $10\text{--}11 \text{ \AA}$ (assuming the position of the α -carbon did not change). Figure 9.15 indicates that the energy of a Lys side chain would change by $4kT$ over the $15\text{-}\text{\AA}$ distance from the membrane surface to the membrane center. A movement of $10 \text{ \AA}$ thus would correspond to two-thirds of $4kT$, or $8kT/3$ —almost twice the average translation kinetic energy of a molecule in the gas phase ($3kT/2$).
 24. In a hydrophobic environment, the aspartate carboxyl group will be more stable in the protonated (uncharged) form than in the deprotonated (charged) form.
 25. In a hydrophobic environment, the side chains of lysine and arginine would be more stable in their deprotonated (uncharged) forms than in the protonated (charged) forms. As a result, the pK_a values of these residues would be lowered significantly in a hydrophobic environment.
 26. Based on the discussion in problems 24 and 25 in this chapter, it would be reasonable to imagine that light-induced conformation changes could alter the pK_a values of the proton-transferring moieties in the protein. For example, a conformation change that made the environment around an Asp carboxyl more polar would reduce the pK_a of that group, promoting dissociation (i.e., proton release). An appropriate sequence of such changes could accomplish transmembrane proton transport.
 27. The torsion angles for transmembrane α -helices ($\varphi = -65^\circ$, $\psi = -40^\circ$) differ from those in water-soluble helices ($\varphi = -60^\circ$, $\psi = -45^\circ$). As a result, the carbonyl oxygens do not project outward from the helix axis as much in transmembrane helices, shielding the partial charge on the carbonyls and strengthening intra-helical H-bonds. In addition, the hydroxyls of serines and threonines in membrane proteins can form intra-helical H-bonds with the helix backbone, stabilizing these polar side chains during helix insertion in the membrane. Once in the membrane, Ser and Thr can form inter-helical H-bonds that stabilize helix clusters.
 28. Susanne Dobler and her colleagues have shown that substitution of an asparagine residue with histidine at position 122 (N122H) in the alpha subunit of Na^+, K^+ -ATPase dramatically lowers the binding affinity for cardiac glycosides such as ouabain, allowing the monarchs to thrive on their toxic diet. Dobler and colleagues have identified the same amino acid substitution in certain species of *Coleoptera* (beetles), *Diptera* (flies), and *Heteroptera* (typical bugs), and they have cited these mutations as an example of convergent evolution in insect adaptation.

29. ATP-dependent flippases are closely related to ion pumps like the plasma membrane Na^+, K^+ -ATPase and sarcoplasmic reticulum Ca^{2+} -ATPase (Section 9.8). All these transport enzymes have similar structures, including a transmembrane domain with ten transmembrane α -helices, and they all form an aspartyl-phosphate intermediate and undergo similar catalytic cycles. However, compared to the ATPases in Section 9.8 that transport simple monovalent and divalent cations, the flippases must transport comparatively very large substrates (such as phosphatidylserine) across the plasma membrane. This is referred to as the "giant substrate problem" Jens Andersen and his colleagues have suggested that the flippase known as ATP8A2 creates a hydrophobic gate that separates the entry and exit sites of the transported lipid and directs sequential formation and

annihilation of water-filled cavities that drive the hydrophilic phospholipid head group through the membrane, with the hydrocarbon chains following passively, still in the membrane lipid phase.

30. Structures of intermediate states of the sarcoplasmic reticulum Ca^{2+} -ATPase reveal some of the conformation changes that convert ATP hydrolysis free energy into transport of Ca^{2+} ions from the cytosol to the SR lumen. A structure of the E_1 state (figure) shows two bound Ca^{2+} ions coordinated by side chains of the M4, M5, M6, and M8 transmembrane helices.

In the E_1 state, the Ca^{2+} -binding sites are exposed to the cytosol, permitting Ca^{2+} binding. The M4 helix moves like a piston during the $\text{E}_1 \rightarrow \text{E}_2$ enzyme transition, carrying along the Ca^{2+} bound to the carboxyl group of Glu³⁰⁹ (E309 shown in the figure). In the E_2 state, Glu³⁰⁹ and the other Ca^{2+} site ligands are exposed to the opposite side of the membrane, facilitating Ca^{2+} release into the lumen. In this transition, the M4 helix moves toward the lumen like a piston or pump rod by 5.5 Å (see figure). In the $\text{E}_2 \rightarrow \text{E}_1$ transition of the dephosphoenzyme, M4 moves a similar distance in the opposite direction toward the cytosol. Similar movements of transmembrane helices are involved in the transport cycles of the other P-type ATPases.

31. Gram-negative bacteria have a cell wall which includes an outer membrane adorned with a tightly packed layer of lipopolysaccharide (LPS) molecules (Section 7.4). The transport of LPS from inner membrane to outer membrane is accomplished by a

seven-subunit protein complex (LptA-G). Subunits LptF, LptG, and LptB comprise an ABC transporter complex (Section 9.8). Yihua Huang and Changjiang Dong and their respective coworkers have determined the structures of the LptD and LptE subunits of the transporters from *S. typhimurium* and *S. flexneri*, respectively (see figure on next page. LptD in orange and pink; LptE in blue). The LptD–LptE dimer in the outer membrane functions to collect LPS molecules as they cross the intermembrane space and deposit them in the outer monolayer of the outer membrane. LPS molecules migrate from the inner membrane through LptC and LptA and through the jellyroll structure and into the cavity of the β -barrel. The LptE subunit is also inserted into that cavity, where it can interact with the sugar chains of the transported LPS molecules, as they traverse this cavity and are inserted into the outer leaflet of the outer membrane.

32. Point (b)—that proteins can be anchored to the membrane via covalent links to lipid molecules—was not part of the Singer–Nicolson fluid mosaic model.

Think-Pair-Share Question:

- drug concentration in reservoir
- hydrophobicity/hydrophilicity of drug molecule
- chemical nature of polymer layer
- thickness of polymer layer
- thickness of skin layer
- integrity of skin layer (healthy or wounded)

Chapter 10

1.

2. See Figure 10.14.

3. Pentose, D, aldose, β , furanose.

4.

5. $f_A = 0.29$; $f_G = 0.22$; $f_C = 0.25$; $f_T = 0.28$.6. The number of A and T residues = 3.14×10^9 each; the number of G and C residues = 2.68×10^9 each.

7. 5'-TAGTGACAGTTGCGAT-3'.

8. The structure is built from 3'-deoxyribonucleotides; not 2'-deoxyribonucleotides.

9. 5'-ATCGCAACTGTCAC-3'.

10. 5'-TACGGTCTAAGCTGA-3'.

11. There are two possibilities, a and b. (E = *EcoRI* site; B = *BamHI* site.) Note that b is the reverse of a.

a.

b.

12. a. GGATCCCGGGTCGACTGCAG;

b. GTCGACCCGGGATCCTGCAG.

SmaI products: a. GGATCCC and GGGTCGACTGCAG.

b. GTCGACCC and GGGATCCTGCAG.

13. Synthesis of a polynucleotide 100 residues long requires formation of 99 phosphodiester bonds. $\Delta G^{\circ'}$ for phosphodiester synthesis (assuming it is the same magnitude but opposite sign as that for phosphoric anhydride cleavage of an NTP to give NMP + PP_i) is +32.3 kJ/mol. $\Delta G^{\circ'}_{\text{overall}} = (99)(+32.3) = 3198 \text{ kJ/mol}$.

14. a. Hydrogen bonding and van der Waals interactions between amino acid side chains and DNA, and ionic interactions of amino acid side chains with the nucleic acid backbone phosphate groups. Double-helical DNA does not present hydrophobic regions for interaction with proteins because of base-pair stacking.

b. Proteins can recognize specific base sequences if they can fit within the major or minor groove of DNA and "read" the

H-bonding pattern presented by the edges of the bases in the groove. The dimensions of an α -helix are such that it fits snugly within the major groove of B-DNA; then, depending on the amino acid sequence of the protein, the side chains displayed on the circumference of the α -helix have the potential to form H bonds with H-bonding functions provided by the bases.

15. a. The restriction endonuclease must be able to recognize a specific nucleotide sequence in the DNA that has twofold rotational symmetry.

b. In order to read a base sequence within DNA, either the restriction endonuclease must interact with the bases by direct access, for example, by binding in the major groove, or the restriction endonuclease must be able to "read" the base sequence by indirect means, for example, if the base sequence imparts some local variation in the cylindrical surface of the DNA that the enzyme might recognize.

c. The restriction endonuclease must be able to cleave both DNA strands, often in a staggered fashion.

d. An obvious solution to the requirements listed in (a) and (c) would be a homodimeric subunit organization for restriction endonucleases.

16. a. The ribose group of nucleosides greatly increases the water solubility of the base.

b. Ribose has fewer hydroxyl groups and thus less likelihood to undergo unwanted side reactions.

c. The absence of the 2-OH in 2-deoxyribose leads to a polynucleotide sugar-phosphate backbone that is more stable because it is not susceptible to alkaline hydrolysis.

17. 963,520,000 base pairs.

18. a. Phosphate groups bear a negative electrical charge at neutral pH.

b. Cleavage of phosphoric anhydride bonds is strongly exergonic and can provide the thermodynamic driving force for diverse metabolic reactions.

c. Cleavage of phosphoric anhydride bonds is strongly exergonic and can provide the thermodynamic driving force for phosphodiester bond formation in polynucleotide synthesis.

19. Once in every 4.4×10^{12} nucleotides.

20. A DNA sequence 16 nucleotides long.
21. The strategy for protein sequencing by Edman degradation, as described in Figure 4.8a and Section 5.4, could be adapted, replacing Edman's reagent with snake venom phosphodiesterase acting on an immobilized nucleotide sequence.
22. 3.59×10^{12} D.
23. The use of bases as "information symbols" in metabolism allows the cell to allocate portions of its phosphorylation potential (as total NTP) to dedicated tasks, as in GTP for protein synthesis, CTP for phospholipid synthesis, UTP for carbohydrate synthesis, with ATP serving the central role. Enzymes in these pathways selectively bind the proper nucleotide through recognition of the particular base.
24. The most prominent structural feature of the DNA double helix in terms of structural complementarity is found in the canonical base-pairing of A with T and G with C. Base pairing is essential to DNA replication (preservation of the genetic information) and transcription (expression of genetic information).

Think-Pair-Share Question:

If one considers every A/T combination as "0" and every C/G combination as "1," then this dsDNA code would read:

From left to right:

01001011001100001111110011110000010101110100010

From right to left:

01000101111010100000111100111110000110011010010

If one considers every A/T combination as "1" and every C/G combination as "0," then this dsDNA code would read:

From left to right:

101101001100111100000011000011111010100001011101

From right to left:

10111010000101011110000110000001111001100101101

Chapter 11

1.

2. Sanger's method of DNA sequencing.

3. Original nucleotide: 5'-GTTTAAATTTGTCATTAACC.

4. a. 10.5 base pairs per turn; b. $\Delta\phi = 34.3^\circ$; c (true repeat) = 6.72 nm.

5. 27.3 nm; 122 base pairs.

6. 4.35 μm .

7. $L_0 = 160$. If $W = -12$, $L = T + W = 160 + (-12) = 148$.
 $\sigma = \Delta L/L_0 = -12/160 = -0.075$.

8. For 1 turn of B-DNA (10 base pairs): $L_B = 1.0 + W_B$.
 For Z-DNA, 10 base pairs can form only 10/12 turn (0.833 turn), and $L_Z = 0.833 + W_Z$.
 For the transition B-DNA to Z-DNA, strands are not broken, so $L_B = L_Z$; that is, $1.0 + W_B = 0.833 + W_Z$, or $W_Z - W_B = +0.167$.
 (In going from B-DNA to Z-DNA, the change in W , the number of supercoils, is positive. This result means that, if B-DNA contains negative supercoils, their number will be reduced in

Z-DNA. Thus, all else being equal, negative supercoils favor the B $\rightarrow$ Z transition.)

9. $6 \times 10^9 \text{ bp} / 200 \text{ bp} = 3 \times 10^7$ nucleosomes.

The length of B-DNA $6 \times 10^9 \text{ bp}$ long = $(0.34 \text{ nm})(6 \times 10^9) = 2.04 \times 10^9 \text{ nm}$ (more than 2 meters!). The height of 3×10^7 nucleosomes = $(6 \text{ nm})(3 \times 10^7) = 18 \times 10^7 \text{ nm}$ (0.18 meter).

10. From Figure 11.35, similarly shaded regions indicate complementary sequences joined via intrastrand hydrogen bonds:

11. Increasing order of T_m : yeast < human < salmon < wheat < *E. coli*.

12. In 0.2 M Na^+ , $T_m(^{\circ}\text{C}) = 69.3 + 0.41(\%G + C)$:

Rats ($\%G + C$) = 40%, $T_m = 69.3 + 0.41(40) = 85.7^{\circ}\text{C}$

Mice ($\%G + C$) = 44%, $T_m = 69.3 + 0.41(44) = 87.3^{\circ}\text{C}$

Because mouse DNA differs in GC content from rat DNA, they could be separated by isopycnic centrifugation in a CsCl gradient.

13. GC content = 0.714 (from Table 10.1 and equations used in problem 3, Chapter 10). $\rho = 1.660 + 0.098(\text{GC}) = 1.730 \text{ g/mL}$.
 14. See Figure 11.37 and compare your structure with the base pair formed between G18 and $\psi 55$ in yeast phenylalanine tRNA, which has a single H bond between the 2-amino group of G ($2\text{-NH}_2 \cdots \text{O}=\text{C}$) and the O atom at position 4 in ψ .
 15. Assuming the plasmid is in the B-DNA conformation, where each pair contributes 0.34 nm to the length of the molecule, the circumference of a perfect circle formed from pBR322 would be $(0.34 \text{ nm/bp})(4363 \text{ bp}) = 1483 \text{ nm} = 1.48 \mu\text{m}$.

The *E. coli* K12 chromosome laid out as a perfect circle would have a circumference of $(0.34 \text{ nm/bp})(4,639,000 \text{ bp}) = 1,577,260 \text{ nm} = 1.58 \text{ mm}$.

The diameter of a B-DNA molecule is about 2.4 nm (see Table 11.2). For pBR322, the length/diameter ratio would be $1480/2.4 = 616.7$. For the *E. coli* K12 chromosome, the length/diameter ratio would be $1,577,260/2.4 = 657,192$.

16. (a) Z-DNA; (b) cruciform; (c) triplex DNA; (d) tRNA; (e) type-II restriction endonuclease site.
 17. a. Serine, threonine, asparagine, glutamine: these amino acids contain functional groups with dipoles that are capable of forming hydrogen bonds water molecules or other functional groups with dipoles.
 b. Lysine, arginine, histidine: these amino acids contain positively charged amino acids capable of interaction with the negatively charged polyphosphate backbone of DNA.
 c. Tryptophan: the structure of this amino acid contains fused rings with one a heterocyclic ring suitable for intercalating with the base structures of DNA.
 18. Rely on the features in Figure 11.35 to draw a tRNA cloverleaf with the anticodon positioned at nucleotides 34 to 36: CUG.

20. Erythromycin is within the palm of the mitten.
 21. a. Tumor necrosis factor
 b. 31,575,565 bp to 31,578,336 bp
 c. 4 exons
 d. 233 amino acid residues
 22. The DNA in such a thermophilic organism would be subjected to very high temperatures that might denature the DNA. Because G:C base pairs are more heat stable than A:T base pairs, one might expect DNA from a thermophilic organism to have a high G + C content.
 23. DNA is the material of heredity; that is, genetic information. This information is encoded in the sequence of bases in DNA, so this is its most important structural feature. The double-stranded nature of DNA and the complementary base sequence of the two strands are also crucial structural features in the transmission of genetic information through DNA replication. Beyond these points, one might cite the structural features of DNA Cq that impart stability to the double helix and structural aspects that render DNA less susceptible to degradation.

24. a. Total weight = 6 pg; total length = 1.92 m.

- b. 1.25×10^{16} bp
 c. 1.25×10^{-5} g
 d. 4.685×10^{20} bp
 e. 0.469 g

25. Hyperchromic shift: DNA > RNA, because it is entirely double-stranded and RNA is only partially double-stranded.

Colligative properties: Such properties depend on the number of molecules per gram. DNA molecules are much larger than RNA molecules, so there are fewer of them per gram, and their colligative properties would be less.

Inverted repeats: DNA does not depend on inverted repeats to form secondary structure, but RNA does.

T_m : T_m is the temperature of transition from double-stranded to single-stranded. Virtually all of the bases in DNA are base paired and the T_m depends on relative G:C content. Fewer bases are paired in RNA, so T_m is less definitive.

Buoyant density: RNA is more dense than DNA (see the Buoyant Density of DNA box on page 368).

Chemical and physical stability: DNA lacks a 2'-OH on its ribose rings, so it is much less susceptible to hydrolysis. DNA has been recovered from fossil remains over a million years old.

27.

Think-Pair-Share Question:

From the four different results one can figure out that the overall sequence should read:

TACCGTTAGGCTTGATCC and the original DNA segment would have a sequence of **GGATGCAAGCCTAACGGTA**

Chapter 12

- Cloning: vector, endonuclease, ligase, linkers,
 PCR: DNA polymerase, primer
 RNAi: dicer, siRNA, RISC, passenger strand, guide strand
 CRISPR-Cas9: endonuclease, gRNA, PAM
- Protein: endonuclease, ligase, DNA polymerase, reverse transcriptase, dicer, RISC, Cas9
 RNA: siRNA, passenger strand, guide strand, gRNA
 DNA: vector, linkers, BAC, YAC, HAC, primer, expressed sequence tags, PAM

3. Linear and circular DNA molecules consisting of one or more copies of just the genomic DNA fragment; linear and circular DNA molecules consisting of one or more copies of just the vector DNA; linear and circular DNA molecules containing one or more copies of both the genomic DNA fragment and plasmid DNA.

4.

-GAATTC	CCCGGG	TCTAGA	CTGCAG
<i>EcoRI</i>	<i>BamHI</i>	<i>SalI</i>	<i>SphI</i>
	<i>SmaI</i>	<i>XbaI</i>	<i>PstI</i>

5. a. AAGCTTGAGCTCGAGATCTAGATCGAT

HindIII *XhoI* *XbaI*
SacI *BglIII* *ClaI*

b.

Vector: *HindIII*: 5'-A.....-gap.....CGAT-3': *ClaI*
 3'-TTCGA...-gap.....TA-5'

Fragment: *HindIII*: 5'-AGCTT(NNNN-etc-NNNN)AT-3'
 3'-A(NNNN-etc-NNNN)TAGC-5'

6. N = 3480.

7. N = 10.4 million.

8. N = 367,665

9. 5'-ATGCCGTAGTCGATCAT and
 5'-ATGCTATCTGTCCTATG.

11. 5'-GUUAUA-3' or 5'-UUAUAC-3' or 5'-UAUACA-3'

12. -Thr-Met-Ile-Thr-Asn-Ser-Pro-Asp-Pro-Phe-Ile-His-Arg-Arg-Ala-Gly-Ile-Pro-Lys-Arg-Arg-Pro...

The junction between β -galactosidase and the insert amino acid sequence is between Pro and Asp, so the first amino acid encoded by the insert is Asp. (The polylinker itself codes for Asp just at the *BamHI* site, but in constructing the fusion, this Asp and all of this downstream section of polylinker DNA is displaced to a position after the end of the insert.)

13. 5'(G)AATTCNGGNATGCAYCCNGGNAAR_C^TT_N^YGCNAGY TGG-TTYGTNGGGAATTCTN-

(Note: The underlined triplet AGY represents the middle Ser residue. Ser codons are either AGY or TCN [where Y =

pyrimidine and N = any base]; AGY was selected here so that the mutagenesis of this codon to a Cys codon [TGY] would involve only an A $\rightarrow$ T change in the nucleotide sequence.)

Because the middle Ser residue lies nearer to the 3'-end of this *Eco*RI fragment, the mutant primer for PCR amplification should encompass this end. That is, it should be the primer for the 3 $\rightarrow$ 5' strand of the *Eco*RI fragment:

where the mutated Ser $\rightarrow$ Cys triplet is underlined, NNN = several extra bases at the 5'-end of the primer to place the *Eco*RI site internal, N_c = the nucleotide complementary to the nucleotide at this position in the 5' $\rightarrow$ 3' strand, and R_c = the pyrimidine complementary to the purine at this position in the 5' $\rightarrow$ 3' strand.

14. The number of sequence possibilities for a polymer is given by x^y , where x is the number of different monomer types and y is the number of monomers in the oligomers. Thus, for RNA oligomers 15 nucleotides long: $x^y = 4^{15} = 1,073,741,824$. For pentapeptides, $x^y = 20^5 = 3,200,000$.
15. a. 16 b. 64 c. $N = 4^x$ in which N is the number of possible oligonucleotides and x is the length of the oligonucleotide.

16. See Figure 12.19. You would need a *GAL4*-deficient yeast strain expressing a fusion protein composed of the *GAL4* DB domain fused with a cytoskeletal protein (such as actin or tubulin) to serve as the bait. These *GAL4*⁻ cells would be transformed with a cDNA library of human epithelial proteins constructed so that the human proteins were expressed as *GAL4* TA fusion proteins; these fused proteins are the target. Interaction of a target protein with the cytoskeletal protein fused to the *GAL4* DB domain will lead to *GAL4*-driven expression of the *lacZ* gene, whose presence can be revealed by testing for β -galactosidase activity.
17. You would use a *GAL4* negative yeast strain containing two plasmids. One plasmid coding for the DB domain of *GAL4* fused with protein A and one plasmid coding for the TA domain fused with protein B. You would grow this yeast strain in media containing high levels of Ca²⁺ or in the absence or presence of Ca²⁺-channel opening agents (see Section 9.8). If proteins A and B interact the *lacZ* reporter gene will be activated. See Figure 12.19.
18. See Figure 12.10 for isolation of mRNA and Figure 12.11 for preparation of a cDNA library from mRNA. The mRNA would be isolated, and the cDNA libraries would be prepared from two batches of yeast cells, one grown aerobically and one grown anaerobically.
19. See Figure 12.12. Differently labeled single-stranded cDNA from separate libraries prepared from aerobically versus anaerobically grown yeast cells would be hybridized with a DNA microarray (gene chip) of yeast genes.

20. An antibody against hexokinase A could be used to screen the yeast cDNA library to identify a yeast colony expressing this protein (see discussion in Section 12.3 on Screening cDNA Expression Libraries with Antibodies). Once a sample of the putative yeast hexokinase A protein was isolated, its identity could be confirmed by peptide mass fingerprinting using mass spectrometry (see in Section 5.4 on "Peptide Mass Fingerprinting").
21. The experiment in problem 19 identified the cDNA clone for the protein, but this clone will not have the regulatory elements (promoter) necessary for the experiment at hand. Using the cDNA clone as a probe, the genomic clone for this *nox* gene could be identified in a yeast genomic library. Cloning and sequencing a genomic clone would identify putative promoter regions that could be fused to the coding region of green fluorescent protein (GFP) to create a reporter gene construct (see Figure 12.18) that would "light up" more and more as oxygen levels declined.
22. AUGCAGGAGGGUGGCGAGAGGGGCCGAGAUUGG_GUUUUACAGCUAUGCU-
23. 5'-AAUCGCAUUGCAGCUUC-3'
24. a.

b. The U base is still attached to a deoxyribose.

c.

25. This purpose of this question is to encourage students to explore the extensive genome databases. Course instructors can adapt this question to a variety of purposes.
26. Insertion of DNA at any of the following restriction sites would render cells harboring the recombinant plasmid ampicillin-sensitive: *Ssp*I, *Sca*I, *Pvu*I, *Pst*I, and *Ppa*I.
27. The respective codons are Trp = UGG; Cys = UGC and UGU. Thus, changing only the third base G in the Trp codon to a pyrimidine (either C or U) would yield a Cys codon. In this case, there are now six differences in codon possibilities, so $2^6 = 64$ different oligonucleotides must be synthesized.

Think-Pair-Share Question:

- Using "classic" organic/medicinal chemistry, find/design an inhibitor for this enzyme.
- Using RNAi technology with a specifically designed guide strand to target the RNA transcript of this gene. The guide strand should be complementary to the portion of the RNA transcript that contains the mutation.
- Using any of the CRISPR-Cas9 approaches to either eliminate the gene or to alter/reverse the mutation back to the "normal" status.

Chapter 13

- Enzyme A has similar affinities for D-hexose carbohydrates, but a lesser affinity for D-ribose. Enzyme B has a higher affinity for D-ribose and a lesser affinity for the D-hexoses. Enzyme B acts specifically on D-ribose.
- $v/V_{\max} = 0.8$.
- $v = 91 \mu\text{mol/mL} \cdot \text{sec}$.
- $K_s = 1.43 \times 10^{-5} M$; $K_m = 3 \times 10^{-4} M$. Because k_2 is 20 times greater than k_{-1} , the system behaves like a steady-state system.
- If the data are graphed as double-reciprocal Lineweaver–Burk plots:
 - $V_{\max} = 51 \mu\text{mol/mL} \cdot \text{sec}$ and $K_m = 3.2 \text{ mM}$.
 - Inhibitor (2) shows competitive inhibition with a $K_i = 2.13 \text{ mM}$. Inhibitor (3) shows noncompetitive inhibition with a $K_i = 4 \text{ mM}$.
- For inhibitor A: $K_i' = 283 \text{ mM}$ and $K_i = 24.3 \text{ mM}$
For inhibitor B: $K_i' = 8 \text{ mM}$ and $K_i = 13.1 \text{ mM}$
-

- In (a), $V_{\max}$ doubles, but K_m is constant.
 - In (b), $V_{\max}$ halves, but K_m is constant.
 - In (c), $V_{\max}$ is constant, but the apparent K_m increases.
 - In (d), $V_{\max}$ decreases, but K_m is constant.
 - In (e), $V_{\max}$ decreases, K_m decreases, but the ratio $K_m/V_{\max}$ is constant.
- The slope is given by $K_m^B/V_{\max}(K_S^A/[A] + 1)$.
 - y-intercept = $((K_m^A/[A]) + 1)/V_{\max}$.
 - The horizontal and vertical coordinates of the point of intersection are $1/[B] = -K_m^A/K_S^A K_m^B$ and $1/v = 1/V_{\max}(1 - (K_m^A/K_S^A))$.
 - Top left: (1) Competitive inhibition (I competes with S for binding to E). (2) I binds to and forms a complex with S.
Top right: (1) Pure noncompetitive inhibition. (2) Random, single-displacement bisubstrate reaction, where A doesn't affect B binding, and vice versa. (Other possibilities include [3] Irreversible inhibition of E by I; [4] $1/v$ vs. $1/[S]$ plot at two different concentrations of enzyme, E.)
Bottom left: (1) Mixed noncompetitive inhibition. (2) Ordered single-displacement bisubstrate mechanism.
Bottom right: (1) Uncompetitive inhibition. (2) Double-displacement (ping-pong) bisubstrate mechanism.
 - Clancy must drink 694 mL of wine, or about one 750-mL bottle.
 - $K_S = 5 \mu M$; b. $K_m = 30 \mu M$; c. $k_{\text{cat}} = 5 \times 10^3 \text{ sec}^{-1}$; d. $k_{\text{cat}}/K_m = 1.67 \times 10^8 M^{-1} \text{ sec}^{-1}$; e. Yes, because k_{cat}/K_m approaches the limiting value of $10^9 M^{-1} \text{ sec}^{-1}$; f. $V_{\max} = 10^{-5} \text{ mol/mL} \cdot \text{sec}$; g. $[S] = 90 \mu M$; h. $V_{\max}$ would equal $2 \times 10^{-5} \text{ mol/mL} \cdot \text{sec}$, but $K_m = 30 \mu M$, as before.
 - $V_{\max} = 132 \mu\text{mol mL}^{-1} \text{ sec}^{-1}$; b. $k_{\text{cat}} = 44,000 \text{ sec}^{-1}$; c. $k_{\text{cat}}/K_m = 24.4 \times 10^8 M^{-1} \text{ sec}^{-1}$; d. Yes! k_{cat}/K_m actually exceeds the theoretical limit of $10^9 M^{-1} \text{ sec}^{-1}$ in this problem; e. The rate at which E encounters S; the ultimate limit is the rate of diffusion of S.
 - $V_{\max} = 1.6 \mu\text{mol mL}^{-1} \text{ sec}^{-1}$; b. $v = 1.45 \mu\text{mol mL}^{-1} \text{ sec}^{-1}$; c. $k_{\text{cat}}/K_m = 1.6 \times 10^8 M^{-1} \text{ sec}^{-1}$; d. Yes.
 - $V_{\max} = 6 \mu\text{mol mL}^{-1} \text{ sec}^{-1}$; b. $k_{\text{cat}} = 1.2 \times 10^6 \text{ sec}^{-1}$; c. $k_{\text{cat}}/K_m = 1 \times 10^8 M^{-1} \text{ sec}^{-1}$; d. Yes! k_{cat}/K_m approaches the theoretical limit of $10^9 M^{-1} \text{ sec}^{-1}$; e. The rate at which E encounters S; the ultimate limit is the rate of diffusion of S.
 - $V_{\max} = 64 \mu\text{mol mL}^{-1} \text{ sec}^{-1}$; b. $k_{\text{cat}} = 1.28 \times 10^4 \text{ sec}^{-1}$; c. $k_{\text{cat}}/K_m = 1.4 \times 10^8 M^{-1} \text{ sec}^{-1}$; d. Yes! k_{cat}/K_m approaches the theoretical limit of $10^9 M^{-1} \text{ sec}^{-1}$.
 - $V_{\max} = 120 \text{ mmol mL}^{-1} \text{ sec}^{-1}$; b. $v = 104.7 \text{ mmol mL}^{-1} \text{ sec}^{-1}$; c. $k_{\text{cat}}/K_m = 3.64 \times 10^8 M^{-1} \text{ sec}^{-1}$; d. Yes! k_{cat}/K_m approaches the theoretical limit of $10^9 M^{-1} \text{ sec}^{-1}$.
 - For enzyme A: catalytic efficiency = $450 (\text{s mM})^{-1}$.
For enzyme B: catalytic efficiency = $576 (\text{s mM})^{-1}$.
 - Starting from $V_{\max}^f = k_2[E_T]$ and $V_{\max}^r = k_{-1}[E_T]$ for the maximal rates of the forward and reverse reactions, respectively, and the Michaelis constants $K_m^S = (k_{-1} + k_2)/k_1$ and $K_m^P = (k_{-1} + k_2)/k_{-2}$ for S and P, respectively,
$$v = (V_{\max}^f [S]/K_m^S) - (V_{\max}^r [P]/K_m^P) / (1 + [S]/K_m^S + [P]/K_m^P)$$
 - At equilibrium, $v = 0$ and $K_{\text{eq}} = [P]/[S] = V_{\max}^f K_m^P / V_{\max}^r K_m^S$.
 - S is the preferred substrate; its K_m is smaller than the K_m for T, so a lower [S] will give $v = V_{\max}/2$, compared with [T].
 - k_{cat}/K_m defines catalytic efficiency. k_{cat}/K_m for S = $2 \times 10^7 M^{-1} \text{ sec}^{-1}$; k_{cat}/K_m for T = $4 \times 10^7 M^{-1} \text{ sec}^{-1}$, so the enzyme is a more efficient catalysis with T as substrate.

20. As lemon juice is rich in organic acids, the acidity of the lemon juice may denature proteins in the sliced apples, including the polyphenol oxidase, and may render this enzyme inactive.
21. Maximum enzymatic activity is obtained (and detected) if $[S]$ is much higher than K_m .
22. Increased temperature may denature an enzyme and render it inactive.
23. a. Because the enzyme shows maximal activity at or below 40°C , it seems more like a mammalian enzyme than a plant enzyme, which would be expected to have a broader temperature optimum because plants experience a broader range of temperatures.
- b. An enzyme from a thermophilic bacterium growing at 80°C would show an activity versus temperature profile similar to his one but shifted much farther to the right.

Think-Pair-Share Question:

a.

- b. The number of moles can be calculated by dividing the amount of poly- or oligosaccharide (0.5 g) by its molecular mass. As the polysaccharide is degraded, the molecular mass declines, but the amount of poly- or oligosaccharide remains at 0.5 g. As a function of the reaction time one divides 0.5 g with the appropriate molecular mass to obtain the number of moles as a function of the reaction time. The velocity of the reaction can be determined as $D\text{moles}/D\text{time}$. One can plot the number of moles as a function of reaction time and obtain the velocity of the reaction from the slope of the best-fitting line through the data points (linear regression). This is shown in the next chart with linear regression results shown for polysaccharide D.
- c. The slopes in chart c) follow the same pattern as the slopes for chart b). This indicates that the slope of the plot of $(1/\text{mol mass})$ as a function of reaction time is another, relative, measure of the velocity of the reaction. This is useful if the amount of polysaccharide is not known.

Chapter 14

1. a. Nucleophilic attack by an imidazole nitrogen of His⁵⁷ on the $-\text{CH}_2-$ carbon of the chloromethyl group of TPCK covalently inactivates chymotrypsin. (See *The Student Solutions Manual, Study Guide and Problems Book* for structures.)
- b. TPCK is specific for chymotrypsin because the phenyl ring of the phenylalanine residue interacts effectively with the binding pocket of the chymotrypsin active site. This positions the chloromethyl group to react with His⁵⁷.
- c. Replacement of the phenylalanine residue of TPCK with arginine or lysine produces reagents that are specific for trypsin.
2. a. The structures proposed by Craik et al., 1987 (*Science* 237:905–907) are shown here. (If you look up this reference, note that the letters A and B of the figure legend for Figure 3 of this article actually refer to parts B and A, respectively. Reverse either the letters in the figure or the letters in the figure legend and it will make sense.)

- b. Asn¹⁰² of the mutant enzyme can serve only as a hydrogen-bond donor to His⁵⁷. It is unable to act as a hydrogen-bond acceptor, as aspartate does in native trypsin. As a result, His⁵⁷ is unable to act as a general base in transferring a proton from

Ser¹⁹⁵. This presumably accounts for the diminished activity of the mutant trypsin.

3. Oxygen is more electronegative than sulfur, and serine is capable of making stronger hydrogen bonds. Electrostatics and mechanistic preferences may explain the preferences for serine and cysteine. See Gisdon, F. J., et al., 2022. Serine and cysteine peptidases: so similar, yet different. How the active-site electrostatics facilitates different reaction mechanisms. *J. Phys. Chem. B* **126**:4035–4048. The presence of the methyl group in proximity to the alcohol within threonine may lead to steric hindrance in enzymatic reactions involving the alcohol functional group.

5.

6. The enzyme-catalyzed rate is given by:

$$v = k_e[ES] = k_e'[EX^\ddagger]$$

$$K_e^\ddagger = \frac{[EX^\ddagger]}{[ES]}$$

$$\Delta G_e^\ddagger = -RT \ln K_e^\ddagger$$

$$K_e^\ddagger = e^{-\Delta G_e^\ddagger/RT}$$

$$[EX^\ddagger] = K_e^\ddagger[ES] = e^{-\Delta G_e^\ddagger/RT}[ES]$$

So $k_e[ES] = k_e'e^{-\Delta G_e^\ddagger/RT}[ES]$

or $k_e = k_e'e^{-\Delta G_e^\ddagger/RT}$

Similarly, for the uncatalyzed reaction:

$$k_u = k_u'e^{-\Delta G_u^\ddagger/RT}$$

4. a. The usual explanation for the inhibitory properties of pepstatin is that the central amino acid, statine, mimics the tetrahedral amide hydrate transition state of a good pepsin substrate with its unique hydroxyl group.
- b. Pepsin and other aspartic proteases prefer to cleave peptide chains between a pair of hydrophobic residues, whereas HIV-1 protease preferentially cleaves a Tyr-Pro amide bond. Because pepstatin more closely fits the profile of a pepsin substrate, we would surmise that it is a better inhibitor of pepsin than of HIV-1 protease. In fact, pepstatin is a potent inhibitor of pepsin ($K_i < 1$ nM) but only a moderately good inhibitor of HIV-1 protease, with a K_i of about 1 μ M.

Assuming that $k_u' \cong k_e'$

Then $\frac{k_e}{k_u} = \frac{e^{-\Delta G_e^\ddagger/RT}}{e^{-\Delta G_u^\ddagger/RT}}$

$$\frac{k_e}{k_u} = e^{(\Delta G_u^\ddagger - \Delta G_e^\ddagger)/RT}$$

7. This problem is solved best by using the equation derived in problem 4.

$$\frac{k_e}{k_u} = e^{(\Delta G_u^\ddagger - \Delta G_e^\ddagger)/RT}$$

Using this equation, we can show that the difference in activation energies for the uncatalyzed and catalyzed hydrolysis reactions ($\Delta G_u - \Delta G_e$) is 92 kJ/mol.

8. Trypsin catalyzes the conversion of chymotrypsinogen to π -chymotrypsin, and chymotrypsin itself catalyzes the conversion of π -chymotrypsin to α -chymotrypsin.
9. The mechanism suggested by Lipscomb is a general base pathway in which Glu²⁷⁰ promotes the attack of water on the carbonyl carbon of the substrate:

10. Using the equation derived in problem 4, it is possible to calculate the ratio k_e/k_u as 1.86×10^{12} .
11. If the concentration of free enzyme is equal to the concentration of enzyme–ligand complex, the concentration of ligand would be $1 \times 10^{-27} \text{ M}$. This corresponds to 1.67×10^3 liters per molecule.
12. a. The dissociation constant K_S for compound B is low indicating that the compound can bind into the active site of the enzyme (stronger than compound A). However, as compound B is lacking the carbonyl group ($\text{C}=\text{O}$) it can not proceed with the reaction as shown for compound A. This leads to higher values for K_T for compound B.
b. When A and B are mixed together with the enzyme, compound B could act as a competitive inhibitor for the enzyme's action on compound A.
13. $\Delta G = -154 \text{ kJ/mol}$. This value is intermediate between noncovalent forces (H bonds are typically 10 to 30 kJ/mol) and covalent bonds (300 to 400 kJ/mol).
14. a. The total amount of enzyme is given by $[\text{E}]_T = [\text{E}] + [\text{EL}]$.
b. K_D represents the concentration of L needed to achieve 50% saturation of the enzyme similar as for K_M .
15. $\lambda = 0.63 \text{ \AA}$
16. As discussed in Section 6.4g organic solvents, detergents or agents like urea or guanidine hydrochloride can denature proteins and render enzymes inactive.
17. Assuming that the rate of gluconeogenesis would be equal to the slowest step in the pathway, with $k = 2 \times 10^{-20}/\text{sec}$, and

assuming a cellular concentration of fructose-1,6-bisphosphatase of 0.031 (see Table 18.2), the rate of sugar synthesis would be $2 \times 10^{-20}/\text{sec} \times 0.031 \text{ mM}$, or $6.2 \times 10^{-22} \text{ mM/sec}$. Assuming a total human cell volume of 40 L, this corresponds to 2.48×10^{-23} moles glucose/sec. Assuming 30 ATP per glucose (under cellular conditions) and 50 kJ/mole of ATP hydrolyzed, we find that the rate of energy production is $(2.48 \times 10^{-23}) \times (30 \text{ ATP/glucose}) \times (30.5 \text{ kJ/mole})$, or $2.269 \times 10^{-20} \text{ kJ/sec}$. Converting to kilocalories and years, we find that the time to synthesize the needed glucose with an uncatalyzed reaction would be 2.8×10^{15} years, or roughly 200,000 times the lifetime of the universe so far.

18. The correct answer is c. The stomach is a very acidic environment, whereas the small intestine is slightly alkaline. The lower part of the figure shows that enzyme X has optimal activity near pH 2, whereas enzyme Y works best at a pH near 8.
19. The correct answer is a. The two enzymes have nonoverlapping pH ranges, so it is highly unlikely that they could operate in the same place at the same time.
20. The correct answer is b. Only enzyme A has a temperature range that encompasses human body temperature (37°C).
21. The correct answer is d. The activities of the two enzymes overlap between 40° and 50°C .
22. The correct answer is c. We have no information on the pH behavior of enzymes A and B, nor on the behavior of X and Y as a function of temperature. The only answer that is appropriate to the data shown is c.
23. The only possible answer is b, because a “leveling off” implies that all the enzyme is saturated with S.
24. The correct answer is c. In order to bring the substrate into the transition state, an enzyme must enjoy environmental conditions that favor catalysis. There is no activity apparent for enzyme Y below pH 5.5.
25. Serine and aspartic proteases both exhibit general acid–base catalysis, but only the serine proteases employ covalent catalysis. The steps that lead to peptide bond cleavage are similar in the two mechanisms: Proton abstraction forms a nucleophilic species that attacks the carbonyl carbon of the bond to be cleaved, and then protonation of the amide nitrogen facilitates bond cleavage.
Observation of burst kinetics with model substrates (esters) could provide evidence for a covalent mechanism. X-ray crystallography and NMR could provide evidence for involvement of low-barrier hydrogen bonds. (See Kidd, R. E., 1999. *Protein Science* 8:410–417.)
26. The published structure of the PAF-acetylhydrolase reveals that Ser²⁷³ is the active site residue that initiates the esterase reaction:

27. The serine- β -lactamase mechanism involves nucleophilic attack by a Ser-O⁻ as shown below:

Metallo- β -lactamases require zinc for activity and catalysis. In the recently discovered New Delhi metallo- β -lactamase, a hydroxyl anion that is stabilized by two Zn²⁺ ions cleaves the β -lactam ring by nucleophilic attack. The mechanism is similar to the serine- β -lactamase, except that the stabilized hydroxyl group is the attacking nucleophile.

Step 2: Using Figure 14.12 as a model show the function of the histidine residue to catalyze the base hydrolysis of the ester bond between serine and the remaining portion of the substrate; completing the hydrolysis of the substrate.

- b. The presence of the phenylalanine residue in the active site may affect the substrate preference of the enzyme: preferring substrates with a hydrophobic portion close to the ester bond. Structure A may be too hydrophilic to bind in the active site, while structure C, though hydrophobic, may be too “bulky” to fit into the active site. Structure B may have the optimal hydrophobicity and size to interact with the phenylalanine residue of the active site and promote optimal binding and chemical reactivity.

Chapter 15

- As [P] rises, the rate of P formation shows an apparent decline, as enzyme-catalyzed conversion of $P \rightarrow S$ becomes more likely.
 - Availability of substrates and cofactors.
 - Changes in [enzyme] due to enzyme synthesis and degradation.
 - Covalent modification.
 - Allosteric regulation.
 - Specialized controls, such as zymogen activation, isozyme variability, and modulator protein influences.
- Induction will lead to an increase in the amount of enzyme and thus an increase in the metabolic activity due to the enzyme. Repression will have the opposite effect.

28. Dorothee Kern and her colleagues have used a combination of nuclear magnetic resonance measurements, pre-steady-state kinetics, molecular dynamics simulations, and X-ray crystallography of active complexes to show that an essential Mg²⁺ ion in the active site plays two very different roles in catalysis of the kinase reaction. During the reaction, the active site of the enzyme adopts both open and closed conformations. The open conformation is solvent-accessible, and in the closed conformation the γ -phosphoryl group is positioned for transfer.

The single Mg²⁺ ion at the active site plays two very different roles: it increases the rate of phosphoryl transfer in the active site by a factor of 10⁵, an effect that depends on limiting active site dynamics (motions) so that the active site geometry favors phosphoryl transfer. The second role of Mg²⁺ is essentially opposite in nature—it greatly accelerates the lid-opening conformation change (by a factor of 10³), thus facilitating product release at the end of the reaction cycle.

Think-Pair-Share Question:

- a. Step 1: Using Figure 14.20 as a model, show the covalent binding of the alcohol group of serine to the substrate creating an ester bond between the substrate and serine as shown for structure B.

- If the proteases were made as active enzymes they would digest the proteins inside the cells of the pancreas, destroying them from within.
- By regulating the first (or an early) enzyme of a pathway the decision to commit the substrate to the entire pathway, and the synthesis of product F, can be made before intermediates B, C, D, and E accumulate, thus saving the cell from the buildup of unneeded metabolites.
- Monod, Wyman, Changeux allosteric system:

Lineweaver–Burk plot

Hanes–Woolf plot

6. Using the curves for negative cooperativity, as shown in Figure 15.8, as a guide:

7. For $n = 2.8$, $Y_{\text{lungs}} = 0.98$ and $Y_{\text{capillaries}} = 0.77$.

For $n = 1.0$, $Y_{\text{lungs}} = 0.79$ and $Y_{\text{capillaries}} = 0.61$.

Thus, with an n of 2.8 and a P_{50} of 26 torr, hemoglobin becomes almost fully saturated with O_2 in the lungs and drops to 77% saturation in resting tissue, a change of 21%. If n of 1.0 and a P_{50} of 26 torr, hemoglobin would become only 79% saturated with O_2 in the lungs and would drop to 61% in resting tissue, a change of 18%. The difference in hemoglobin O_2 saturation conditions between the values for $n = 2.8$ and 1.0 (21% – 18%, or 3% saturation) seems small, but note that the potential for O_2 delivery (98% saturation versus 79% saturation) is large and becomes crucial when pO_2 in actively metabolizing tissue falls below 40 torr.

8. More glycogen phosphorylase will be in the glycogen phosphorylase a (more active) form, but caffeine promotes the less active T conformation of glycogen phosphorylase.

9. 8.7 L

10. Yes. Any triphosphate nucleotide can be converted into its cyclic counterpart as long as the appropriate cyclase enzyme is present.
11. Over time, stored erythrocytes will metabolize 2,3-BPG via the pathway of glycolysis. If [BPG] drops, hemoglobin may bind O_2 with such great affinity that it will not be released to the tissues (see Figure 15.29). The patient receiving a transfusion of [BPG]-depleted blood may actually suffocate.
12. a. By definition, when $[P_i] = K_{0.5}$, $v = 0.5 V_{\text{max}}$.
 b. In the presence of AMP, at $[P_i] = K_{0.5}$, $v = 0.85 V_{\text{max}}$ (from Figure 15.15c).
 c. In the presence of ATP, at $[P_i] = K_{0.5}$, $v = 0.12 V_{\text{max}}$ (from Figure 15.15b).
13. The inhibition of phosphodiesterase would lead to more cAMP and greater activation of the cascade that promotes the activity of glycogen phosphorylase, leading to more glycogen hydrolysis.
14. If G_{α} -GTPase activity is inactivated, the interaction between G_{α} and adenylyl cyclase will be persistent, adenylyl cyclase will be active, [cAMP] will rise, and glycogen levels will fall because glycogen phosphorylase will be predominantly in the active, phosphorylated a form.
15. Inhibition of adenylyl cyclase leads to less cAMP and less activation of glycogen phosphorylase, the enzyme that hydrolyzes glycogen according to the cascade shown in Figure 15.18. Inhibition of the GTPase activity of the G-protein keeps it in a permanently active state, promoting the activity of adenylyl cyclase and the production of cAMP. This will lead to more activation of glycogen phosphorylase and less glycogen storage.
16. An excess of a negatively cooperative allosteric inhibitor could never completely shut down the enzyme. Because the enzyme leads to several essential products, inhibition by one product might starve the cell for the others.
17. If both enzymes were active in an uncontrolled fashion, every round of kinase/phosphatase activity would lead to a net result of $ATP + H_2O \rightarrow ADP + P_i$.
18. a. $-R(R/K)X(S^*/T^*)-$
 b. $-K R K Q I A V R G L-$
19. Ligand binding is the basis of allosteric regulation, and allosteric effectors are common metabolites whose concentrations reflect prevailing cellular conditions. Through reversible binding of such ligands, enzymatic activity can be adjusted to the momentary needs of the cell. On the other hand, allosteric regulation is inevitably determined by the amounts of allosteric effectors at any moment, which can be disadvantageous. Covalent modification, like allosteric regulation, is also rapid and reversible because the converter enzymes act catalytically. Furthermore, covalent modification allows cells to escape allosteric regulation by covalently locking the modified enzyme in an active (or inactive) state, regardless of effector concentrations. One disadvantage is that covalent modification systems are often elaborate cascades that require many participants.
20. Sick-cell anemia is the consequence of Hb S polymerization through hydrophobic contacts between the side chain of Val β 6 and a pocket in the EF corner of β -subunits. Potential drugs might target this interaction directly or indirectly. For example, a drug might compete with Val β 6 side chain for binding in the EF corner. Alternatively, a useful drug might alter the conformation of Hb S such that the EF corner was no longer accessible or accommodating to the Val β 6 side chain. Another possibility might be to create drugs that deter the polymerization process in other ways through alterations in the surface properties between Hb S molecules.

21. Nitric oxide is covalently attached to Cys93 β . Thus, the interaction is not reversible binding, as in allosteric regulation. On the other hand, the reaction of NO $\cdot$ with this cysteine residue is apparently spontaneous, and no converter enzyme is needed to add or remove it. Thus, the regulation of covalent modification that is afforded by converter enzyme involvement is obviated. The Hb:NO $\cdot$ interaction illustrates that nature does not always neatly fit the definitions that we create.

22. Pro: Lactate is a metabolic indicator of the need for oxygen; it binds to Mb at a distinct site (the allosteric site?), and it lowers Mb's affinity for O₂.

Con: Mb is a monomeric protein. Traditionally, allosteric phenomena have been considered the realm of oligomeric proteins. How then is Mb "allosteric"? Since a ligand-induced conformational change in a monomeric protein can affect binding of "substrate" (i.e., O₂), the definition of allostery may need to be broadened.

25. Negative cooperativity in NAD⁺ binding to glyceraldehyde-3-P dehydrogenase:

26. Mass spectrometry is a prominent tool in proteomics. Proteomics would reveal the presence of acetylated forms of metabolic enzymes.

27. Hyperventilation results in decreased blood pCO₂, which in turn leads to an increase in pH. Thus, the affinity of Hb for O₂ increases (less O₂ will be released to tissues). Hypoventilation has exactly the opposite effects on pCO₂ and pH; thus, hypoventilation leads to a diminished affinity of Hb for O₂ (more O₂ will be released to the tissues).

28. When hormone disappears, the hormone:receptor complex dissociates, the GTPase activity of the G α subunit cleaves bound GTP

to GDP + P_i, and the affinity of G α -GDP for adenylyl cyclase is low, so it dissociates and adenylyl cyclase is no longer activated. Residual cAMP will be converted to 5'-AMP by phosphodiesterase, and the catalytic subunits of protein kinase A will be bound again by the regulatory subunits, whose cAMP ligands have dissociated. When protein kinase A becomes inactive, phosphorylase kinase will revert to the unphosphorylated, inactive form through loss of phosphoryl groups. Phosphoprotein phosphatase 1 will act on glycogen phosphorylase *a*, removing the phosphoryl group from Ser¹⁴ and thereby converting glycogen phosphorylase to the less active, allosterically regulated *b* form.

Think-Pair-Share Question:

- the metabolism of the intracellular parasite may generate elevated levels of lactic acid, acidifying the intracellular environment.
- O_2 has lower affinity for hemoglobin in acidic environments, creating deoxyhemoglobin
- in its deoxy state Hb S is more likely to form insoluble complexes with other Hb S molecules leading to the deformation of the RBC
- the deformed RBC is more likely to be destroyed by the liver or spleen; parasite and all.

Chapter 16

1. The pronghorn antelope is truly a remarkable animal, with numerous specially evolved anatomical and molecular features. These include a large windpipe (to draw in more oxygen and exhale more carbon dioxide), lungs that are three times the size of those of comparable animals (such as goats), and lung alveoli with five times the surface area so that oxygen can diffuse more rapidly into the capillaries. The blood contains larger numbers of red blood cells and thus more hemoglobin. The skeletal and heart muscles are likewise adapted for speed and endurance. The heart is three times the size of that of comparable animals and pumps a proportionally larger volume of blood per contraction. Significantly, the muscles contain much larger numbers of energy-producing mitochondria, and the muscle fibers themselves are shorter and thus designed for faster contractions. All these characteristics enable the pronghorn antelope to run at a speed nearly twice the top speed of a thoroughbred racehorse and to sustain such speed for up to 1 hour.
2. Refer to Figure 16.9. The step in which the myosin head conformation change occurs, is the step that should be blocked by β,γ -methylene-ATP, because hydrolysis of ATP should occur in this step and β,γ -methylene-ATP is nonhydrolyzable.
3. Phosphocreatine is synthesized from creatine (via creatine kinase) primarily in muscle mitochondria (where ATP is readily generated) and then transported to the sarcoplasm, where it can act as an ATP buffer. The creatine kinase reaction in the sarcoplasm yields the product creatine, which is transported back into the mitochondria to complete the cycle. Like a number of other mitochondrial proteins, the expression of mitochondrial creatine kinase is directed by mitochondrial DNA, whereas sarcoplasmic creatine kinase is derived from information encoded in nuclear DNA.
4. Note in step 3 of Figure 16.9 that it is ATP that stimulates dissociation of myosin heads from the actin filaments—the dissociation of the cross-bridge complex. When ATP levels decline (as happens rapidly after death), large numbers of myosin heads are unable to dissociate from actin and the muscle becomes stiff and unable to relax.
5. The skeletal muscles of the average adult male have a cross-sectional area of approximately $35,000\text{ cm}^2$. The gluteus maximus muscles represent approximately 300 cm^2 of this total. Assuming 4 kg of maximal tension per square centimeter of cross-sectional area, one calculates a total tension for the gluteus maximus of 1200 kg (as stated in the problem). The same calculation shows that the total tension that could be developed by all the muscles in the body is $140,000\text{ kg}$ (or 154 tons)!
6. Taking $55,000\text{ g/mol}$ divided by $6.02 \times 10^{23}/\text{mol}$ and by 1.3 g/mL , one obtains a volume of $7.03 \times 10^{-20}\text{ mL}$. Assume a sphere and use the volume of a sphere ($V = (4/3)\pi r^3$) to obtain a radius of $25.6\text{ \AA}$. The diameter of the tubulin dimer (see Figure 16.12) is 8 nm , or $80\text{ \AA}$, and two times the radius we calculated here is approximately $51\text{ \AA}$, a reasonable value by comparison.

7. The presence of the two different subunits allows for the differential binding of the two heads of kinesin during its step-by-step movement over the tubulin structure. The conformational differences in the head groups of kinesin based upon the presence of ADP or ATP could lead to different affinities for either the a or b subunit. This could allow for the step-by-step movement of kinesin over tubulin that may not have happened if tubulin was built from one monomer or more than two monomers.
8. A liver cell is $20,000\text{ nm}$ long, which would correspond to 5000 tubulin monomers if using the value of Figure 16.12, and about 7800 tubulin monomers using the value of $25.6\text{ \AA}$ calculated in problem 6.
9. 4 inches (length of the giant axon) = 10.16 cm . Movement at 2 to $5\text{ }\mu\text{m/sec}$ would correspond to a time of 5.6 to 14 hours to traverse this distance.
10. $88,900\text{ s}$ or 24.7 hours ; $11,112,500$ units of tubulin.
11. 14 nm is $140\text{ \AA}$, which would be approximately 93 residues of a coiled coil.
12. The presence of LC 1 is needed for ATPase activity, as mentioned in Section 16.2b.
13. Sequence (b). In sequence (a) the fourth amino acid is hydrophobic but not small. In sequence (c) the first amino acid is not hydrophobic. In sequence (d) the sixth amino acid is not charged.
14. Using Equation 9.1, one can calculate a ΔG of $17,100\text{ J/mol}$ for this calcium gradient.
15. Using Equation 3.8, one can calculate a cellular ΔG of $-48,600\text{ J/mol}$ for ATP hydrolysis.
16. Using equation 3.8 the chart can be constructed.

17. $17,100\text{ J}$ are required to transport 1 mole of calcium ions. Two moles of calcium would require $34,200\text{ J}$, and three would cost $51,300\text{ J}$. Thus, the gradient of problem 10 would provide enough energy to drive the transport of two calcium ions per ATP hydrolyzed.
18. Energy (or work) = force $\times$ distance. If 1 ATP is hydrolyzed per step and the cellular value of $\Delta G'$ for ATP hydrolysis is -50 kJ/mol , then the calculation of force exerted by a motor is force = $50\text{ kJ/mol}/(\text{step size})$. The SI unit of force is the newton, and $1\text{ newton} \cdot \text{meter} = 1\text{ J}$.
 For the kinesin-1 motor, $50\text{ kJ/mol}/(8 \times 10^{-9}\text{ m}) = 6.25 \times 10^{12}$ newtons.
 For the myosin-V motor, $50\text{ kJ/mol}/(36 \times 10^{-9}\text{ m}) = 1.39 \times 10^{12}$ newtons.
 For the dynein motor, $50\text{ kJ/mol}/(28 \times 10^{-9}\text{ m}) = 1.78 \times 10^{12}$ newtons.

19. Perhaps the simplest way to view this problem is to consider the potential energy change for lifting a 10-kg weight 0.4 m.
 $E = mgh = (10 \text{ kg}) \cdot (9.8 \text{ m/sec}^2) \cdot (0.4 \text{ m}) = 39.2 \text{ J}$. Now, if 1 ATP is expended per myosin step along an actin filament,
 $39.2 \text{ J}/(50 \text{ kJ/mol}) = 7.8 \times 10^{-4} \text{ mol}$.

Then, $(7.8 \times 10^{-4} \text{ mol}) \cdot (6.02 \times 10^{23}) = 4.72 \times 10^{20}$ molecules of ATP expended, one per step. So there must be 4.72×10^{20} myosin steps along actin. However, the stepping process is almost certainly not 100% efficient. As shown in the Critical Developments in Biochemistry box “Molecular ‘Tweezers’ of Light Take the Measure of a Muscle Fiber’s Force” in Section 16.2, a step size of 11 nm against a force of 4 pN would correspond to an energy expended per myosin per step of $4.4 \times 10^{-20} \text{ J}$. With this assumed energy expended per step, we can calculate $39 \text{ J}/(4.4 \times 10^{-20} \text{ J}) = 8.86 \times 10^{20}$ steps total.

If we take the step size value for skeletal myosin from the Critical Developments in Biochemistry box “Molecular ‘Tweezers’ of Light Take the Measure of a Muscle Fiber’s Force” in Section 16.2, as 11 nm, one myosin head would have to take $0.4 \text{ m}/11 \times 10^{-9} \text{ m}$ or 3.64×10^7 steps to raise the weight a distance of 0.4 m. Taking $(8.86 \times 10^{20} \text{ steps total})/(3.64 \times 10^7 \text{ steps per myosin}) = 2.43 \times 10^{13}$ myosin heads involved per 11-nm step.

20. All these are smooth muscle except for the diaphragm. (See <http://chanteur.net/contribul/index.htm#http://chanteur.net/contribulcJMdiaph.htm> for an explanation of the common misconception that the diaphragm is smooth muscle.)
21. 1, a; 2, e; 3, d; 4, c; 5, b.
22. This exercise is left to the student and will presumably be different for every student.
23. The 80 Å step of the kinesin motor is a 0.008 μm step. To cover 10.16 cm would require 12.7 million steps.
24. The correct answer is d, although each answer is reasonable. ATP is needed for several processes involved in muscle relaxation. Salt imbalances can also prevent normal muscle function, and interrupted blood flow could prevent efficient delivery of oxygen needed for ATP production during cellular respiration.
25. The correct answer is a. Understanding the inheritance pattern of sex-linked traits is essential. Males always inherit sex-linked traits (on the X chromosome) from their mothers. In addition, sex-linked traits are much more commonly expressed in males because they have only one X chromosome.
26. This exercise is left to the student and will presumably be different for every student.
27. This exercise is left to the student and will presumably be different for every student.
28. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

Suggested answer:

The polysaccharide should be a heteropolysaccharide to provide diversity in structural elements capable of secondary interactions with the domains of the motor proteins.

The polysaccharide should be long enough to span enough length within or outside a cell.

One could suggest the requirement the polysaccharide to be charged (containing uronic acids or phosphorylated or sulfate units) to expand its secondary interaction possibilities. Basic polysaccharides are polyalcohols and secondary interactions are limited to hydrogen bonds. Charged functional groups on a polysaccharide could provide more diverse and stronger interaction capabilities with motor proteins.

The polysaccharide should be capable of bundling with other polysaccharides to make sturdy fiber-like structures.

The motor proteins should have hydrophilic polysaccharide-binding domains to interact with the hydrophilic polysaccharide structure.

Chapter 17

- 6.5×10^{12} (6.5 trillion) people.
- Consult Table 17.2.
- During daytime plants are considered photoautotrophic because of the photosynthesis process. During nighttime their metabolism is chemoautotrophic because of the aerobic oxidation of organic compounds.
- O_2 , H_2O , and CO_2 .
- See Section 17.3.
- Catabolic pathways increase entropy and lower the enthalpy of biomolecules while anabolic pathways decrease entropy and store enthalpy in biomolecules.
- Carbon is more electronegative than hydrogen, but less electronegative than oxygen. In chemical bonds between carbon and hydrogen the electrons are closer to carbon than to hydrogen. In chemical bonds between carbon and oxygen the valence electrons are closer to oxygen than to carbon. In chemical bonds between carbon and oxygen, carbon “loses” its electrons to oxygen. In CH_4 the oxidation number of carbon is -4 while in CO_2 the oxidation number of carbon is $+4$.
- Consult Figure 17.5.
- Consult *Corresponding Pathways of Catabolism and Anabolism Differ in Important Ways*, Section 17.3f. See also Figure 17.8.
- See *The ATP Cycle*, Section 17.3g; *NAD^+ Collects Electrons Released in Catabolism*, Section 17.3h; and *NADPH Provides the Reducing Power for Anabolic Processes*, Section 17.3i.
- NADP^+ has a phosphate group bonded to the 2' carbon of the ribose unit. This difference in structure allows for the differential use of NAD^+/NADH for catabolic reactions and $\text{NADP}^+/\text{NADPH}$ for anabolic reactions.
- In terms of quickness of response, the order is allosteric regulation > covalent modification > enzyme synthesis and degradation. See *The Student Solutions Manual, Study Guide and Problems Book* for further discussions.
- See “Metabolic Pathways Are Compartmentalized within Cells,” in Section 17.4, and discussions in *The Student Solutions Manual, Study Guide and Problems Book*.
- Many answers are possible here. Some examples: Large numbers of metabolites in tissues and fluids; great diversity of structure of biomolecules; need for analytical methods that can detect and distinguish many different metabolites, often at very low concentrations; need to understand relationships between certain metabolites; time and cost required to analyze and quantitate many metabolites in a tissue or fluid.

15. Mass spectrometry provides great sensitivity for detection of metabolites. NMR offers a variety of methods for resolving and discriminating metabolites in complex mixtures. Other comparisons and contrasts are discussed in the references at the end of the chapter.
16. See Figure 13.23; A Deeper Look box “The Coenzymes of the Pyruvate Dehydrogenase Complex,” in Section 19.2, and the A Deeper Look box “Activation of Vitamin B₁₂,” in Section 23.3.
17. The genome is the entire hereditary information in an organism, as encoded in its DNA or (for some viruses) RNA. The transcriptome is the set of all messenger RNA molecules (transcripts) produced in one cell or a population of cells under a defined set of conditions. The proteome is the entire complement of proteins produced by a genome, cell, tissue, or organism under a defined set of conditions. The metabolome is the complete set of low molecular weight metabolites present in an organism or excreted by it under a given set of physiological conditions. The fluxome is all of the metabolic fluxes in a metabolic network. It represents systems-level information on those cellular processes defined by the metabolic network.
18. A mechanism for liver alcohol dehydrogenase:

19. TCA cycle: in mitochondria; converts acetate units to CO₂ plus NADH and FADH₂.
Glycolysis: in cytosol; converts glucose to pyruvate.
Oxidative phosphorylation: in mitochondria; uses electrons (from NADH and FADH₂) to produce ATP.
Fatty acid synthesis: in cytosol; uses acetate units to synthesize fatty acids.
20. Most discussions of ocean sequestration of CO₂ are devoted to capture of CO₂ by phytoplankton or injection of CO₂ deep in the ocean. However, the A Deeper Look box “Calcium Carbonate—A Biological Sink for CO₂” in Section 17.1 offers another possibility—carbon sequestration in the shells of corals, mollusks, and crustaceans. This approach may be feasible. However, there are indications that these classes of sea organisms are already suffering from global warming and from pollution of ocean water.
21. ³²P and ³⁵S both decay via beta particle emission. A beta particle is merely an electron emitted by a neutron in the nucleus. Thus, beta decay does not affect the atomic mass, but it does convert a neutron to a proton. Thus, beta emission changes ³²P to ³²S and converts ³⁵S to ³⁵Cl:

The decay equation is a first-order decay equation:

$$A/A_0 = e^{-0.693/t_{1/2}}$$

Thus, after 100 days of decay, the fraction of ³²P remaining would be 0.786% and the fraction of ³⁵S remaining would be 45%.

22. DNA, RNA, nucleotides, some classes of glycerophospholipids, hexosamines and related molecules.
23. a. Chemoautotroph
b. Photoautotroph
c. Chemoheterotroph
24. The correct answer is b. Obligate anaerobes can survive only in the absence of oxygen.
25. The correct answer is c, mass spectrometry.
26. Consult the PSAFE entry for alcohol dehydrogenase.

Think-Pair-Share Question:

Other alternative metabolic diagrams that could be considered:

Oxygen-centric: focused on the increase or decrease in carbon-bonded oxygen atoms (this leaves out the addition of oxygen atoms from phosphate or sulfate functional groups).

Nitrogen-centric: focused on the increase or decrease in carbon-bonded nitrogen atoms.

- a. carbon-centric: A → E → G + H → CO₂
- b. electron-centric: A → C → D → E
- c. oxygen-centric: A → B → C → D → E → F → G + H → CO₂
- d. nitrogen-centric: A → B → G → NH₃

Chapter 18

1. a. Phosphoglucose isomerase, fructose biphosphate aldolase, triose phosphate isomerase, glyceraldehyde-3-P dehydrogenase, phosphoglycerate mutase, and enolase.
b. Hexokinase/glucokinase, phosphofructokinase, phosphoglycerate kinase, pyruvate kinase, and lactate dehydrogenase.
c. Hexokinase and phosphofructokinase.
d. Phosphoglycerate kinase and pyruvate kinase.
- e. According to Equation 3.8, reactions in which the number of reactant molecules differs from the number of product molecules exhibit a strong dependence on concentration. That is, such reactions are extremely sensitive to changes in concentration. Using this criterion, we can predict from Table 19.1 that the free energy changes of the fructose biphosphate aldolase and glyceraldehyde-3-P dehydrogenase reactions will be strongly influenced by changes in concentration.
- f. Reactions that occur with ΔG near zero operate at or near equilibrium. See Table 18.1 and Figure 18.22.
2. The carboxyl carbon of pyruvate derives from carbons 3 and 4 of glucose. The keto carbon of pyruvate derives from carbons 2 and 5 of glucose. The methyl carbon of pyruvate is obtained from carbons 1 and 6 of glucose.
3. Increased [ATP], [citrate], or [glucose-6-phosphate] inhibits glycolysis. Increased [AMP], [fructose-1,6-bisphosphate], or [fructose-2,6-bisphosphate] stimulates glycolysis.
4. BDAEC
5. See *The Student Solutions Manual, Study Guide and Problems Book* for discussion.
6. e) a) d) b) c)

- The mechanisms for fructose bisphosphate aldolase and glyceraldehyde-3-P dehydrogenase are shown in Figures 18.12 and 18.13, respectively.
- The relevant reactions of galactose metabolism are shown in Figure 18.24. See *The Student Solutions Manual, Study Guide and Problems Book* for mechanisms.
- Iodoacetic acid would be expected to alkylate the reactive active-site cysteine that is vital to the glyceraldehyde-3-P dehydrogenase reaction. This alkylation would irreversibly inactivate the enzyme.
- Ignoring the possibility that ^{32}P might be incorporated into ATP, the only reaction of glycolysis that utilizes P_i is glyceraldehyde-3-P dehydrogenase, which converts glyceraldehyde-3-P to 1,3-bisphosphoglycerate. $^{32}\text{P}_i$ would label the phosphate at carbon 1 of 1,3-bisphosphoglycerate. The label will be lost in the next reaction, and no other glycolytic intermediates will be directly labeled. (Once the label is incorporated into ATP, it will also show up in glucose-6-P, fructose-6-P, and fructose-1, 6-bisphosphate.)
- Oxidation occurs in the conversion of glyceraldehyde-3-phosphate to 3-phosphoglycerate and NAD^+ is the oxidizing agent.
- The sucrose phosphorylase reaction leads to glucose-6-P without the need for the hexokinase reaction. Direct production offers the obvious advantage of saving a molecule of ATP.
- All of the kinases involved in glycolysis, as well as enolase, are activated by Mg^{2+} ion. A Mg^{2+} deficiency could lead to reduced activity for some or all of these enzymes. However, other systemic effects of a Mg^{2+} deficiency might cause even more serious problems.
- Through enediol isomerism, D-glucose, D-fructose and D-mannose are interchangeable. D-galactose is related to D-tagatose through enediol isomerism.

- $[\text{GA} - 3\text{P}]/[\text{DHAP}]$ should be 0.052 or about 1/19.
- +1.08 kJ/mol.
- a. -31.7 kJ/mol.
b. $K_{\text{eq}} = 194,850$.
c. $[\text{Pyr}]/[\text{PEP}] = 24,356$.
- a. -13.8 kJ/mol.
b. $K_{\text{eq}} = 211$.
c. $[\text{FBP}]/[\text{F-6-P}] = 528$.
- a. -19.1 kJ/mol.
b. $K_{\text{eq}} = 1651$.
c. $[\text{ATP}]/[\text{ADP}] = 13.8$.
- $\Delta G^{\circ'} = -33.9$ kJ/mol.
- An 8% increase in $[\text{ATP}]$ changes the $[\text{AMP}]$ concentration to $20 \mu\text{M}$ (from $5 \mu\text{M}$).

22.

23.

24. Pyruvate kinase deficiency primarily affects red blood cells, which lack mitochondria and can produce ATP only via glycolysis. Absence of pyruvate kinase reduces the production of ATP by glycolysis in red cells, which in turn reduces the activity of the Na,K-ATPase (see Chapter 9). This results in alterations of electrolyte (Na^+ and K^+) concentrations, which leads to cellular distortion, rigidity, and dehydration. Compromised red blood cells are destroyed by the spleen and liver.
25. As discussed in Section 18.7a diets rich in fructose will be processed by the liver and the carbohydrate will be turned into fatty acids and stored as triglycerides in the adipose tissues. One can fool the customer, but not our biochemistry!
26. The best answer is d. PFK is more active at low ATP than at high ATP, and F-2,6-bisP activates the enzyme.
27. Hexokinase is inhibited by high concentrations of glucose-6-P, so glycolysis would probably stop at such a high level of glucose-6-P. Also, the increased concentration of glucose-6-P would change the cellular ΔG of the hexokinase reaction to approximately $-22,000 \text{ J/mol}$.
28. This exercise is left to the student and will presumably be different for every student.
29. This exercise is left to the student and will presumably be different for every student.
30. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

$^{14}\text{CH}_3\text{—CH}_2\text{OH}$ would be obtained if C1 or C6 in D-glucose were labeled. $\text{CH}_3\text{—}^{14}\text{CH}_2\text{OH}$ would be obtained if C2 or C5 in D-glucose were labeled. $^{14}\text{CO}_2$ would be obtained if C3 or C4 in D-glucose were labeled. The same results would have been obtained if D-mannose or D-fructose were used as starting molecules.

Chapter 19

- Glutamate enters the TCA cycle via a transamination to form α -ketoglutarate. The γ -carbon of glutamate entering the cycle is equivalent to the methyl carbon of an entering acetate. Thus, no radioactivity from such a label would be lost in the first or second cycle, but in each subsequent cycle, 50% of the total label would be lost (see Figure 19.15).
- CFABED
- d) f) b) c) a) e)
- NAD^+ activates pyruvate dehydrogenase and isocitrate dehydrogenase and thus would increase TCA cycle activity. If NAD^+ increases at the expense of NADH , the resulting decrease in NADH likewise would activate the cycle by stimulating citrate synthase and α -ketoglutarate dehydrogenase. ATP inhibits pyruvate dehydrogenase, citrate synthase, and isocitrate dehydrogenase; reducing the ATP concentration thus would activate the cycle. Isocitrate is not a regulator of the cycle, but increasing its concentration would mimic an increase in acetate flux through the cycle and increase overall cycle activity.
- For most enzymes that are regulated by phosphorylation, the covalent binding of a phosphate group at a distant site induces a conformation change at the active site that either activates or inhibits the enzyme activity. On the other hand, X-ray crystallographic studies reveal that the phosphorylated and unphosphorylated forms of isocitrate dehydrogenase share identical structures with only small (and probably insignificant) conformation changes at Ser^{113} , the locus of phosphorylation. What phosphorylation *does* do is block isocitrate binding (with no effect on the binding affinity of NADP^+). As shown in Figure 2 of the paper cited in the problem (Barford, D., 1991. Molecular mechanisms for the control of enzymic activity by protein phosphorylation. *Biochimica et Biophysica Acta* 1133:55–62), the γ -carboxyl group of bound isocitrate forms a hydrogen bond with the hydroxyl group of Ser^{113} . Phosphorylation apparently prevents isocitrate binding by a combination of a loss of the crucial H bond between substrate and enzyme and by repulsive electrostatic and steric effects.
- A mechanism for the first step of the α -ketoglutarate dehydrogenase reaction:

12. A mechanism for pyruvate decarboxylase:

13. Ca²⁺ can be predicted to activate both the pyruvate dehydrogenase complex and the TCA cycle as they lead to the production of ATP. Contracting muscles need ATP for contraction to occur.
14. [isocitrate]/[citrate] = 0.1. When [isocitrate] = 0.03 mM, [citrate] = 0.3 mM.
15. ¹⁴CO₂ incorporation into TCA via the pyruvate carboxylase reaction would label the —CH₂—COOH carboxyl carbon in oxaloacetate. When this entered the TCA cycle, the labeled carbon would survive only to the α-ketoglutarate dehydrogenase reaction, where it would be eliminated as ¹⁴CO₂.
16. ¹⁴C incorporated in a reversed TCA cycle would label the two carboxyl carbons of oxaloacetate in the first pass through the cycle. One of these would be eliminated in its second pass through the cycle. The other would persist for more than two cycles and would be eliminated slowly as methyl carbons in acetyl-CoA in the reversed citrate synthase reaction.
17. The labeling pattern would be the same as if methyl-labeled acetyl-CoA was fed to the conventional TCA cycle (see Figure 19.15).

18.

19.

20. For the malate dehydrogenase reaction,

with the value of $\Delta G^{\circ'}$ being +30 kJ/mol. Then

$$\Delta G^{\circ'} = -RT \ln K_{\text{eq}} = -(8.314 \text{ J/mol} \cdot \text{K})(298) \ln \left(\frac{[1]x}{[20][2.2 \times 10^{-4}]} \right)$$

$$\frac{-30,000 \text{ J/mol}}{2478 \text{ J/mol}} = \ln (x/4.4 \times 10^{-3})$$

$$-12.1 = \ln (x/4.4 \times 10^{-3})$$

$$x = -RT \ln K_{\text{eq}}$$

$$x = [\text{oxaloacetate}] = 0.024 \mu\text{M}$$

Using the dimensions given in the problem, one can calculate a mitochondrial volume of $1.57 \times 10^{-15} \text{ L}$. $(0.024 \times 10^{-6} \text{ M}) \cdot (1.57 \times 10^{-15} \text{ L}) \cdot (6.02 \times 10^{23} \text{ molecules/mole}) = 22.7$, or about 23 molecules of OAA in a mitochondrion ("pOAA" = 7.62).

21. This exercise is left to the student. Review of the calculation of oxidation numbers should be a prerequisite for answering this problem.

22. This exercise is left to the student.

23. 2*R*, 3*R*-fluorocitrate is converted by aconitase to 2-fluoro-*cis*-aconitate. This intermediate then rotates 180 degrees in the active site. Addition of hydroxide at the C4 position is followed by double bond migration from C3-C4 to C2-C3, to form 4-hydroxy-*trans*-aconitate. This product remains tightly bound at the aconitase active site, inactivating the enzyme. Studies by Lauble et al. (The reaction of fluorocitrate with aconitase and the crystal structure of the enzyme-inhibitor complex. *Proceedings of the National Academy of Sciences U.S.A.* **93**:13699–13703 (1996)) have shown that the inhibitory product can be displaced by a 10⁶-fold excess of isocitrate.

24. The post translational modification of cysteine residues by fumarate is termed a succination and proceeds via a Michael addition:

25. Only eight ATPs would be generated in the succinyl-CoA synthetase (and nucleoside diphosphate kinase) reaction of the TCA cycle itself.
26. d is false. Succinyl-CoA is an inhibitor of citrate synthase.
27. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

C¹⁸O₂ and NADD (isotopically labeled NADH where H is replaced with a D).

Chapter 20

1. The cytochrome couple is the acceptor, and the donor is the (bound) FAD/FADH₂ couple, because the cytochrome couple has a higher (more positive) reduction potential.

$$\Delta \mathcal{E}_o' = 0.254 \text{ V} - 0.02 \text{ V}^*$$

*This is a typical value for enzyme-bound [FAD].

$$\Delta G^{\circ'} = -n\mathcal{F}\Delta \mathcal{E}_o' = -43.4 \text{ kJ/mol.}$$
2. a. a1. UQ a2. FAD a3. cytochrome c (Fe³⁺)
 b. b1. FMNH₂ b2. UQH₂ b3. a-ketoglutarate
3. $\Delta \mathcal{E}_o' = -0.03 \text{ V}$; $\Delta G^{\circ'} = 5790 \text{ J/mol.}$
4. The net result of the reduction of NAD⁺ is that a proton is consumed. Adding an appropriate term to Equation 3.33 yields:

$$\mathcal{E} = \mathcal{E}_o' - RT \ln [\text{H}^+] + (RT/n\mathcal{F} \ln ([\text{ox}]/[\text{red}]])$$
5. Cyanide acts primarily via binding to cytochrome a₃, and the amount of cytochrome a₃ in the body is much lower than the amount of hemoglobin. Nitrite anion is an effective antidote for cyanide poisoning because of its unique ability to oxidize ferrohemeoglobin to ferrihemeoglobin, a form of hemeoglobin that competes very effectively with cytochrome a₃ for cyanide. The amount of ferrohemeoglobin needed to neutralize an otherwise lethal dose of cyanide is small compared with the total amount of hemoglobin in the body. Even though a small amount of hemoglobin is sacrificed by sequestering the cyanide in this manner, a “lethal dose” of cyanide can be neutralized in this manner without adversely affecting oxygen transport.
6. You should advise the wealthy investor that she should decline this request for financial backing. Uncouplers can indeed produce dramatic weight loss, but they can also cause death. Dinitrophenol was actually marketed for weight loss at one time, but sales were discontinued when the potentially fatal nature of such “therapy” was fully appreciated. Weight loss is best achieved by simply making sure that the number of calories of food eaten is less than the number of calories metabolized. A person who metabolizes about 2000 kJ (about 500 kcal) more than he or she consumes every day will lose about a pound in about 8 days.)
7. The calculation in Section 20.4 assumes the same conditions as in this problem (1 pH unit gradient across the membrane and an electrical potential difference of 0.18 V). The transport of 1 mole of H⁺ across such a membrane generates 23.3 kJ of energy. For three moles of H⁺, the energy yield is 69.9 kJ. Then, from Equation 3.8, we have:

$$69,900 \text{ J/mol} = 30,500 \text{ J/mol} + RT \ln ([\text{ATP}]/[\text{ADP}][\text{P}_i])$$

$$39,400 \text{ J/mol} = RT \ln ([\text{ATP}]/[\text{ADP}][\text{P}_i])$$

$$[\text{ATP}]/[\text{ADP}][\text{P}_i] = 4.36 \times 10^6 \text{ M}^{-1} \text{ at } 37^\circ\text{C.}$$

In the absence of the proton gradient, this same ratio is $7.25 \times 10^{-6} \text{ M}^{-1}$ at equilibrium!

8. The succinate/fumarate redox couple has the highest (that is, most positive) reduction potential of any of the couples in glycolysis and the TCA cycle. Thus, oxidation of succinate by NAD⁺ would be very unfavorable in the thermodynamic sense.
 Oxidation of succinate by NAD⁺:

$$\Delta \mathcal{E}_o' \approx -0.35 \text{ V}; \Delta G^{\circ'} \approx 67,500 \text{ J/mol.}$$

On the other hand, oxidation of succinate is quite feasible using enzyme-bound FAD.
 Oxidation of succinate by [FAD]:

$$\Delta \mathcal{E}_o' \approx 0, \Delta G^{\circ'} \approx 0, \text{ depending on the exact reduction potential for bound FAD.}$$
9. a. $\Delta G^{\circ'} = -48.2 \text{ kJ/mol}$
 b. $\Delta G^{\circ'} = -67.7 \text{ kJ/mol}$
10. a. -73.3 kJ/mol.
 b. $K_{\text{eq}} = 7.1 \times 10^{12}.$
 c. $[\text{ATP}]/[\text{ADP}] = 19.7.$
11. a. -151.5 kJ/mol.
 b. $K_{\text{eq}} = 3.54 \times 10^{26}.$
 c. $[\text{ATP}]/[\text{ADP}] = 8.8.$
12. a. -219 kJ/mol.
 b. $K_{\text{eq}} = 2.63 \times 10^{38}.$
 c. $[\text{ATP}]/[\text{ADP}] = 3340$
13. a. -217 kJ/mol.
 b. $K_{\text{eq}} = 1.08 \times 10^{38}.$
 c. $[\text{ATP}]/[\text{ADP}] = 3340.$
14. a. -26 kJ/mol.
 b. $K_{\text{eq}} = 3.68 \times 10^4.$
 c. $[\text{NAD}^+]/[\text{NADH}] = 1.48.$
15. a. $\Delta G^{\circ'} = -26 \text{ kJ/mol}$
 b. $\Delta G^{\circ'} = -6.6 \text{ kJ/mol}$
16. a. $K_{\text{eq}} = 4.8 \times 10^3.$
 b. $+48 \text{ kJ/mol.}$
 c. $[\text{ATP}]/[\text{ADP}] = 2.3.$
17. The two heme molecules are surrounded by different protein domains and this difference in microenvironment leads to different reduction potentials.
18. This answer should be based on the information in Section 20.2 and should be in the student's own words.
19. This answer should be based on the information in Section 20.2 and should be in the student's own words.
20. Yes. As shown in Figure 17.1 H₂O is oxidized to O₂ by photoautotrophic organisms.
21. Several mechanisms are possible. See, for example, the mechanisms in the following references: Pryor, W. A., and Porter, N. A., 1990. Suggested mechanisms for the production of 4-hydroxy-2-nonenal from the autoxidation of polyunsaturated fatty acids. *Free Radical Biology and Medicine* 8:541–543;

and Niki, E., Yoshida, Y., Saito, Y., and Noguchi, N., 2005. Lipid peroxidation: Mechanisms, inhibition, and biological effects. *Biochemical and Biophysical Research Communications* 338:668–676.

22. A calculation similar to that in problem 20 in Chapter 19 yields about 15 H^+ in a typical mitochondrion.
23. In the succinate dehydrogenase reaction, a two-electron transfer reaction (the conversion of succinate to fumarate) must be coupled to iron–sulfur centers, which can transfer only one electron at a time. FAD can carry on both one-electron and two-electron transfers and thus is ideally suited for this reaction.
24. a. $\text{Fe}^{3+} + \text{e}^- \longrightarrow \text{Fe}^{2+}$
 b. $\text{SO}_4^{2-} + 9 \text{ H}^+ + 8 \text{ e}^- \longrightarrow \text{HS}^- + 4 \text{ H}_2\text{O}$
 c. $2 \text{ NO}_3^- + 12 \text{ H}^+ + 10 \text{ e}^- \longrightarrow \text{N}_2 + 6 \text{ H}_2\text{O}$
 d. $\text{S} + \text{H}^+ + 2 \text{ e}^- \longrightarrow \text{HS}^-$
25. The answer is a. The mitochondrial ATPase reaction proceeds via nucleophilic $\text{S}_{\text{N}}2$ -type substitution.
26. At 298 K, doubling the proton gradient would change ΔG by 1717 J/mole. The mitochondrial membrane potential would have to change by approximately 18 mV. The student should decide whether this change should be positive or negative.
27. This exercise is left to the student and will presumably be different for every student.
28. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

1. The movement of electrons through an increased number of complexes would significantly increase the probability that oxygen would encounter the flow of electrons with an increased probability for oxygen to be partially reduced and to produce harmful reactive oxygen species (ROS).
2. The direct reduction of oxygen by NADH is very exergonic (see the discussions in Section 20.2). This release of energy may raise temperatures inside the mitochondria or cells to dangerous levels.
3. The electron transport with accompanying proton translocation is not a discrete, step-wise process, but a continuous process. The number of complexes I, III, and IV are likely to be different from the number of ATP synthase complexes and ATP/ADP translocators. This will ensure a balanced in and out flow of protons across the mitochondrial inner membrane.
4. The proton transport through the various complexes would have to involve amino acid residues with sufficiently different pK_{b} values to drive the movement of protons within and from one complex to the next and ultimately towards the final reduction reaction. Given the limited number of side chains capable of binding protons, the options to have proton transport through the various complexes may be limited. Proton transport through the various complexes could induce conformational changes in the various proteins involved, but could this be associated with movement of additional electrons across the inner membrane? Cytochrome c could still serve as a collector of electrons at the intermembrane space side of the mitochondria and still deliver electrons to the final complex for the reduction of oxygen. Could

the excess amounts of electrons on cytochrome c on the intermembrane space side drive ATP synthesis? It would require a totally different ATP synthase complex.

Chapter 21

1. A redox-sensitive ion like Fe^{2+} may absorb any electrons from photoexcited chlorophyll and short-circuit the induction of photosynthetic electron transport.
2. Efficiency = $\Delta G^\circ / (\text{light energy input}) = n\mathcal{F}\Delta\mathcal{E}_\circ' / (Nh\nu/\lambda) = 0.564$.
3. $\Delta G^\circ = -n\mathcal{F}\Delta\mathcal{E}_\circ'$, so $\Delta G^\circ / -n\mathcal{F} = \Delta\mathcal{E}_\circ'$. $n = 4$ for $2 \text{ H}_2\text{O} \longrightarrow 4 \text{ e}^- + 4 \text{ H}^+ + \text{O}_2$. $\Delta\mathcal{E}_\circ' = (\mathcal{E}_\circ'(\text{primary oxidant}) - \mathcal{E}_\circ'(\frac{1}{2} \text{ O}_2/\text{H}_2\text{O})) = +0.0648 \text{ V}$. Thus, $\mathcal{E}_\circ'(\text{primary oxidant}) = 0.881 \text{ V}$.
4. ΔG for ATP synthesis = $+50,336 \text{ J/mol}$. $\Delta\mathcal{E}_\circ' = +0.34 \text{ V}$.
5. Reduced plastoquinone = PQH_2 ; oxidized plastoquinone = PQ ; Reduced plastocyanin = $\text{PC}(\text{Cu}^+)$; plastocyanin = $\text{PC}(\text{Cu}^{2+})$:

$$\text{PQH}_2 + 2 \text{ H}^+_{\text{stroma}} + 2 \text{ PC}(\text{Cu}^{2+}) \longrightarrow \text{PQ} + 2 \text{ PC}(\text{Cu}^+) + 4 \text{ H}^+_{\text{thylakoid lumen}}$$
6. Noncyclic photophosphorylation: 3 ATP would be synthesized from 8 quanta, which equates to $2.67 \text{ } h\nu/\text{ATP}$. Cyclic photophosphorylation theoretically yields $2 \text{ H}^+/h\nu$, so if 14 H^+ yield 3 ATP, $7 \text{ } h\nu$ yield 3 ATP, which equates to $2.33 \text{ } h\nu/\text{ATP}$.
7. In mitochondria, H^+ translocation leads to a decline in intermembrane space pH and hence cytosolic pH, because the outer mitochondrial membrane is permeable to protons. Thus, the eukaryotic cytosol pH is at risk from mitochondrial proton translocation. So, mitochondria rely on a greater membrane potential ($\Delta\psi$) and a smaller ΔpH to achieve the same proton-motive force. Because proton translocation in eukaryotic photosynthesis deposits H^+ into the thylakoid lumen, the cytosol does not experience any pH change and ΔpH is not a problem. Moreover, the light-induced efflux of Mg^{2+} from the lumen diminishes $\Delta\psi$ across the thylakoid membrane, so a greater contribution of ΔpH to the proton-motive force is warranted.
8. Replacement of Tyr by Phe would greatly diminish the possibility of e^- transfer between water and P680^+ , limiting the ability of P680^+ to regain an e^- and return to the P680 ground state.
9. Assuming 12 c -subunits means 12 H^+ are needed to drive one turn of the c -subunit rotor and the synthesis of 3 ATP by the CF_1 part of the ATP synthase. If the *R. viridis* cytochrome bc_1 complex drives the translocation of $2 \text{ H}^+/\text{e}^-$, then $2 \text{ } h\nu$ gives 4 H^+ , and $6 \text{ } h\nu$ gives 12 H^+ and thus 3 ATP (thus, $2 \text{ } h\nu$ yield 1 ATP).
10. $\Delta G^\circ = -n\mathcal{F}\Delta\mathcal{E}_\circ' = -2(96,485 \text{ J/volt} \cdot \text{mol})$
 $(\mathcal{E}_\circ'(1,3\text{-BPG/Gal3P}) - \mathcal{E}_\circ'(\text{NADP}^+/\text{NADPH})) =$
 $-(192,970 \text{ J/volt} \cdot \text{mol})(-0.29 \text{ V} - (-0.32 \text{ V})) = -192,970$
 $(0.03) \text{ J/mol} = -5,789 \text{ J/mol}$.
11. Use the first eight reactions in Table 21.1 to show that:

$$\text{CO}_2 + \text{Ru-1,5-BP} + 3 \text{ H}_2\text{O} + 2 \text{ ATP} + 2 \text{ NADPH} + 2 \text{ H}^+ \longrightarrow \text{glucose} + 2 \text{ ADP} + 4 \text{ P}_i + 2 \text{ NADP}^+$$
12. Radioactivity will be found in C-1 of 3-phosphoglycerate; C-3 and C-4 of glucose; C-1 and C-2 of erythrose-4-P; C-3, C-4, and C-5 of sedoheptulose-1,7-bisP; and C-1, C-2, and C-3 of ribose-5-P.

13. It would be present in some P_i and in all the reaction intermediates.
14. Yes. The generation of oxygen and the movement of electrons during the light reactions create opportunities to generate ROS.
15. Light induces three effects in chloroplasts: (1) pH increase in the stroma, (2) generation of reducing power (as ferredoxin), and (3) Mg^{2+} efflux from the thylakoid lumen. Key enzymes in the Calvin–Benson CO_2 fixation pathway are activated by one or more of these effects. In addition, rubisco activase is activated indirectly by light, and, in turn, activates rubisco.
16. The proton-motive force would be dissipated by the production of heat and no ATP would be generated by photosynthesis.
17. The following series of reactions accomplishes the conversion of 2-phosphoglycolate to 3-phosphoglycerate:

18. Considering the reactions involving water separately:
1. ATP synthesis: $18 \text{ ADP} + 18 \text{ P}_i \longrightarrow 18 \text{ ATP} + 18 \text{ H}_2\text{O}$
2. NADP^+ reduction and the photolysis of water:
- $$12 \text{ H}_2\text{O} + 12 \text{ NADP}^+ \longrightarrow 12 \text{ NADPH} + 12 \text{ H}^+ + 6 \text{ O}_2$$
3. Overall reaction for hexose synthesis:
- $$6 \text{ CO}_2 + 12 \text{ NADPH} + 12 \text{ H}^+ + 18 \text{ ATP} + 12 \text{ H}_2\text{O} \longrightarrow \text{glucose} + 12 \text{ NADP}^+ + 6 \text{ O}_2 + 18 \text{ ADP} + 18 \text{ P}_i$$
- $$\text{Net: } 6 \text{ CO}_2 + 6 \text{ H}_2\text{O} \longrightarrow \text{glucose} + 6 \text{ O}_2$$

Of the 12 waters consumed in O_2 production in reaction 2 and the 12 waters consumed in the reactions of the Calvin–Benson cycle (reaction 3), 18 are restored by H_2O release in phosphoric anhydride bond formation in reaction 1.

19. a. $2 \text{ NO}_3^- \longrightarrow 2 \text{ NO}_2^- + \text{O}_2$ and $2 \text{ SO}_4^{2-} \longrightarrow 2 \text{ SO}_3^{2-} + \text{O}_2$
- b. No protons are generated that could help enhance the proton-motive force and the electrons lost by oxygen atoms are captured by the nitrogen or sulfur atoms.
20. a. If the number of c-subunits increases, the H^+/ATP ratio will increase.
- b. If the number of c-subunits increases, Δp can be smaller. (More protons moving down a shallower Δp will yield the same overall ΔG for ATP synthesis.)
21. a. 870-nm light: $\Delta G = -192 \text{ kJ/mol}$
- b. 700-nm light: $\Delta G = -259 \text{ kJ/mol}$
- c. 680-nm light: $\Delta G = -269 \text{ kJ/mol}$
22. $\Delta G = +35.1 \text{ kJ}$
23. $\Delta G = -950 \text{ kJ}$
24. Phenolic radicals (tyrosine radicals) are more stable than alcoholic (serine or threonine) radicals. This makes phenolic radicals more likely to be generated and to be part of an electron transport system.
25. Complex organic molecules and water serve as sources of electrons in the electron transport systems that ultimately generate ATP.
26. Ideally, accessory light-harvesting pigments would absorb visible light of wavelengths that the chlorophylls do not absorb, that is, light in the 470 to 620 nm wavelength range.
- 27.

28. Consult the Active Model for PSII on the PSFAE website and explore the nature of surface residues on PSII.
29. Using the same PSFAE entry for PSII from question 28, determine from the Ramachandran plot whether the canonical ϕ, ψ values of $\phi = -45$ degrees and $\psi = -60$ degrees are found in PSII α -helices.

Think-Pair-Share Question:

a.

b.

Chapter 22

1. The reactions that contribute to the equation discussed under *Coupling with Hydrolysis of ATP and GTP Drives Gluconeogenesis* in Section 22.1 are:

Summing these four reactions produces the equation discussed under *Coupling with Hydrolysis of ATP and GTP Drives Gluconeogenesis* in Section 22.1.

2. 1. it preserves NADPH levels for other anabolic reactions like the biosynthesis of fatty acids
2. it depletes cytosolic NADH levels such that pyruvate is not reduced to lactate
3. it depletes cytosolic NADH levels such that oxaloacetate is not reduced to malate
3. This problem essentially involves consideration of the three unique steps of gluconeogenesis. The conversion of PEP to pyruvate was shown in Chapter 18 to have a $\Delta G^{\circ'}$ of -31.7 kJ/mol . For the conversion of pyruvate to PEP, we need only add the conversion of a GTP to GDP + P_i (equivalent to ATP to ADP + P_i) to the reverse reaction. Thus:

Then, using Equation 3.8:

$$\Delta G = 1.2 \text{ kJ/mol} + RT \ln \left(\frac{[\text{PEP}][\text{ADP}]^2[\text{P}_i]}{[\text{Py}][\text{ATP}]^2} \right)$$

$$\Delta G \text{ (in erythrocytes)} = -31.96 \text{ kJ/mol}$$

In the case of the fructose-1,6-bisphosphatase reaction, $\Delta G^{\circ'} = -16.3 \text{ kJ/mol}$ (see Equation 18.6).

$$\Delta G = -16.7 \text{ kJ/mol} + RT \ln \left(\frac{[\text{F-6-P}][\text{P}_i]}{[\text{F-1,6-BP}]} \right)$$

$$\Delta G \text{ (in erythrocytes)} = -36.5 \text{ kJ/mol}$$

For the glucose-6-phosphatase reaction, $\Delta G^{\circ'} = -13.9 \text{ kJ/mol}$ (see Table 3.2). $\Delta G = -13.9 \text{ kJ/mol} + RT \ln \left(\frac{[\text{Glu}][\text{P}_i]}{[\text{G-6-P}]} \right) = -21.1 \text{ kJ/mol}$. From these ΔG values and those in Table 18.1, ΔG for gluconeogenesis = -87.7 kJ/mol .

4. CO_2 is a good leaving group because of the chemical stability of CO_2 and the fact that it can react with H_2O to make bicarbonate $\text{HCO}_3^- + \text{H}^+$.
5. Inhibition by $25 \mu\text{M}$ fructose-2,6-bisphosphate is approximately 94% at $25 \mu\text{M}$ fructose-1,6-bisphosphate and approximately 44% at $100 \mu\text{M}$ fructose-1,6-bisphosphate.
6. Glucagon promotes gluconeogenesis in liver cells. As an inhibitor of fructose-1,6-bisphosphatase, fructose-2,6-bisphosphate inhibits the gluconeogenesis pathway. In this context one could predict glucagon would inhibit the activity of phosphofructokinase-2 to lower the levels of fructose-2,6-bisphosphate.
7. The hydrolysis of UDP-glucose to UDP and glucose is characterized by a $\Delta G^{\circ'}$ of -31.9 kJ/mol . This is more than sufficient to overcome the energetic cost of synthesizing a new glycosidic bond in a glycogen molecule. The net $\Delta G^{\circ'}$ for the glycogen synthase reaction is -13.3 kJ/mol .
8. Muscle cells do not contain glucose-6-phosphatase activity.

9. According to Table 24.1, a 70-kg person possesses 1920 kJ of muscle glycogen. Without knowing how much of this is in fast-twitch muscle, we can simply use the fast-twitch data from the A Deeper Look box "Carbohydrate Utilization and Exercise" in Section 22.5 to calculate a rate of energy consumption. The plot in the A Deeper Look box shows that glycogen supplies are exhausted after 60 minutes of heavy exercise. Ignoring the curvature of the plot, 1920 kJ of energy consumed in 60 minutes corresponds to an energy consumption rate of 533 J/sec.
10. Although other inhibitory processes might also occur, enzymes with mechanisms involving formation of Schiff base intermediates with active-site lysine residues are likely to be inhibited by sodium borohydride (see Chapter 18, problem 18). The transaldolase reaction of the pentose phosphate pathway involves this type of active-site intermediate and would be expected to be inhibited by sodium borohydride.
11. Substrate availability determines the direction of the reversible reactions.
12. Glycogen molecules do not have any free reducing ends, regardless of the size of the molecule. If branching occurs every 8 residues and each arm of the branch has 8 residues (or 16 per branch point), a glycogen molecule with 8000 residues would have about 500 ends. If branching occurs every 12 residues, a glycogen molecule with 8000 residues would have about 334 ends.
13. a. Increased fructose-1,6-bisphosphate would activate pyruvate kinase, stimulating glycolysis.
b. Increased blood glucose would decrease gluconeogenesis and increase glycogen synthesis.
c. Increased blood insulin inhibits gluconeogenesis and stimulates glycogen synthesis.
d. Increased blood glucagon inhibits glycogen synthesis and stimulates glycogen breakdown.
e. Because ATP inhibits both phosphofructokinase and pyruvate kinase, and because its level reflects the energy status of the cell, a decrease in tissue ATP would have the effect of stimulating glycolysis.
f. Increasing AMP would have the same effect as decreasing ATP—stimulation of glycolysis and inhibition of gluconeogenesis.
g. Fructose-6-phosphate is not a regulatory molecule and decreases in its concentration would not markedly affect either glycolysis or gluconeogenesis (ignoring any effects due to decreased [G-6-P] as a consequence of decreased [F-6-P]).
14. Yes. As discussed in Chapter 18, D-mannose, D-fructose and D-galactose can be converted into D-glucose-6-phosphate which could be a substrate for glycogen synthesis or could be used as a precursor for the pentose phosphate pathway.
15. The glycerol backbone of the triacylglycerides could enter the gluconeogenesis pathway when converted into dihydroxyacetone-phosphate or glyceraldehyde-3-phosphate.
16. At 298 K, assuming roughly equal concentrations of glycogen molecules of different lengths, the glucose-1-P concentration would be about 0.286 mM.

17. All four of these reactions begin with the formation of *N*-carboxybiotin:

The carboxylation of β -methylcrotonyl-CoA occurs as follows:

The carboxylations of geranyl-CoA and urea are shown here:

The mechanism of the carboxyltransferase reaction is a combination of the pyruvate carboxylase mechanism (shown in Figure 22.3) and a reverse propionyl-CoA carboxylase reaction.

18. a. The mechanism of the acetolactate synthase reaction.

b. The phosphoketolase reaction.

19. The malate/aspartate shuttle provides oxaloacetate or NADH into the cytosol.
20. Metformin both stimulates glucose uptake by peripheral tissues and enhances the binding of insulin to its receptors. Glipizide complements the actions of metformin by stimulating increased insulin secretion by the pancreas.

21. Epalrestat and tolrestat do not resemble the transition state for aldose reductase, and evidence from studies by Franklin Prendergast and others (Ehrig, T., Bohren, K., Prendergast, F., and Gabbay, K., 1994. Mechanism of aldose reductase inhibition: Binding of NADP⁺/NADPH and alrestatin-like inhibitors. *Biochemistry* 33:7157–7165) show that these inhibitors probably bind to the enzyme:NADP⁺ complex at a site other than the active site.

22.

23. Carbons 1, 2, and 5 of ribose-5-P will be labeled.

24.

25.

26. Carbons 2 and 4 end up in carbons 1 and 3 of pyruvate.

27. The reference by Hurley et al. in the “Further Reading” for this chapter suggests a mechanism based on structural data on glycogenin. Nucleophilic attack by Asp¹⁶² on the C-1 of glucose (in UDP-glucose) forms a covalent enzyme-substrate intermediate. Subsequent nucleophilic attack by the hydroxyl oxygen of Tyr¹⁹⁴ of glycogenin produces the tyrosyl glucose that forms the foundation for synthesis of glycogen particles.

28. During the first few seconds of exercise, existing stores of ATP are consumed and creatine phosphate then provides additional ATP via the creatine kinase reaction. For the next 90 seconds or so, anaerobic metabolism (conversion of glucose to lactate via glycolysis) provides energy. At this point, aerobic metabolism begins in earnest, delivering significant energy resources to sustain long-term exercise.

29. Creatine phosphate provides ATP to muscle via the creatine kinase reaction:

The creatine kinase reaction

During periods of energy abundance, muscles store ATP equivalents in the form of creatine phosphate. When the muscles demand energy, creatine kinase runs in the reverse direction, converting creatine phosphate to ATP.

30. This exercise is left to the student and will presumably be different for every student.
31. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

Suggested products or intermediates:

- a. ATP to provide chemical energy needed for cell growth.
- b. Glyceraldehyde-3-phosphate/dihydroxyacetone phosphate as backbones for the glycerol moieties of glycerophospholipids. Increased cell growth requires the making of new membranes and leads to a higher demand for the biosynthesis of glycerophospholipids.
- c. Ribose-5-phosphate for the synthesis of new DNA.
- d. NADPH for the synthesis of fatty acids needed for the biosynthesis of glycerophospholipids as discussed in point b.

Chapter 23

1. Assuming that all fatty acid chains in the triacylglycerol are palmitic acid, the fatty acid content of the triacylglycerol is 95% of the total weight. On the basis of this assumption, one can calculate that 30 lb of triacylglycerol will yield 118.7 L of water.
2. 11-*cis*-Heptadecenoic acid is metabolized by means of seven cycles of β -oxidation, leaving a propionyl-CoA as the final product. However, the fifth cycle bypasses the acyl-CoA dehydrogenase reaction because a *cis*-double bond is already present at the proper position. Thus, β -oxidation produces 7 NADH (= 18.9 ATP), 6 FADH₂ (= 9.6 ATP), and 7 acetyl-CoA (= 74.9 ATP), for a total of 103.4 ATP. Propionyl-CoA is converted to succinyl-CoA (with expenditure of 1 ATP), which can be converted to oxaloacetate in the TCA cycle (with production of 1 GTP, 1 FADH₂, and 1 NADH). Oxaloacetate can be converted to pyruvate (with no net ATP formed or consumed), and pyruvate can be metabolized in the TCA cycle (producing 1 GTP, 1 FADH₂, and 4 NADH). The net for these conversions of propionate is 17.7 ATP. Together with the results of β -oxidation, the total ATP yield for the oxidation of one molecule of 11-*cis*-heptadecenoic acid is 121.1 ATP.
3. Instead of invoking hydroxylation and β -oxidation, the best strategy for oxidation of phytanic acid is α -hydroxylation, which places a hydroxyl group at C-2. This facilitates oxidative α -decarboxylation, and the resulting acid can react with CoA to form a CoA ester. This product then undergoes six cycles of β -oxidation. In addition to CO₂, the products of this pathway are three molecules of acetyl-CoA, three molecules of propionyl-CoA, and one molecule of 2-methylpropionyl-CoA.
4. Although acetate units cannot be used for net carbohydrate synthesis, oxaloacetate can enter the gluconeogenesis pathway in the PEP carboxykinase reaction. (For this purpose, it must be converted to malate for transport to the cytosol.) Acetate labeled at the carboxyl carbon will first label (equally) the C-3 and C-4 positions of newly formed glucose. Acetate labeled at the methyl carbon will label (equally) the C-1, C-2, C-5, and C-6 positions of newly formed glucose.
5. This exercise is left to the student, in consultation with the references suggested in the problem.
6. ATP and NADH
7. The catabolism of fatty acids in the peroxisomes leads to less production of ATP. ATP is an allosteric regulator that in general inhibits the catabolism of nutrients and promotes “storage” of nutrients (glycogen, fatty acids). In this context, ATP could promote weight gain and less production of ATP could result in less weight gain.
8. Albumin binds hydrophobic substances including drugs. The presence of free fatty acids may compete with drugs for binding to albumin, changing the transportation (and thus pharmacology) of drugs.
9. Fat is capable of storing more energy (37 kJ/g) than carbohydrate (16 kJ/g). Ten pounds of fat contains $10 \times 454 \times 37 = 167,980$ kJ of energy. This same amount of energy would require $167,980/16 = 10,499$ g, or 23 lb, of stored carbohydrate.
10. The enzyme methylmalonyl-CoA mutase, which catalyzes the third step in the conversion of propionyl-CoA to succinyl-CoA, is B₁₂-dependent. If a deficiency in this vitamin occurs, and if large amounts of odd-carbon fatty acids were ingested in the diet, L-methylmalonyl-CoA could accumulate.
11. a. Myristic acid:

$$\text{CH}_3(\text{CH}_2)_{12}\text{COOH} + 100.7 \text{ P}_i + 100.7 \text{ ADP} + 20 \text{ O}_2 \longrightarrow 100.7 \text{ ATP} + 14 \text{ CO}_2 + 114.1 \text{ H}_2\text{O}$$
- b. Stearic acid:

$$\text{CH}_3(\text{CH}_2)_{16}\text{COOH} + 130.7 \text{ P}_i + 130.7 \text{ ADP} + 26 \text{ O}_2 \longrightarrow 130.7 \text{ ATP} + 18 \text{ CO}_2 + 147.7 \text{ H}_2\text{O}$$
- c. α -Linolenic acid:

$$\text{C}_{17}\text{H}_{29}\text{COOH} + 123.5 \text{ P}_i + 123.5 \text{ ADP} + 25 \text{ O}_2 \longrightarrow 123.5 \text{ ATP} + 18 \text{ CO}_2 + 142.5 \text{ H}_2\text{O}$$
- d. Arachidonic acid:

$$\text{C}_{19}\text{H}_{31}\text{COOH} + 121.9 \text{ P}_i + 121.9 \text{ ADP} + 24.5 \text{ O}_2 \longrightarrow 121.9 \text{ ATP} + 20 \text{ CO}_2 + 139.9 \text{ H}_2\text{O}$$
12. During the hydration step, the elements of water are added across the double bond. Also, the proton transferred to the acetyl-CoA carbanion in the thiolase reaction is derived from the solvent, so each acetyl-CoA released by the enzyme would probably contain two tritiums. Seven tritiated acetyl-CoAs thus would derive from each molecule of palmitoyl-CoA metabolized, each with two tritiums at C-2.
13. It would be present in the carbonyl oxygen of acetyl-coenzyme A units.
14. A carnitine deficiency would presumably result in defective or limited transport of fatty acids into the mitochondrial matrix and reduced rates of fatty acid oxidation.
15. When blood sugar levels are low it indicates that the “energy” content of the blood is low. By activating lipase, glucagon provides energy to the tissues in the form of free fatty acids.
16. The presence of the villi significantly enhances the surface area of the epithelial cells of the digestive system. It allows for an efficient absorption of the digested dietary nutrients.
17. $1.3 \text{ grams} \times 37 \text{ kJ/gram} = 48,000 \text{ J}$. This at first seems like a remarkably small amount of energy to sustain the hummingbird during a 500-mile flight at 50 mph. However, keep in mind that the hummingbird weighs only 3 to 4 grams, and see Problem 18.

18. 48,000 J in 10 hours is 4800 J/hr. If the hummingbird consumes 250 mL per hour during migration, this means that it is consuming 4800/250 or 19.2 J/mL of oxygen consumed. If a human consumes 12.7 kcal/min while running, this is equivalent to $12,700 \times 4.184 \text{ J/cal} = 53.1 \text{ kJ/min}$; $48,000 \text{ J}/53,100 \text{ J/min} =$

0.9 minute. So a human could run for only less than a minute on the energy consumed by the hummingbird (only 3 to 4 g) on a 500-mile flight. A typical person would have to run about 40 miles to lose 1 lb of fat.

19. A mechanism for the HMG-CoA synthase reaction:

20.

21. The changes in oxidation state of cobalt in the course of any B_{12} -dependent reaction arise from homolytic cleavages of the $Co^{3+}-C$ bonds involved. Moreover, in the $Co^{3+}-C$ bonds shown in a typical B_{12} -dependent reaction, the two electrons of
22. See the following mechanisms:

the bond are not ascribed to the Co^{3+} atom in the calculation of the Co oxidation state. Thus, when the $Co-C$ bond is cleaved homolytically, one electron reverts to the Co, changing its oxidation state from $3+$ to $2+$.

23.

24. This exercise is left to the student and should be based on the reference provided in the problem.

25. It may be presumed that the oxidation of the acyl chain is accomplished via a two-electron transfer, whereas the steps involved in reoxidation of FADH_2 by ETF are one-electron transfers. FAD/FADH_2 can participate both in one-electron and two-electron transfers, whereas NAD^+/NADH can participate only in two-electron transfers.

26. The sequence of reactions involving creation of a double bond, then hydration across it, followed by oxidation is what happens to succinate in the TCA cycle. (This same sequence of reactions is also employed in fatty acid synthesis and in both the catabolism and anabolism of amino acids.) Clearly, this sequence of three reactions must represent an optimal mechanistic strategy for the chemistry achieved.

27. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

a.

* Stearic acid:

- Eight cycles of β -oxidation generating 8 NADH, 8 FADH_2 , and 9 acetyl-CoA.
- Each acetyl-CoA yields 3 NADH, 1 FADH_2 , and 1 GTP.
- Grand totals: 35 NADH, 17 FADH_2 , 130.7 ATP.

* Oleic acid:

- Seven cycles of β -oxidation generating 7 NADH, 7 FADH_2 , and 8 acetyl-CoA.
- One β -oxidation cycle generating only 1 NADH and 1 acetyl-CoA.
- Each acetyl-CoA yields 3 NADH, 1 FADH_2 , and 1 GTP.
- Grand totals: 35 NADH, 16 FADH_2 , 129.1 ATP.

* Linoleic acid:

- Six cycles of β -oxidation generating 6 NADH, 6 FADH_2 , and 7 acetyl-CoA.
- Two cycles of β -oxidation cycle generating only 2 NADH and 2 acetyl-CoA.
- One dehydrogenase reaction generating 1 FADH_2 .
- One reductase reaction consuming 1 NADPH.
- Each acetyl-CoA yields 3 NADH, 1 FADH_2 , and 1 GTP.
- Grand totals: 35 NADH, 16 FADH_2 , $129.1 - 4 = 125.1$ ATP.

* α -linolenic acid:

- Five cycles of β -oxidation generating 5 NADH, 5 FADH_2 , and 6 acetyl-CoA.
- Three cycles of β -oxidation cycle generating only 3 NADH and 3 acetyl-CoA.
- One dehydrogenase reaction generating 1 FADH_2 .
- One reductase reaction consuming 1 NADPH.
- Each acetyl-CoA yields 3 NADH, 1 FADH_2 , and 1 GTP.
- Grand totals: 35 NADH, 15 FADH_2 , $127.5 - 4 = 123.5$ ATP.

* γ -linolenic acid:

- Five cycles of β -oxidation generating 5 NADH, 5 FADH_2 , and 6 acetyl-CoA.
- Three cycles of β -oxidation generating only 3 NADH and 3 acetyl-CoA.
- One dehydrogenase reaction generating 1 FADH_2 .
- One reductase reaction consuming 1 NADPH.
- Each acetyl-CoA yields 3 NADH, 1 FADH_2 , and 1 GTP.
- Grand totals: 35 NADH, 15 FADH_2 , $127.5 - 4 = 123.5$ ATP.

b. The actual β -oxidation cycles do not produce any water; they consume water. Excess water is produced from the NADH- or FADH_2 -induced electron transport and the consequent reduction of O_2 to H_2O . Thus, the differences in amount of FADH_2 generated from the different C18 fatty acids will lead to differences in water produced.

Chapter 24

1. The equations needed for this problem are found under the discussion “Reduction of the Beta-Carbonyl Group Follows a Now-Familiar Route” in Section 24.1. See *The Student Solutions Manual, Study Guide and Problems Book* for details.
2. Carbons C-1 and C-6 of glucose become the methyl carbons of acetyl-CoA that is the substrate for fatty acid synthesis. Carbons C-2 and C-5 of glucose become the carboxyl carbon of acetyl-CoA for fatty acid synthesis. Only citrate that is immediately exported to the cytosol provides glucose carbons for fatty acid synthesis. Citrate that enters the TCA cycle does not immediately provide carbon for fatty acid synthesis.
3. A suitable model, based on the evidence presented in this chapter, would be that the fundamental regulatory mechanism in ACC is a polymerization-dependent conformation change in the protein. All other effectors—palmitoyl-CoA, citrate, and phosphorylation-dephosphorylation—may function primarily by shifting the inactive protomer-active polymer equilibrium. Polymerization may bring domains of the protomer (i.e., bicarbonate-, acetyl-CoA-, and biotin-binding domains) closer together or may bring these domains on separate protomers close to each other. See *The Student Solutions Manual, Study Guide and Problems Book* for further details.
4. They both involve the removal of a hydrogen from the $-\text{CH}_3$ portion of the acetyl group.
5. The phosphopantetheine may function, at least to some extent, as a flexible “arm” to carry acyl groups between the malonyl transferase and ketoacyl-ACP synthase active sites. The phosphopantetheine is approximately 1.9 nm in length, setting an absolute upper-limit distance between these active sites of 3.8 nm. However, on the basis of modeling considerations, it seems likely that the distance between these sites is smaller than this upper-limit value.
6. Two electrons pass through the chain from NADH to FAD to the two cytochromes of the cytochrome b_5 reductase and then to the desaturase. Together with two electrons from the fatty acyl substrate, these electrons reduce an O_2 to two molecules of water. The hydrogen for the waters that are formed in this way comes from the substrate (2H) and from two protons from solution.
7. When blood sugar levels are low or high it means that the caloric content of the blood is low or high. When caloric content is low, there is a need to tap into the caloric reserves rather than promoting storage of calories. This is promoted by glucagon. When caloric content is high, there is no need to tap into the caloric reserves, but a need to store calories away. This is promoted by insulin.
8. $\text{Ethanolamine} + \text{glycerol} + 2 \text{ fatty acyl-CoA} + 2 \text{ ATP} + \text{CTP} + \text{H}_2\text{O} \longrightarrow \text{phosphatidylethanolamine} + 2 \text{ ADP} + 2 \text{ CoA} + \text{CMP} + \text{PP}_i + \text{P}_i$
9. The glycolysis pathway leads to the production of pyruvate from carbohydrates. This pyruvate can then be converted into acetyl-coenzyme A for fatty acid biosynthesis. The glycolysis pathway also provides dihydroxyacetonephosphate that can serve as the backbone for the glycerol portion of the triacylglycerides.
10. The conversion of acetyl-CoA to lanosterol can be written as:
 $18 \text{ Acetyl-CoA} + 13 \text{ NADPH} + 13 \text{ H}^+ + 18 \text{ ATP} + 0.5 \text{ O}_2 \longrightarrow \text{lanosterol} + 18 \text{ CoA} + 13 \text{ NADP}^+ + 18 \text{ ADP} + 6 \text{ P}_i + 6 \text{ PP}_i + \text{CO}_2$
 The conversion of lanosterol to cholesterol is complicated; however, in terms of carbon counting, three carbons are lost in

the conversion to cholesterol. This process might be viewed as 1.5 acetate groups for the purpose of completing the balanced equation.

11.

12. The numbers 1 to 4 in the cholesterol structure indicate the carbon positions of mevalonate as shown (note that the numbering shown here is not based on the systematic numbering of mevalonate):

13. The O-linked saccharide domain of the LDL receptor probably functions to extend the receptor domain away from the cell surface and above the glycocalyx coat so that the receptor can recognize circulating lipoproteins.
14. As shown in Figures 24.19 and 24.22, the syntheses (in eukaryotes) of phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylglycerol are dependent upon CTP. A CTP deficiency would be likely to affect all these synthetic pathways.
15. It “costs” 1 ATP to form a malonyl-CoA. Each cycle of the fatty acyl synthase consumes 2 NADPH molecules, each worth 3.5 ATP. Thus, each of the seven cycles required to form a palmitic acid consumes 8 ATPs. A total of 56 ATPs are consumed to synthesize one molecule of palmitic acid.

16. The mechanism of the 3-ketosphinganine synthase reaction is shown in the following figure:

17. FAD is required for the eukaryotic reaction that converts stearic acid to oleic acid because the oxidation of a single bond to a double bond in stearic acid involves NADH and thus requires a two-electron transfer, whereas the reoxidation of FADH₂ to FAD is accomplished by electron transfer to cytochrome *b*₅. Cytochromes are capable of one-electron transfers only, so

FADH₂/FAD is required because it can participate both in one-electron and two-electron transfers.

18. See Chapter 23, problem 13, for a mechanism for the HMG-CoA synthase reaction.

19. A mechanism for the β -ketoacyl ACP synthase reaction:

β -Ketoacyl ACP synthase

20. This exercise is left to the student.
21. This exercise is left to the student.
22. This exercise is left to the student.
23. Figure 23.23 details the oxidation of acetyl-CoA in peroxisomes in which O_2 is reduced to H_2O_2 and then to H_2O . Figure 24.14 details the action of a desaturase in which O_2 is reduced to H_2O .
24. One way to accommodate the extreme bodily changes accompanying hibernation could involve changes in insulin responsiveness and sensitivity. During the preparation for hibernation, increased insulin sensitivity in adipose tissue could enable the bear to store large amounts of fat. During winter hibernation, greatly reduced insulin sensitivity would promote lipolysis and consumption of fat stores. A return to normal insulin sensitivity would be expected when the bear emerges from hibernation in the spring.
25. The phosphatidylinositol cycle described in the referenced article describes a cyclical metabolic pathway in which the intermediates of the cycle are regenerated each time the cycle goes around. Two of the enzymes in the cycle, diacylglycerol kinase- ϵ and CDP-DAG synthase-2, prefer substrates with the selected fatty acids (stearic acid and arachidonic acid). As a consequence, preferential incorporation of these acyl chains into phosphatidylinositol occurs in each turn of the cycle, and this enrichment is magnified over repeated cycles. The lipid intermediates of the cycle have to be segregated from other forms in the cell, because most species of these intermediates would not be enriched with 1-stearoyl-2-arachidonoyl species.

The phosphatidylinositol cycle. Abbreviations: PI, phosphatidylinositol; PI4P, phosphatidylinositol-4-P; PI4P5K, phosphatidylinositol-4-P 5-kinase; PIP2, phosphatidylinositol-4,5-bisphosphate; PLC, phospholipase C; DGK ϵ , diacylglycerol kinase, ϵ -isoform; CDS2, CDP-DAG synthase, 2-isoform; PIS, phosphatidylinositol synthase.

26. Palmitic acid must be elongated and then unsaturated to form linoleic acid. The elongation process involves a thio-lyase reaction to add two carbons to palmitoyl-CoA and then reduction of a carbonyl to a hydroxyl, dehydration to form a double bond, and then reduction of the double bond to a single bond. These last three reactions are the reverse of what happens in TCA, in the conversion of succinate to fumarate, then malate, then oxaloacetate. These same three reactions

occur in β -oxidation, in fatty acid synthesis, and in amino acid synthesis and degradation.

27. $11 \text{ Acetyl-CoA} + 10 \text{ ATP}^{4-} + 20 \text{ NADPH} + 10 \text{ H}^+ \longrightarrow \text{behenoyl-CoA} + 20 \text{ NADP}^+ + 10 \text{ CoASH} + 10 \text{ ADP}^{3-} + 10 \text{ P}_i^{2-}$
28. This exercise is left to the student and will presumably be different for every student.
29. This exercise is left to the student and will presumably be different for every student.
30. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

Possible targets could be:

- a. inhibition of pancreatic lipase to lower uptake of fatty acids from dietary sources
- b. interfere with the biosynthesis or function of bile acids to lower the efficiency of the digestion and absorption of dietary lipids
- c. interfere with the biosynthesis/packaging into chylomicrons of triacylglycerides in the epithelial cells of the digestive system
- d. promote the catabolism of fatty acids, either in the mitochondria or in the peroxisomes
- e. inhibit the anabolism of fatty acids and triacylglycerides
- f. interfere with assembly of VLDL particles in the liver
- g. block LDL receptor on surface of adipocytes
- h. block the actions of ChREBP (see Chapter 22)

Chapter 25

1. The oxidation number of N in nitrate is +5; in nitrite, +3; in NO, +2; in N_2O , +1; and in N_2 , 0.
2. a. Assume that nitrate assimilation requires four NADPH equivalents per NO_3^- reduced to NH_4^+ . Four NADPH have a metabolic value of 14 ATP.
b. Nitrogen fixation requires $8 e^-$ (see Equation 25.3) and 16 ATPs (see Figure 25.6) per N_2 reduced. If 4 NADH provide the requisite $8 e^-$, each NADH having a metabolic value of 3 ATPs, then 28 ATP equivalents are consumed per N_2 reduced in biological nitrogen fixation (or 14 ATP equivalents per NH_4^+ formed).
3. Carbon typically makes four chemical bonds because of its four valence electrons in the 2s and 2p orbitals. The six bonds between the iron atoms and the single carbon atom must involve the two core electrons in the 1s orbital of carbon in addition to the valence electrons.
4. The transformation of the carbonyl carbon ($C=O$) into the amine ($-CH-NH_3^+$) is a reduction. Oxidation number of carbon changes from +2 to 0.
5. a. [ATP] increase will favor adenylation; the value of n will be greater than 6 ($n > 6$).
b. An increase in P_{IIA}/P_{IID} will favor adenylation; the value of n will be greater than 6 ($n > 6$).
c. An increase in the $[\alpha KG]/[Gln]$ ratio will favor deadenylation; $n < 6$.
d. $[P_i]$ decrease will favor adenylation; $n > 6$.

6. Two ATPs are consumed in the carbamoyl-P synthetase-I reaction, and two phosphoric anhydride bonds (equal to two ATP equivalents) are expended in the argininosuccinate synthetase reaction. Thus, four ATP equivalents are consumed in the urea cycle, as one urea and one fumarate are formed from one CO₂, one NH₃, and one aspartate.
7. Protein catabolism to generate carbon skeletons for energy production releases the amino groups of amino acids as excess nitrogen, which is excreted in the urine, principally as urea.
8. The hydrolysis of the coenzyme A portion from succinyl-coenzyme A in this step provides the energy needed. Thioesters are high-energy bonds and their hydrolysis releases energy.
9. One ATP in reaction 1, one NADPH in reaction 2, one NADPH in reaction 11, and one succinyl-CoA in reaction 12 add up to 10 ATP equivalents, assuming each NADPH is worth 4 ATPs. (The succinyl-CoA synthetase reaction of the citric acid cycle [see Figure 19.11] fixes the metabolic value of succinyl-CoA versus succinate at 1 GTP [= 1 ATP].)

10. From Figure 25.36: ¹⁴C-labeled carbon atoms derived from ¹⁴C-2 of PEP are shaded yellow.

11. 1. 2 aspartate $\longrightarrow$ *transamination* $\longrightarrow$ 2 oxaloacetate.
 2. 2 oxaloacetate + 2 GTP $\longrightarrow$ *PEP carboxykinase* $\longrightarrow$ 2 PEP + 2 CO₂ + 2 GDP.
 3. 2 PEP + 2 H₂O $\longrightarrow$ *enolase* $\longrightarrow$ 2 2-PG.
 4. 2 2-PG $\longrightarrow$ *phosphoglyceromutase* $\longrightarrow$ 2 3-PG.
 5. 2 3-PG + 2 ATP $\longrightarrow$ *3-P glycerate kinase* $\longrightarrow$ 2 1,3-bisPG + 2 ADP.
 6. 2 1,3-bisPG + 2 NADH + 2 H⁺ $\longrightarrow$ *G-3-P dehydrogenase* $\longrightarrow$ 2 G-3-P + 2 NAD⁺ + 2 P_i.
 7. 1 G-3-P $\longrightarrow$ *triose-P isomerase* $\longrightarrow$ 1 DHAP.
 8. G-3-P + DHAP $\longrightarrow$ *aldolase* $\longrightarrow$ fructose-1,6-bisP.
 9. F-1,6-bisP + H₂O $\longrightarrow$ *FBPase* $\longrightarrow$ F-6-P + P_i.
 10. F-6-P $\longrightarrow$ *phosphoglucisomerase* $\longrightarrow$ G-6-P.
 11. G-6-P + H₂O $\longrightarrow$ *glucose phosphatase* $\longrightarrow$ glucose + P_i.
- Net: 2 aspartate + 2 GTP + 2 ATP + 2 NADH + 6 H⁺ + 4 H₂O $\longrightarrow$ glucose + 2 CO₂ + 2 GDP + 2 ADP + 4 P_i + 2 NAD⁺

(Note that 4 of the 6 H⁺ are necessary to balance the charge on the 4 carboxylate groups of the 2 OAA and the loss of amino groups from Asp is ignored.)

(As a consequence of reaction [1], 2 α -keto acids [e.g., α -ketoglutarate] will receive amino groups to become 2 α -amino acids [e.g., glutamate].)

12. Alanine: glutamate:pyruvate aminotransferase.

Arginine: from glutamate via ornithine, so it's glutamate dehydrogenase.

Aspartate: glutamate:oxaloacetate aminotransferase.

Asparagine: from aspartate, so it's the glutamate:oxaloacetate aminotransferase.

Cysteine: cysteine is formed from serine, so it's glutamate via 3-phosphoserine aminotransferase.

Glutamate: glutamate dehydrogenase or alternatively, GOGAT.

Glutamine: glutamine synthetase.

Glycine: glycine is formed from serine, so it's glutamate via 3-phosphoserine aminotransferase.

Histidine: from glutamate via L-histidinol phosphate aminotransferase.

Isoleucine: glutamate: α -keto- β -methylvalerate aminotransferase.

Leucine: glutamate: α -ketoisocaproate aminotransferase.

Lysine: from glutamate via saccharopine formation by a glutamate-dependent NADPH dehydrogenase; in bacteria, lysine is synthesized from aspartate, so it's glutamate:oxaloacetate aminotransferase.

Methionine: from aspartate, so it's glutamate:oxaloacetate aminotransferase.

Phenylalanine: glutamate:phenylpyruvate aminotransferase (= phenylalanine aminotransferase).

Proline: from glutamine, so it's glutamate dehydrogenase.

Serine: glutamate via 3-phosphoserine aminotransferase.

Threonine: from aspartate, so it's glutamate:oxaloacetate aminotransferase.

Tryptophan: from serine via tryptophan synthase, so its α -amino group comes from serine, which gets its amino group from glutamate via 3-phosphoserine aminotransferase.

Tyrosine: glutamate:4-hydroxyphenylpyruvate aminotransferase (= tyrosine aminotransferase).

Valine: glutamate: α -ketoisovalerate aminotransferase.

13. Biosynthesis of lysine in fungi (see Figure 25.24) and biosynthesis of leucine (see Figure 25.30).

14. Pyridoxal (vitamin B₆), because it is the precursor to pyridoxal-P, the key coenzyme in aminotransferase reactions, as well as other aspects of amino acid metabolism.

15. The conversion of homocysteine to methionine is folate-dependent; dietary folate absorption is dependent on vitamin B₁₂ for removal of methyl groups added to folate during digestion; finally, the α -amino group of homocysteine formed in the methionine biosynthetic pathway comes from aspartate via the pyridoxal-P-dependent glutamate:oxaloacetate aminotransferase.

16. The BCKDH complex is structurally and functionally analogous to the pyruvate dehydrogenase complex and the α -ketoglutarate dehydrogenase complexes. See Figure 19.4; the reaction mechanism for the pyruvate dehydrogenase complex is essentially the same as that of the BCKDH complex.

17. Aspartame is a *N*- α -L-aspartyl-L-phenylalanine-1-methyl ester that is broken down in the digestive tract and phenylalanine is released. Phenylalanine is the substance that phenylketonurics must avoid.

18. Glyphosate inhibits 3-enolpyruvylshikimate-5-P synthase, an essential enzyme in the biosynthesis of chorismate. Not only is chorismate the precursor for synthesis of the aromatic amino acids Phe, Tyr, and Trp, it is also the precursor for formation of lignin, a major structural component in plant cell walls, as well as other essential substances such as folate, coenzyme Q, plastoquinone, and vitamins E and K.

19. Glycine is formed from serine, which is formed from 3-phosphoglycerate. Carbons 3 and 4, 2 and 5, and 1 and 6 of glucose contribute carbons 1, 2, and 3 of 3-phosphoglycerate, respectively. The β -carbon of serine derives from the 3-C in 3-phosphoglycerate, the C $_{\alpha}$ -carbon atom in serine comes from 3-phosphoglycerate C-2, and the carboxyl-C in serine comes from C-1 of 3-PG. It is these latter two carbons of 3-PG that are found in glycine; that is, C-1 and C-2 of 3-PG; C-1 of 3-PG came

from C-3 and C-4 in glucose, and C-2 of 3-PG came from C-2 and C-5 in glucose.

20. Degradation of leucine or lysine can yield acetyl-coenzyme A. There is no metabolic pathway that can achieve glucose synthesis from acetyl-CoA.
21. Serine is an important precursor for glycine synthesis.
22. Consult <https://www.rcsb.org> to view pdb id = 1LM1.
23. The liver converts amino acids to glucose to provide a source of energy for other cells, such as nerve and red blood cells. Conversion of amino acids to glucose by gluconeogenesis requires energy; for example, six ATP equivalents are needed to form glucose from aspartic acid.
24. GS monomers are inactive because GS active sites require elements of protein structure contributed by adjacent subunits in the GS₁₂ dodecamer.
25. Four of the six carbons in the ring of Tyr come from erythrose-4-P and the remaining two from PEP; the carboxyl-C, C_α, and C_β of Tyr come from PEP. Degradation of Tyr to acetoacetate + fumarate yields acetoacetate composed from the C_α and C_β plus 2 C atoms from the ring, which are either both from E-4-P or one each from E-4-P and PEP, depending on the orientation of the ring (rotation about the C_β-ring C bond). Fumarate will be composed from 2 C atoms from PEP and 2 from E-4-P or 3 C atoms from E-4-P and 1 from PEP.
26. Consult the PSFAE website entry for glutamine synthetase to discover the answer.
27. Consult the PSFAE website entry for glutamate-oxaloacetate transaminase I to compose your answer.

Think-Pair-Share Question:

- a. Step 2: reduction of carboxylic acid carbon (oxidation number +3) to aldehyde carbon (oxidation number +1). Step 4: reduction of HC=N— to H₂C—NH (oxidation number of carbon changes from +1 to −1).
- b. Step 3: reduction of carboxylic acid carbon (oxidation number +3) to aldehyde carbon (oxidation number +1).
- c. Step 7: reduction of carboxylic acid carbon (oxidation number +3) to aldehyde carbon (oxidation number +1). Step 8: reduction of aldehyde carbon (oxidation number +1) to amine carbon (oxidation number −1). Caution: steps 4 and 9 in this pathway are oxidations, not reductions.
- d. Step 2: reduction of carboxylic acid carbon (oxidation number +3) to aldehyde carbon (oxidation number +1). Step 3: reduction of aldehyde carbon (oxidation number +1) to primary alcohol carbon (oxidation number −1).
- e. Step 3: reduction of ketone carbon (oxidation number +2) to secondary alcohol carbon (oxidation number 0).
- f. Caution: step 3 is an oxidation. Step 4: reduction of ketone carbon (oxidation number +2) to amine carbon (oxidation number 0); compensated for a reverse oxidation of glutamate to α-ketoglutarate.

Chapter 26

1. See Figures 26.2 (purines) and 26.13 (pyrimidines).
2. Assume ribose-5-P is available.

Purine synthesis: 2 ATP equivalents in the ribose-5-P pyrophosphokinase reaction, 1 in the GAR synthetase reaction, 1 in the FGAM synthetase reaction, 1 in the AIR carboxylase reaction, 1 in the CAIR synthetase reaction, and 1 in the SCAIR synthetase reaction yields IMP, the precursor common to ATP and GTP. Net: 7 ATP equivalents.

- a. *ATP:* 1 GTP (an ATP equivalent) is consumed in converting IMP to AMP; 2 more ATP equivalents are needed to convert AMP to ATP. Overall, ATP synthesis from ribose-5-P onward requires 10 ATP equivalents.
- b. *GTP:* 2 high-energy phosphoric anhydride bonds from ATP, but 1 NADH is produced in converting IMP to GMP; 2 more ATP equivalents are needed to convert GMP to GTP. Overall, GTP synthesis from ribose-5-P onward requires 8 ATP equivalents.

Pyrimidine synthesis: Starting from HCO₃[−] and Gln, 2 ATP equivalents are consumed by CPS-II, and an NADH equivalent is produced in forming orotate. OMP synthesis from ribose-5-P plus orotate requires conversion of ribose-5-P to PRPP at a cost of 2 ATP equivalents. Thus, the net ATP investment in UMP synthesis is just 1 ATP.

- c. *UTP:* Formation of UTP from UMP requires 2 ATP equivalents. Net ATP equivalents in UTP biosynthesis = 3.
- d. *CTP:* CTP biosynthesis from UTP by CTP synthetase consumes 1 ATP equivalent. Overall ATP investment in CTP synthesis = 4 ATP equivalents.

3. BEADC

4. “ATP consumption” refers to the hydrolysis of the high-energy bonds in ATP. This does not involve any changes in the adenine component of ATP. The energy in ATP is consumed, but not the adenine content.

5. a. See Figure 26.6.

b. See Figure 26.17.

c. See Figure 26.17.

6. a. Azaserine inhibits glutamine-dependent enzymes, as in steps 2 and 5 of IMP synthesis (glutamine:PRPP amidotransferase and FGAM synthetase), as well as GMP synthetase (step 2, Figure 26.5), and CTP synthetase (Figure 26.16).
- b. Methotrexate, an analog of folic acid, antagonizes THF-dependent processes, such as steps 4 and 10 (GAR transformylase and AICAR transformylase) in purine biosynthesis (Figure 26.3), and the thymidylate synthase reaction (Figure 26.26) of pyrimidine metabolism.
- c. Sulfonamides are analogs of *p*-aminobenzoic acid (PABA). Like methotrexate, sulfonamides antagonize THF formation. Thus, sulfonamides affect nucleotide biosynthesis at the same sites as methotrexate, but only in organisms such as prokaryotes that synthesize their THF from simple precursors such as PABA.
- d. Allopurinol is an inhibitor of xanthine oxidase (Figure 26.10).
- e. 5-Fluorouracil inhibits the thymidylate synthase reaction (Figure 26.26).

7. UDP, via conversion to dUDP (Figure 26.24), is ultimately a precursor to dTTP, which is essential to DNA synthesis.
8. See Figure 26.23.
9. a. Oxidation of water to oxygen in the photosynthesis process (see Chapter 21).
b. Glucose is a source of ribose and NADPH (needed for the reductase action) through the PPP (see Chapter 22).
10. Ribose, as ribose-5-P, is released during nucleotide catabolism (as in Figure 26.8). Ribose-5-P is catabolized via the pentose phosphate pathway and glycolysis to form pyruvate, which enters the citric acid cycle. From Chapter 22, problem 17, note that 3 ribose-5-P (in the form of 1 ribose-5-P and 2 xylulose-5-P) would give a net consumption of 2 ATPs and a net production of 8 ATPs and 5 NADH (= 15 ATPs), when converted to 5 pyruvate. If each pyruvate is worth 15 ATP equivalents (as in a prokaryotic cell), the overall yield of ATP from 3 ribose-5-P is $75 \text{ ATP} + 23 \text{ ATP} - 2 \text{ ATP} = 96 \text{ ATP}$. Net yield per ribose-5-P is thus 32 ATP equivalents.
11. Comparing Figures 26.3 and 25.40, note that AICAR (5-aminoimidazole-4-carboxamide ribonucleotide) is a common intermediate in both pathways. It is a product of step 5 of histidine biosynthesis (Figure 25.40) and step 9 of purine biosynthesis (Figure 26.3). Thus, formation of AICAR as a by-product of histidine biosynthesis from PRPP and ATP bypasses the first nine steps in purine synthesis. However, cells require greater quantities of purine than of histidine, and these nine reactions of purine synthesis are essential in satisfying cellular needs for purines.
12. See the following figure:

Step 6

Step 8

Step 9

13. $\text{Aspartate} + \text{GTP}^{4-} + \text{H}_2\text{O} \longrightarrow \text{fumarate} + \text{NH}_4^+ + \text{GDP}^{3-} + \text{P}_i^{2-}$
14. 1. $\text{Uric acid} + 2 \text{H}_2\text{O} + \text{O}_2 \xrightarrow{\text{urate oxidase}} \text{allantoin} + \text{H}_2\text{O}_2 + \text{CO}_2$
 2. $\text{Allantoin} + \text{H}_2\text{O} \xrightarrow{\text{allantoinase}} \text{allantoic acid} + \text{glyoxylic acid}$
 3. $\text{Allantoic acid} + \text{H}_2\text{O} \xrightarrow{\text{allantoicase}} 2 \text{urea}$
 4. $2 \text{Urea} + 2 \text{H}_2\text{O} \xrightarrow{\text{urease}} 2 \text{CO}_2 + 2 \text{HN}_3$

15.

16. ATCase (subunit organization $\alpha_6\beta_6$) consists of six functional units, each composed of one α -subunit and one β -subunit, best described as $(\alpha\beta)_6$.
17. From these starting materials to UTP in a eukaryotic cell, where mitochondrial oxidation of dihydroorotate via a coenzyme Q-linked flavoprotein would yield 1.5 ATPs, has a net cost of 2.5 ATPs. From UTP to dTTP would require an ATP at the CTP synthetase step; recovery of an ATP in the nucleoside diphosphate kinase reaction $\text{ADP} + \text{CTP} \rightarrow \text{CDP} + \text{ATP}$; an NADPH (= 4 ATP equivalents) in converting $\text{CDP} \rightarrow \text{dCDP}$, recovery of an ATP equivalent in the deoxycytidylate kinase reaction $\text{dCDP} + \text{ADP} \rightarrow \text{dCMP} + \text{ATP}$, deamination of dCMP to dUMP by dCMP deaminase; conversion of dUMP to dTMP by thymidylate synthase and then 2 ATP equivalents to form dTTP. Net: 7.5 ATP equivalents versus 10 ATP for ATP synthesis via the purine biosynthetic pathway.

18. 1. $\text{UMP} + \text{ATP} \longrightarrow \text{UDP} + \text{ADP}$
 2. $\text{UDP} + \text{NADPH} \longrightarrow \text{dUDP} + \text{NADP}^+ + \text{OH}^-$
 3. $\text{dUDP} + \text{ATP} \longrightarrow \text{dUTP} + \text{ADP}$
 4. $\text{dUTP} + \text{H}_2\text{O} \longrightarrow \text{dUMP} + \text{PP}_i$
 5. $\text{PP}_i + \text{H}_2\text{O} \longrightarrow 2 \text{P}_i$
 6. $\text{dUMP} + \text{N}^5, \text{N}^{10}\text{-methylene-THF} \longrightarrow \text{dTMP} + \text{DHf}$
 Net: $\text{UMP} + \text{N}^5, \text{N}^{10}\text{-methylene-THF} + 2 \text{ATP} + \text{NADPH} + 2 \text{H}_2\text{O} \longrightarrow \text{dTMP} + \text{DHf} + 2 \text{ADP} + 2 \text{P}_i + \text{OH}^- + \text{NADP}^+$
- R^{23} , $\text{R}^{178'}$, $\text{R}^{179'}$, and R^{218} in thymidylate synthase are hydrogen-bond donors to the phosphate group of the substrate, dUMP. See Kawase, S., Cho, S. W., Rozell, J., and Stroud, R. M., 2000. Replacement set mutagenesis of the four phosphate-binding arginine residues of thymidylate synthase. *Protein Engineering* 13:557–563. (The other substrate, $\text{N}^5, \text{N}^{10}$ -methylene-THF bears negative charge on its glutamate units, and without knowledge of thymidylate synthase structure and function, would also be a possibility.)

19. Possibilities include glutamine phosphoribosyl pyrophosphate amidotransferase (see Figure 26.3), adenine phosphoribosyl transferase and hypoxanthine–guanine phosphoribosyl transferase (see Figure 26.7), ribose-5-phosphate pyrophosphokinase (see Figure 26.3), and enzymes of the pyrimidine salvage pathway.
20. Explore pdb id = 7DFR. Note the proximity of the 4-position of the nicotinamide ring (the hydride donor) to the 7-position of folate (the hydride acceptor). Note that polar groups on the substrates are solvent-exposed.
21. View pdb id = 1RAA to see that the CTP-binding sites on the R-subunits are dominated by β -strands. View pdb id = 1RAA to see the ATCase substrate-binding sites (evident from the location of the substrate analog *N*-2-(phosphonoacetyl)-L-asparagine). The allosteric (CTP-binding) sites and the active sites are at opposite ends of the protein. Thus, CTP binding is communicated to the active site via ligand-induced conformational changes extending across the entire protein. R-state ATCase is represented by pdb id = 2IPO; T-state by pdb id = 1RAA.
22. There is a high demand for DNA replication and thus the biosynthesis of nucleotides during embryonic growth. The importance of folic acid in the biosynthesis of nucleotides is one of the rationales why pregnant women are recommended to take in extra amounts of folic acid.
23. The anticancer agents are not selective, affecting cancer and normal cells leading to side effects. However, because cancer cells have a much higher demand for nucleotide biosynthesis, the anticancer agents affect cancer cells much more than normal cells.
24. If GMP levels are high (but GDP or AMP is not), ribose-5-P pyrophosphokinase will not be inhibited, glutamine-PRPP amidotransferase will be roughly 50% inhibited due to GMP binding at the G nucleotide allosteric site, and IMP dehydrogenase will be blocked, so IMP is directed toward AMP synthesis to give a balanced amount of A versus G nucleotides.
25. Carbons 1 and 6.
26. Consult the PSafe website entry for CTP synthetase to discover the answer.
27. Consult the PSafe website entry for HGPRT to compose your answer.

Think-Pair-Share Question:

Building block: part of the structure of DNA, RNA, NAD^+ , NADP^+ , FAD, Coenzyme A

Regulation: as ATP it serves as a donor of phosphoryl groups in protein kinase reactions; source of cAMP; source of AMP for adenylation; as ATP, ADP, or AMP it can act as a direct allosteric regulator; as ATP it can serve to recycle GTP from GDP for G-proteins

Energy source: as ATP it serves as high-energy compound that donates phosphoryl, pyrophosphoryl, or adenylyl groups.

Autacoid: Adenosine is a local regulator of physiological processes in mammals.

Chapter 27

1. a. $K_{eq} = 360,333$.
b. Assuming $[ATP] = [ADP]$, [pyruvate] must be greater than 360,333 [PEP] for the reaction to proceed in reverse.
c. $K_{eq} = 0.724$.
d. $[PEP]/[pyruvate] = 724$.
e. Yes. Both reactions will be favorable as long as $[PEP]/[pyruvate]$ falls between 0.0000028 and 724.
2. Energy charge = 0.945; phosphorylation potential = $1111 M^{-1}$.
3. (1) The number of protons flowing across the inner membrane during the electron transport in complex I, III and IV is not stoichiometric. (2) The number of complexes that couple proton transport to electron transport is not stoichiometric. Electron transport could have existed with more or less complexes to transport protons across the inner membrane. (3) The number of subunits in the c ring of the ATP complex is not a chemical constant across Nature; it determines how many protons need to flow through the complex to drive one revolution of the F_0 part of the F_1F_0 -ATP synthase.
4. 8 mM ATP will last 1.12 sec. Because the equilibrium constant for creatine-P + ADP $\rightarrow$ Cr + ATP is 175, [ATP] must be less than 1750 [ADP] for the reaction creatine-P + ADP $\rightarrow$ Cr + ATP to proceed to the right when $[Cr-P] = 40$ mM and $[Cr] = 4$ mM.
5. From Equation 3.42, $\mathcal{E}(NAD^+/NADPH) = -0.350$ V; $\mathcal{E}(NAD^+/NADH) = -0.281$ V; thus, $\Delta\mathcal{E} = 0.069$ V, and $\Delta G = -13,316$ J/mol. If an ATP “costs” 50 kJ/mol, this reaction can produce about 0.27 ATP equivalent at these concentrations of NAD^+ , NADH, $NADP^+$, and NADPH.
6. NADH is used in gluconeogenesis.
7. Assume that the K_{eq} for $ATP + AMP \rightarrow 2 ADP = 1.2$ (see legend to Figure 27.2). When $[ATP] = 7.2$ mM, $[ADP] = 0.737$ mM and $[AMP] = 0.063$ mM. When $[ATP]$ decreases by 10% to 6.48 mM, $[ADP] + [AMP] = 1.52$ mM and thus $[ADP] = 1.30$ mM and $[AMP] = 0.22$ mM. A 10% decrease in $[ATP]$ has resulted in a $0.22/0.063 = 3.5$ -fold increase in $[AMP]$.
8. J (the flux of F-6-P through the substrate cycle) at low $[AMP] = 0.1$; J at high $[AMP] = 8.9$. Therefore, the flux of F-6-P through the cycle has increased 89-fold.
9. Inhibition of acetyl-CoA carboxylase will lower the concentration of malonyl-CoA. Because malonyl-CoA inhibits uptake of fatty acids (see Figure 24.16), decreases in $[malonyl-CoA]$ favor fatty acid synthesis.
10. Ethanol oxidation to acetate yields 2 NADH in the cytosol, each worth 1.5 ATPs. The acetyl thiokinase reaction consumes 2 ATP equivalents in converting acetate to acetyl-CoA (due to $ATP \rightarrow AMP + PP_i$). Combustion of acetyl-CoA $\rightarrow 2 CO_2$ in a liver cell yields a net of 10 ATPs. Therefore, the net yield of ATP from ethanol in a liver cell is 11 ATPs. Glucose $\rightarrow 6 CO_2$ in a liver cell yields 30 ATPs (see Table 20.4) or 5 ATP/C atom. Ethanol $\rightarrow 2 CO_2$ gives 11 ATPs or 5.5 ATP/C atom.
11. $Palmitoyl-CoA \rightarrow 8$ acetyl-CoA yields 7 NADH and 7 $[FADH_2] = 21 + 14 = 35$. Eight acetyl-CoA $\rightarrow$ palmitoyl-CoA requires $14 NADPH + 7 ATP = -63$ ATP (negative sign denotes ATP consumed). The $palmitoyl-CoA \rightleftharpoons 8$ acetyl-CoA conversion is favorable in both directions provided the free energy release is more than 1750 kJ/mol in the catabolic (acetyl-CoA forming) direction (the energy necessary to produce 35 ATP equivalents at a cost of 50 kJ/mol each) and less than 3150 kJ/mol in the anabolic (palmitoyl-CoA forming) direction (the energy released from 63 ATP equivalents).
12. Cellular respiration releases 2870 kJ/mol of glucose under standard-state conditions (and about the same amount under cellular conditions). Assuming the cell is a bacterial cell where cellular respiration produces 38 ATPs, the total cost of ATP synthesis is $38(50) = 1900$ kJ/mol. Thus, the overall free energy change = $-2870 + 1900 = -970$ kJ/mol. Because $\Delta G^{\circ'} = -RT \ln K_{eq}$, $K_{eq} = e^{391.4447} = 10^{168}$. This is a very large number! It will be even larger for a cell where ATP yields per glucose are less.
Carbon dioxide fixation leads to glucose synthesis at the cost of 12 NADPH and 18 ATP = 66 ATP equivalents. At 50 kJ/mol, the energy investment from ATP is -3300 kJ/mol and the value of a glucose is $+2870$ kJ/mol. Thus, $\Delta G^{\circ'} = -430$ kJ/mol = $-RT \ln K_{eq}$. $K_{eq} = e^{173.52} = 10^{75}$, which is also a very large number!
13. ATP is an allosteric regulator directly activating or inhibiting enzymes or protein kinases. ATP serves as a source of cAMP and provides phosphoryl groups for protein kinases, indirectly affecting the activity and function of many enzymes or proteins.
14. The amino group on the side chain of lysine is positively charged making it suitable for interactions with negatively charged functional groups such as DNA backbone phosphates. Acetylation of the amino group abolishes its positive charge and its capacity to interact with negatively charged functional groups. Acetylated histone proteins interact much less with DNA compared to deacetylated histone proteins.
15. Glycogen phosphorylase, phosphorylase kinase, glycogen synthase, PFK-1, PFK-2, FBPase, and glucose-6-P phosphatase are liver enzymes that act specifically in glycogenolysis or gluconeogenesis; these enzymes are potential targets to control blood glucose levels.
16. Contracting muscles promote the uptake of glucose from the circulation. Exercising lowers blood sugar levels without the need for insulin and can help lower high blood sugar levels for both types of diabetes.
17. From Figure 27.12: The “limit production” list would include NPY, AgRP, and ghrelin; the “raise levels” list would include cholecystokinin, leptin, insulin, melanocortins, and PYY_{3-36} .
18. Leptin injection in *ob/ob* mice decreases food intake, raises fatty acid oxidation levels, and lowers body weight. Obese humans are not usually defective in leptin production. Indeed, because leptin is produced in adipocytes, obese individuals may already have high levels of leptin, so leptin injection has limited success.
19. No, although NPY is an orexigenic agent, it is not necessarily an obesity-promoting hormone. Mice deficient in melanocortin production, melanocortin receptors, or leptin receptors would have an obese phenotype because all these agents act in appetite-suppressing pathways.
20. Alcohol consumption lowers the $NAD^+/NADH$ ratio, which limits glycolysis because glyceraldehyde-3-P dehydrogenase requires NAD^+ , stimulates gluconeogenesis because NADH favors glyceraldehyde-3-P dehydrogenase working in the glucose synthesis direction, and limits fatty acid oxidation because β -oxidation requires NAD^+ . NADH is also a negative regulator of several citric acid cycle enzymes.
21. The T172D mutant of AMPK mimics the phosphorylated form in having negative charge on the side chain at position 172.

22. a. Fatty acyl-CoA.
b. Transgenic mice lacking functional hypothalamic fatty acid synthase should have elevated [malonyl-CoA]. If hypothalamic levels of malonyl-CoA are high, eating should diminish, as should body fat content. Assuming physical activity is proportional to signals of nutrient availability, physical activity should increase.
23. a. Leptin-deficient mice should respond to regular leptin injections by losing weight.
b. The leptin receptor. Assay wild-type and *db/db* mutant cells for leptin binding ability.
24. The heart is the principal organ using both glucose and fatty acids in the well-fed state; the brain relies mostly on glucose (although adipose tissue also relies on glucose for glycerol production); muscle relies mostly on fatty acids; the brain never uses fatty acids; and muscle produces lactate, which is converted in the liver into glucose.
25. a. Hexokinase is an R enzyme because it is a glycolytic enzyme. Glutamine:PRPP amidotransferase is not an ATP-dependent enzyme, so it is neither an R or a U enzyme. It responds to the adenine nucleotide pool through feedback inhibition by AMP, ADP, and ATP.
b. If $E.C. = 0.5$, hexokinase activity is high and ribose-5-P pyrophosphokinase activity is likely to be low because R-5-P pyrophosphokinase is probably a U enzyme.
c. At $E.C. = 0.95$, the situation reverses and hexokinase activity is low and R-5-P pyrophosphokinase activity is high.

PSAFE Problem. Consult the PSafe website entry for resistin to compose your answer.

Think-Pair-Share Question:

- a. Review all chapters related to the metabolic pathways and their regulation to review the specifics.
Insulin promotes synthesis of glycogen and fatty acids and the activation of glycolysis and pyruvate dehydrogenase. Insulin inhibits glycogen and fatty acid breakdown, pyruvate dehydrogenase and gluconeogenesis; particularly in liver cells.
Glucagon acts in opposite fashion as insulin; particularly in liver cells.
Leptin activates AMPK and Figure 27.6 illustrates the consequences of activation or inhibition by AMPK.
Epinephrine promotes glycogen and fatty acid breakdown, glycolysis and pyruvate dehydrogenase activity, particularly in skeletal muscle cells.
- b. The TCA cycle is an amphibolic pathway. The TCA cycle is useful for both anabolic or catabolic purposes. Thus, hormones that typically inhibit anabolic pathways and activate catabolic pathways or vice versa, do not affect the TCA cycle. The hormones or secondary messengers listed do affect the levels of substrate or product available and as such can, indirectly, affect the TCA cycle.

Chapter 28

1. The density of DNA can be determined by density gradient ultracentrifugation. (a) Assuming DNA replication is semiconservative, the density of the DNA will be $(1.724 + 1.710)/2 = 1.717$ g/mL. (b) If DNA replication is conservative, two bands will be seen upon density gradient ultracentrifugation of the

DNA after one generation of growth on ^{15}N -containing media: a band at density = 1.724 g/mL representing the progeny dsDNA and a parental band at 1.710 g/mL.

2. The 5'-exonuclease activity of DNA polymerase I removes mispaired segments of DNA sequence that lie in the path of the advancing polymerase. Its biological role is to remove mispaired bases during DNA repair. The 3'-exonuclease activity acts as a proofreader to see whether the base just added by the polymerase activity is properly base-paired with the template. If not (that is, if it is an improper base with respect to the template), the 3'-exonuclease removes it and the polymerase activity can try once more to insert the proper base. An *E. coli* strain lacking DNA polymerase I 3'-exonuclease activity would show a high rate of spontaneous mutation.
3. Assume that the polymerization rate achieved by each half of the DNA polymerase III homodimer is 750 nucleotides per sec. The entire *E. coli* genome consists of 4.64×10^6 bp. At a rate of 750 bp/sec per DNA polymerase III homodimer (one at each replication fork), DNA replication would take almost 3100 sec (51.7 min; 0.86 hr). When *E. coli* is dividing at a rate of once every 20 min, *E. coli* cells must be replicating DNA at the rate of 4.64×10^6 bp per 20 min (2.32×10^5 bp/min or 3867 bp/sec). To achieve this rate of replication would require initiation of DNA replication once every 20 min at *ori*, and a minimum of $3933/1500 = 2.57$ replication bubbles per *E. coli* chromosome, or 5.14 replication forks.

5. If there are 40 molecules of DNA polymerase III (as DNA polymerase III homodimers) per *E. coli* cell and *E. coli* growing at its maximum rate has about five replication forks per chromosome, DNA polymerase III availability is sufficient to sustain growth at this rate.
6. The actions of gyrase, helicase (including CMG helicase), replication initiator, DnaC, γ -complex as clamp loader, Cdc6, MCM proteins, and Orc proteins.
7. Okazaki fragments are 1000 to 2000 nucleotides in length. Because DNA replication in *E. coli* generates Okazaki fragments whose total length must be 4.64×10^6 nucleotides, a total of 2300 to 4700 Okazaki fragments must be synthesized. Consider in comparison a human cell carrying out DNA replication. The haploid human genome is 3×10^9 bp, but most cells are diploid (6×10^9 bp). Collectively, the Okazaki fragments must total 6×10^9 nucleotides in length, distributed over 3 to 6 million separate fragments (assuming they are 1 to 2 kb in length).

8. DNA gyrases are ATP-dependent topoisomerases that introduce negative supercoils into DNA. DNA gyrases change the linking number, L , of double-helical DNA by breaking the sugar-phosphate backbone of its DNA strands and then religating them (see Figure 11.26). In contrast, helicases are ATP-dependent enzymes that disrupt the hydrogen bonds between base pairs that hold double-helical DNA together. Helicases move along dsDNA, leaving ssDNA in their wake.
9. Gyrases act as topoisomerases that cut and religate DNA strands. These cuts must be religated properly. Helicases do not cut DNA strands.
10. A diploid human cell contains 6×10^9 bp of DNA. One origin of replication every 300 kbp gives 20,000 origins of replication in 6×10^9 bp. If DNA replication proceeds at a rate of 100 bp/sec at each of 40,000 replication forks (2 per origin), 6×10^9 bp could be replicated in 1500 sec (25 min). To provide 2 molecules of DNA polymerase per replication fork, a cell would require 80,000 molecules of this enzyme.
11. For purposes of illustration, consider how the heteroduplex bacteriophage chromosome in Figure 28.17 might have arisen:

12. The mismatch repair system of *E. coli* relies on DNA methylation to distinguish which DNA strand is “correct” and which is “mismatched”; the unmethylated strand (the newly synthesized one that has not had sufficient time to become methylated is, by definition, the mismatched one). Homologous recombination involves DNA duplexes at similar stages of methylation, neither of which would be interpreted as “mismatched,” and thus the mismatch repair system does not act.
13. B-DNA normally has a helical twist of about 10 bp/turn, so the rotation per residue (base pair), $\Delta\phi$, is 36° . If the DNA is unwound to 18.6 bp/turn, $\Delta\phi$ becomes 19.4° . Thus, the change in $\Delta\phi$ is 16.6° .
14. Replication: SSB; DUE; Tus; S-CDK; Cdc6; MCM proteins; Sid2 & Sid3; Dpb11; Cdc45; GINS complex; geminin

Repair: SSB; PriA; BRCA; Rad54; Ku70/80; DNA ligase 4; photolyase; DNA glycosylase; XPA protein

Recombination & transposition: RecA; RuvC; SSB; Rad51; RAG1 & RAG2; Ku70/80; DNA ligase 4

15. Consider the two DNA duplexes, WC and wc , respectively, displayed as “ladders” in the following figure. The gap at the right denotes the initial cleavage, in this case of the W and w strands. Cleavage by resolvase at the arrows labeled 1 and ligation of like strands (W with w and C with c) will yield patch recombinants; cleavage at the arrows labeled 2 and ligation of like strands gives splice recombinants.

16. The DNA is: GCTA
CGAT

a. HNO_2 causes deamination of C and A. Deamination of C yields U, which pairs the way T does, giving:

GTTA and ACTA and (rarely) ATTA
CAAT TGAT TAAT

Deamination of A yields I, which pairs as G does, giving:

GCTG and GCCA and (rarely) GCCG
CGAC CGGT CGGC

b. Bromouracil usually replaces T, and pairs the way C does:

GCCA and GCTG and (rarely) GCCG
CGGT CGAC CGGC

Less often, bromouracil replaces C, and mimics T in its base-pairing:

GTTA and ACAT and (rarely) ATTA
CAAT TGTA TAAT

c. 2-Aminopurine replaces A and normally base-pairs with T but may also pair with C:

GCTG and GCCA and (rarely) GCCG
CGAC CGGT CGGC

17. a.

5'-AGTTGCCATAGCATGGATCACGACAGTAC
ATA-3'

3'-TCAACTGTATCGTACGTACCTAATACTGTCATG
CTAT-5'

- b.

5'-AGTTGACATAGCATGGATGGATTACGACAGT
ACAATA-3'

3'-TCAAATGTATCGTACGTACCTAATGCTGTCAT
GCTAT-5'

- c.

5'-AGTTGACATAGCATCCATGGATTACGACAGTA
TGATA-3'

3'-TCAAATGTATCGTACGTACCTAATGCTATCAT
GCTAT-5'

- d.
 5'-AGTTGACACAGCATGCATGGATTACGACAGT
 ACGACA-3'
 3'-TCAACTGTATCGTAAGTACCTAATGCTATCATG
 CTAT-5'
18. Transposons are mobile genetic elements that can move from place to place in the genome. Insertion of a transposon within or near a gene may disrupt the gene or inactivate its expression.
 19. Proline
 20. The IgG proteins undergo glycosylation in the ER. Section 7.5e discusses the effects of glycosylation on the properties of proteins.
 21. Hexameric helicases unwind DNA at a cost of 1 ATP/nucleotide. The genome of *E. coli* K12 consists of 4,686,137 nucleotides, so 4,686,137 ATP equivalents would be needed to completely unwind the *E. coli* K12 chromosome.
 22. Antibodies against specific proteins are commonly used protein identification tools. Armed with an antibody specific for DNA polymerase III, another antibody specific for DNA polymerase IV, and a procedure to separate replication forks (large macromolecular complexes) from soluble proteins (gel filtration, centrifugation?), addition of DNA polymerase IV should lead to association of IV with the replication fork and release of III. IV should now be found in the large macromolecular complex and III among the soluble proteins.
 23. Eukaryotic translesion DNA polymerases with small and stubby thumb and finger domains are error-prone because they lack the structural elements ensuring high selectivity for the proper dNTP substrate. Since 3'-exonuclease activity is a proofreading activity, translesion DNA polymerases would not need it.
 24. a. Cells exit the cell at G₁ and enter G₀ because this stage is prior to DNA replication. Once DNA replication takes place, cells move on to mitosis.
 b. Progression through the cell cycle is regulated at checkpoints. Checkpoints, which control whether the cell continues into the next phase, ensure that steps necessary for successful completion of each phase of the cycle are satisfactorily accomplished. If conditions for advancement to the next phase are not met, the cycle is arrested until they are. Checkpoints depend on cyclins and cyclin-dependent protein kinases (CDKs). Cyclins are synthesized at one phase of the cell cycle and degraded at another. CDK interaction with a specific cyclin is essential for the protein kinase activity of the CDK. In turn, these CDKs control events at each phase of the cycle by targeting specific proteins for activation (or inactivation) through phosphorylation. Destruction of the phase-specific cyclin at the end of the phase inactivates the CDK.
 25. Recombination in codon 97 suggests that the *V_k* gene provides codons 94–96, which are GTT CAT CTT and specify Val-His-Leu. The fourth codon is either TTG (Leu), CTG (Leu), or CGG (Arg). CGG (Arg) would be the change. However, the desirability of a change cannot be anticipated.
 26. Consult the PSafe website entry for reverse transcriptase to compose your answer.
 27. Consult the PSafe website entry for RFC to compose your answer.

Think-Pair-Share Question:

1. To detect general mutagenic effects, one could study the growth rate of a cell line or bacteria during or after exposure to the environmental factor. If significant mutations of the genome have occurred, one can assume that growth curve of a cell line or bacteria would be slower compared to the control experiments. With eukaryotic cells one could even look at the chromosomes for any aberrations that may be observable.
2. To detect mutations in a specific gene, one could employ PCR techniques with the proper primers to create a multitude of copies of the gene of interest. The gene then can be sequenced and evaluate for potential mutations.

Chapter 29

1. The first AUG codon is underlined:

5'-AGAUCCGUAUGGCGAUCUCGACGAAGACUCCUA
 GGGAAUCC...

Reading from the AUG codon, the amino acid sequence of the protein is:

(N-term)Met-Ala-Ile-Ser-Thr-Lys-Thr-Pro-Arg-Glu-Ser...

2. See Figure 29.3 for a summary of the events in transcription initiation by *E. coli* RNA polymerase. A gene must have a promoter region for proper recognition and transcription by RNA polymerase. The promoter region (where RNA polymerase binds) typically consists of 40 bp to the 5'-side of the transcription start site. The promoter is characterized by two consensus sequence elements: a hexameric TTGACA consensus element in the –35 region and a Pribnow box (consensus sequence TATAAT) in the –10 region (see Figure 29.4).
3. The fact that the initiator site on RNA polymerase for nucleotide binding has a higher K_m for NTP than the elongation site ensures that initiation of mRNA synthesis will not begin unless the available concentration of NTP is sufficient for complete synthesis of an mRNA.
4. First, transcription is compartmentalized within the nucleus of eukaryotes. Furthermore, in contrast to bacteria (which have only a single kind of RNA polymerase), eukaryotes possess three distinct RNA polymerases—I, II, and III—acting on three distinct sets of genes (see Section 29.3). The subunit organization of these eukaryotic RNA polymerases is more complex than that of their bacterial counterparts. The three sets of genes are recognized by their respective RNA polymerases because they possess distinctive categories of promoters. In turn, all three polymerases interact with their promoters via particular transcription factors that recognize promoter elements within their respective genes. Protein-coding eukaryotic genes, in analogy with prokaryotic genes, have two consensus sequence elements within their promoters, a TATA box (consensus sequence TATAAA) located in the –25 region, and *Inr*, an initiator element that encompasses the transcription start site. In addition, eukaryotic promoters often contain additional short, conserved sequence modules such as enhancers and response elements for appropriate regulation of transcription. Transcription termination differs as well as prokaryotes and eukaryotes. In prokaryotes, two transcription basic termination mechanisms occur: *rho* protein-dependent termination and DNA-encoded termination sites. Transcription in eukaryotes tends to be imprecise, occurring downstream from consensus AAUAAA sequences known as poly(A) addition sites. An important aspect of eukaryotic transcription is post-transcriptional processing of mRNA (see Section 29.5).

5. $\alpha_2\beta\beta'\sigma$: protein complex of prokaryotic RNA polymerase
 TATAAT: Pribnow box as promoter for RNA transcription
 RPBI through 12: polypeptides (subunits) of human and yeast RNA polymerase
 (YSPTSPS)₂₇ or ₅₂: repeat sequence of C-terminal of RPBI
 CREs: *cis*-regulatory elements; promoter sites for eukaryotic RNA transcription
 MREs: metal response elements
 GREs: glucocorticoid response elements
 TBP: TATA-binding protein
 KMTs: lysine methyltransferases
 HTH: helix-turn-helix motif in DNA-binding proteins
 Cys-x₂-Cys-x₁₂-His-x₃-His: repeat sequence of Zn-finger motif in DNA-binding proteins
 AAUAAA: polyadenylation signal for post-transcription processing of RNA.
6. When DNA-binding proteins “read” specific base sequences in DNA, they do so by recognizing a specific matrix of H-bond donors and acceptors displayed within the major groove of B-DNA by the edges of the bases. When DNA-binding proteins recognize a specific DNA region by “shape readout,” the protein is discerning local conformational variations in the cylindrical surface of the DNA double helix. These conformational variations are a consequence of unique sequence information contributed by the base pairs that make up this region of the DNA.
7. The metallothioneine promoter is about 265 bp long. Because each bp of B-DNA contributes 0.34 nm to the length of DNA, this promoter is about 90 nm long, covering 26.5 turns of B-DNA (10 bp/turn). Each nucleosome spans about 146 bp, so about two nucleosomes would be bound to this promoter.
8. If cells contain a variety of proteins that share a leucine zipper dimerization motif but differ in their DNA recognition helices, heterodimeric *bZIP* proteins can form that will contain two different DNA contact basic regions (consider this possibility in light of Figures 29.33 and 29.34). These heterodimers are no longer restricted to binding sites on DNA that are dyad-symmetric; the repertoire of genes with which they can interact thus will be dramatically increased.
9. Exon 17 of the fast skeletal muscle troponin T gene is one of the mutually exclusive exons (see Figure 29.45). Deletion of this exon would cut by half the alternative splicing possibilities, so only 32 different mature mRNAs would be available from this gene. If exon 7, a combinatorial exon, were duplicated, it would likely occur as a tandem duplication. The different mature mRNAs could contain 0, 1, or 2 copies of exon 7. The 32 combinatorial possibilities shown in the center of Figure 29.45 represent those with 0 or 1 copy of exon 7. Those with 2 copies are 16 in number: 456778, 56778, 46778, 6778, 45778, 4778, 5778, 778, 4577, 577, 5677, 45677, 4677, 477, 677, and 77. Given the mutually exclusive exons 17 and 18, 96 different mature mRNAs would be possible.
10. 32, 63, and 127
11. Modifications include acetylation and methylation of Lys residues, methylation of Arg residues, and phosphorylation of Ser residues. The positively charged Lys residues interact electrostatically with phosphate groups on the DNA backbone, so these interactions would be diminished through acetylation. Methylation of Lys and Arg residues introduces bulky aliphatic groups that have the potential to cause steric hindrances between the DNA backbone and the histone tails. Such methylations (as well as the other modifications discussed here) may also establish recognition sites for chromatin-binding proteins that could modulate DNA:histone interactions. Phosphorylation of Ser residues would lead to electrostatic repulsion between the DNA backbone and the histone tails. Collectively, these modifications weaken histone:DNA interactions.
12. Methylation preserves the positive charge on amino groups but provides steric hinderance for other molecules to bind to the positive charge. The positive charge is shielded.
13. Because the *lac* repressor is tetrameric and each subunit has an inducer-binding site, it seems likely that inducer binding is cooperative. Cooperative binding of inducer would be advantageous because the slope of the *lac* operon expression versus [inducer] would be steeper over a narrower [inducer] range.
14. Capping of the 5'-end and polyadenylation of the 3'-end of mRNA protect the RNA from both 5'- and 3'-exonucleolytic degradation. Methylations at the 5'-end enhance the interaction between cap-binding protein eIF4E (see Figure 30.29), thus increasing the likelihood that the mRNA will be translated. Note also in Figure 30.29 that polyadenylation provides a protein-binding site for proper assembly of the 40S initiation complex essential to translation.
15. In the A Deeper Look box “A Mechanism for All Polymerases” in Section 28.2, the argument is made that polymerases have a common enzymatic mechanism for nucleotide addition to a growing polynucleotide chain based on two metal ions coordinated to the incoming nucleotide. These metal ions interact with two aspartate residues that are highly conserved in both DNA and RNA polymerases. The discovery of a second Mg²⁺ ion in the RNA polymerase II active site confirms to the universality of this model.
16. 50 bp of DNA is (50)(0.34 nm/bp) = 17 nm. Because 147 bp of DNA make 1.7 turns around the nucleosome (see Figure 11.29) = 86.4 bp/turn of DNA, 50 bp = 0.58 turns, or slightly more than $\frac{1}{2}$ turn of DNA around the histone core octamer. Promoter and response modules are about 20 to 25 bp.
17. Branch sites are a, c, and g.

18.

19. α -Helices composed of seven to eight residues would have a length of 1.05 to 1.2 nm. The overall diameter of B-DNA is about 2.4 nm, but the diameter at the bottom of major groove is significantly less (as a reference, the $\text{C}_1'-\text{C}_1'$ distance between base-paired nucleotides in separate chains is 1.1 nm). A distance along the B-DNA helix axis of 1.1 nm would correspond to about three base pairs, so if such an α -helix were laid along the major groove, it could not make contacts with more than three base pairs (see also Figure 29.31).
20. Because of its flat structure and aromatic character, Phe is well suited for driving a wedge between stacked bases in DNA or in DNA/RNA hybrids. Other aromatic amino acids are tryptophan, tyrosine and histidine. However, these amino acids contain hydrophilic features in their structure that could make them less efficient. Tryptophan, containing a fused double ring structure, may be too large for this purpose.
21. Phe⁶⁴⁴ acts as a wedge to separate the template and nontemplate strands from one another; Phe⁶⁴⁴ is located at the end of the Y-helix.
22. Hydroxyproline; asparagine; glycine (twice); valine; hydroxytryptophan
23. α -Amanitin binds in the large cleft between the two largest RNA polymerase II subunits, in particular to an α -helix, the "bridge" helix, running across this cleft. Its position in the cleft slows inhibits translocation of DNA and RNA and the entry of the next template nucleotide into the active site.
24. The two protein chains in pdb id = 1GU4 are identical through positions 268 (D) to 333 (Q). Leucines are found at positions 297, 304, 306, 313, 320, 324, 327, and 330. Those at positions 306, 313, 320, and 327 are seven residues apart, as in a leucine zipper. Basic residues (K and R) precede these leucines, occurring at positions 268, 275, 277, 280, 286, 287, 289, 291, 293, 295, and 302.
25. A protein such as CAP that interacts with phosphate groups in the DNA backbone does so via electrostatic interactions based on positively charged Arg and Lys side chains.
26. Chromatin is decompacted by HATs and chromatin remodeling complexes. Histone acetylation by HATs disrupts chromatin structure (see problem 11) and chromatin remodeling complexes then mediate ATP-dependent conformational changes in the chromatin that peels about 50 bp of DNA from the core octamer, exposing the DNA for access by the transcriptional machinery.

Think-Pair-Share Question:

a.

Possible 5' splicing sites are underlined

5'-ACUUGACAGUAGGUAAGUUAGGCCUAUCAUGAUC
GAGGUAAGUCGAGUCUCUUCUACAACCUCAGGAGC
 GAUGUCCUCCAGGCGGACUACGACCUGCGAGUG
 CAGCCCUUCCAGGAUGACGUAGCGAUGAC-3'

Possible branch sites are underlined

5'-ACUUGACAGUAGGUAAGUUAGGCCUAUCAUGAUC
GAGGUAAGUCGAGUCUCUUCUACAACCUCAGGAGC
GAUGUCCUCCAGGCGGACUACGACCUGCGAGUG
CAGCCCUUCCAGGAUGACGUAGCGAUGAC-3'

Possible 3' splicing sites are underlined

5'-ACUUGACAGUAGGUAAGUUAGGCCUAUCAUGAUC
GAGGUAAGUCGAGUCUCUUCUACAACCUCAGGAGC
GAUGUCCUCCAGGCGGACUACGACCUGCGAGUG
CAGCCCUUCCAGGAUGACGUAGCGAUGAC-3'

b. Possible splicing products could be:

Splicing at first 5' splicing site and first 3' splicing site yields:

5'-ACUUGACAGUAGGCGGACUACGACCUGCGAGUG
CAGCCCUUCCAGGAUGACGUAGCGAUGAC-3'

Splicing at first 5' splicing site and second 3' splicing site yields:

5'-ACUUGACAGUAGGAUGACGUAGCGAUGAC-3'

Splicing at second 5' splicing site and first 3' splicing site yields:

5'-ACUUGACAGUAGGUAAGUUAGGCCUAUCAUGAUC
GAGGCGGACUACGACCUGCGAGUGCAGCCCUUCCAG
GAUGACGUAGCGAUGAC-3'

Splicing at second 5' splicing site and second 3' splicing site yields:

5'-ACUUGACAGUAGGUAAGUUAGGCCUAUCAUGAUC
GAGGAUGACGUAGCGAUGAC-3'

Chapter 30

1. The cDNA sequence as presented:

CAATACGAAGCAATCCCGCGACTAGACCTTAAC...

represents six potential reading frames, the three inherent in the sequence as written and the three implicit in the complementary DNA strand, which as written 5'→3', is:

...GTTAAGGTCTAGTCGCGGGATTGCTTCGTATTG

Two of the three reading frames of the cDNA sequence given contain stop codons. The third reading frame is a so-called open reading frame (a stretch of coding sequence devoid of stop codons):

6. The wobble rules state that a first-base anticodon U can recognize either an A or a G in the codon third-base position; first-base anticodon G can recognize either U or C in the codon third-base position; and first-base anticodon I can recognize either U, C, or A in the codon third-base position. Thus, codons with third-base A or G, which are degenerate for a particular amino acid (Table 30.3 reveals that all codons with third-base purines are degenerate, except those for Met and Trp), could be served by single tRNA species with first-base anticodon U. More emphatically, codons with third-base

CAATACGAAGCAATCCCGCGACTAGACCTTAAC...

(alternate codons underlined)

The amino acid sequence it encodes is:

Gln-Tyr-Glu-Ala-Ile-Pro-Arg-Leu-Asp-Leu-Asn....

Two of the three reading frames of the complementary DNA sequence also contain stop codons. The third may be an open reading frame:

...GTTAAGGTCTAGTCGCGGGATTGCTTCGTATTG

(alternate codons underlined)

An unambiguous conclusion about the partial amino acid sequence of this cDNA cannot be reached.

2. A random (AG) copolymer would contain varying amounts of the following codons:

AAA AAG AGA GAA AGG GAG GGA GGG

codons for Lys Lys Arg Glu Arg Glu Gly Gly, respectively.

Therefore, the random (AG) copolymer would direct the synthesis of a polypeptide consisting of Lys, Arg, Glu, and Gly. The relative frequencies of the various codons are a function of the probability that a base will occur in a codon. For example, if the A/G ratio is 5/1, the ratio of AAA/AAG is $(5 \times 5 \times 5) / (5 \times 5 \times 1) = 5/1$. If the 3A codon is assigned a value of 100, then the 2A1G codon has a frequency of 20. From this analysis, the relative abundances of these amino acids in the polypeptide should be:

Lys = 120; Arg = 24; Glu = 24; Gly = 4.8

(Normalized to Lys = 100: Arg = 20; Glu = 20; Gly = 4)

3. Leucine and arginine are coded by six different codons that may differ in the first nucleotide of the codon.
4. Review the information in Section 30.2, noting in particular the two levels of specificity exhibited by aminoacyl-tRNA synthetases (1: at the level at $ATP \rightleftharpoons PP_i$ exchange and aminoacyl adenylate synthesis in the presence of amino acid and the absence of tRNA; and 2: at the level of loading the aminoacyl group on an acceptor tRNA).
5. Base pairs are drawn such that the B-DNA major groove is at the top (see following figure).

pyrimidines (C or U) are always degenerate and could be served by single tRNA species with first-base anticodon G. Wobble involving first-base anticodon I further minimizes the number of tRNAs needed to translate the 61 sense codons. Wobble tends to accelerate the rate of translation because the noncanonical base pairs formed between bases in the third position of codons and bases occupying the first-base wobble position of anticodons are less stable. As a consequence, the codon:anticodon interaction is more transient.

7. The stop codons are UAA, UAG, and UGA.

Sense codons that are a single-base change from UAA include CAA (Gln), AAA (Lys), GAA (Glu), UUA (Leu), UCA (Ser), UAU (Tyr), and UAC (Tyr).

Sense codons that are a single-base change from UAG include CAG (Gln), AAG (Lys), GAG (Glu), UCG (Ser), UUG (Leu), UGG (Trp), UAU (Tyr), and UAC (Tyr).

Sense codons that are a single-base change from UGA include CGA (Arg), AGA (Arg), GGA (Gly), UUA (Leu), UCA (Ser), UGU (Cys), UGC (Cys), and UGG (Trp).

That is, 19 of the 61 sense codons are just a single base change from a nonsense codon.

8. 1. Mutation from AGG (R) or CGG (R): changes the hydrophilic, positively charged arginine into the hydrophobic tryptophan.
2. Mutation from GGG (G): changes the smallest amino acid glycine into the largest amino acid tryptophan.
3. Mutation from UUG (L): changes the smaller, hydrophobic leucine into the larger, hydrophobic tryptophan.
4. Mutation from UCG (S): changes the smaller, hydrophilic serine into the larger, hydrophobic tryptophan.
5. Mutation from UAG or UGA (stop): elongates the translation process further; making for a longer protein.
6. Mutation from UGU or UGC (C): changes the smaller, hydrophilic cysteine (and capable of making disulfide bridges) into the larger, hydrophobic tryptophan.
9. The list of amino acids in problem 7 is a good place to start in considering the answer to this question. Amino acid codons in which the codon base (the wobble position) is but a single base change from a nonsense codon are the more likely among this list because pairing is less stringent at this position. These include UAU (Tyr) and UAC (Tyr) for nonsense codons UAA and UAG, and UGU (Cys), UGC (Cys), and UGG (Trp) for nonsense codon UGA.
10. RNA editing may change A into inosine (I). I behaves like G as it base-pairs with C. The editing of AUG into IUG is similar to changing AUG into GUG and if both can serve as start codon it would not affect the translation process.
11. The more obvious answer to this question is that eukaryotic ribosomes are larger, more complex, and hence slower than prokaryotic ribosomes. In addition, initiation of translation requires a greater number of initiation factors in eukaryotes than in prokaryotes. It is also worth noting that eukaryotic cells, in contrast to prokaryotic cells, are typically under less selective pressure to multiply rapidly.
12. The initiation of translation in prokaryotes depends on the close proximity of an AUG codon to the Shine–Dalgarno sequence. Mutation in that first AUG codon could prevent initiation, and the synthesis of the protein, as any other AUG codons on the mRNA may be too far removed from the Shine–Dalgarno sequence. The initiation of translation in eukaryotes depends on the scanning of the mRNA transcript for an AUG codon close to the 5' end. If the first AUG codon is mutated, a nearby AUG codon could serve as the starting point for translation but would lead to shorter protein sequence.
13. Each amino acid of a protein in an extended β -sheet–like conformation contributes about 0.35 nm to its length. $10 \text{ nm} \div 0.35 \text{ nm per residue} = 28.6 \text{ amino acids}$.
14. Larger, more complex ribosomes offer greater advantages in terms of their potential to respond to the input of regulatory influences, to have greater accuracy in translation, and to enter into interactions with subcellular structures. Their larger size may slow the rate of translation, which in some instances may be a disadvantage.
15. The universal organization of ribosomes as two-subunit structures in all cells—archaea, eubacteria, and eukaryotes—suggests that such an organization is fundamental to ribosome function. Translocation along mRNA, aminoacyl-tRNA binding, peptidyl transfer, and deacylated-tRNA release are processes that require repetitious uncoupling of physical interactions between the large and small ribosomal subunits.
16. Ribozymes are RNA molecules catalyzing biochemical reactions as protein-based enzymes do. 23S rRNA catalyzes the peptidyl transferase reaction and thus is a ribozyme.
17. Prokaryotic cells rely on *N*-formyl-Met-tRNA_i^{Met} to initiate protein synthesis. The tRNA_i^{Met} molecule has a number of distinctive features, not found in noninitiator tRNAs, that earmark it for its role in translation initiation (see Figure 30.16). Furthermore, *N*-formyl-Met-tRNA_i^{Met} interacts only with initiator codons (AUG or, less commonly, GUG). A second tRNA^{Met}, designated tRNA_m^{Met}, serves to deliver methionyl residues as directed by internal AUG codons. Both tRNA_i^{Met} and tRNA_m^{Met} are loaded with methionine by the same methionyl-tRNA synthetase, and AUG is the Met codon, both in initiation and elongation. AUG initiation codons are distinctive in that they are situated about 10 nucleotides downstream from the Shine–Dalgarno sequence at the 5'-end of mRNAs; this sequence determines the translation start site (see Figure 30.18). Eukaryotic cells also have two tRNA^{Met} species, one of which is a unique tRNA_i^{Met} that functions only in translation initiation. Eukaryotic mRNAs lack a counterpart to the prokaryotic Shine–Dalgarno sequence; apparently the eukaryotic small ribosomal subunit binds to the 5'-end of a eukaryotic mRNA and scans along it until it encounters an AUG codon. This first AUG codon defines the eukaryotic translation start site.
18. These three nucleotides on the acceptor stem of tRNA molecules interact with the peptidyl transfer center of 23S rRNA. These three nucleotides on tRNA are unpaired as they need to be free to base-pair with specific G's, C's or U of 23S rRNA (see Section 30.5e).
19. The Shine–Dalgarno sequence is a purine-rich sequence element near the 5'-end of prokaryotic mRNAs (see Figure 30.18). It base-pairs with a complementary pyrimidine-rich region near the 3'-end of 16S rRNA, the rRNA component of the prokaryotic 30S ribosomal subunit. Base pairing between the Shine–Dalgarno sequence and 16S rRNA brings the translation start site of the mRNA into the P site on the prokaryotic ribosome. Because the nucleotide sequence of the Shine–Dalgarno element varies somewhat from mRNA to mRNA, whereas the pyrimidine-rich Shine–Dalgarno-binding sequence of 16S rRNA is invariant, different mRNAs vary in their affinity for binding to 30S ribosomal subunits. Those that bind with highest affinity are more likely to be translated.
20. The most apt account is b. Polypeptide chains typically contain hundreds of amino acid residues. Such chains, attached as a peptidyl group to a tRNA in the P site, would show significant inertia to movement, compared with an aminoacyl-tRNA in the A site.

21. Elongation factors EF-Tu and EF-Ts interact in a manner analogous to the GTP-binding G proteins of signal transduction pathways (see Figure 15.20, as well as Section 32.4). EF-Tu binds GTP and in the GTP-bound form delivers an aminoacyl-tRNA to the ribosome, whereupon the GTP is hydrolyzed to yield EF-Tu:GDP and P_i . EF-Ts mediates an exchange of the bound GDP on EF-Tu:GDP with free GTP, regenerating EF-Tu:GTP for another cycle of aminoacyl-tRNA delivery. The α -subunit of the heterotrimeric GTP-binding G proteins also binds GTP. G_α has an intrinsic GTPase activity and the GTP is eventually hydrolyzed to form G_α :GDP and P_i . Guanine nucleotide exchange factors facilitate the exchange of bound GDP on G_α for GTP, in analogy with EF-Ts for EF-Tu. The amino acid sequences of EF-Tu and G proteins reveal that they share a common ancestry.
22. Four: two in the aminoacyl-tRNA synthetase reaction; one by EF-Tu; one by EF-G.
23. a. You can determine this from their relative sizes.
b. A-site tRNA is orange; the P-site tRNA is blue; the E site-tRNA is red.
c. The peptidyl transferase center; the 50S subunit.
d. The decoding center; the 30S subunit.
24. a. In the cleft between the 30S and 50S subunit.
b. The anticodon ends of the tRNAs.
c. The diphthamide moiety of eEF-2 helps maintain the correct reading frame during translocation.
25. Folding, post-translational modification with carbohydrates or other biomolecules, phosphorylation, intracellular transport to a particular location, anchoring in a membrane.
26. The Q β phage replicase mRNA shows the most consecutive perfect matches (6) complementary to the Shine–Dalgarno sequence.
27. Chloramphenicol consists of an aromatic ring and several polar functions (a nitro group, two —OH groups, and an amine-N). The aromatic ring might intercalate between bases in the 23S rRNA peptidyl transferase site, the polar functions might form H bonds with nitrogenous bases or sugar —OH groups in the rRNA. The —NO₂ group is also rather bulky in addition to being polar, so it could disrupt peptidyl transferase in a number of ways.

Think-Pair-Share Question:

- a. 5'-CGUACUAUGCACGAUUAUCUCAGAACCUGAAACGUAUU-3'
MHDYLR
- b. 1. Mutation occurred before the START codon.
2. Mutation occurred after the STOP codon.
3. Mutation may lead to the same amino acid.
4. Mutation may lead to a similar amino acid and not change the overall functionality of the protein. Examples would be D $\rightarrow$ E, Q $\rightarrow$ N, L $\rightarrow$ I or T $\rightarrow$ S.

5. Mutation may change an amino acid in a non critical part of the protein and not alter the protein's functionality. As long as the protein maintains the required 3D shape, it may still be functional.
6. Mutation may occur in an intron that is cut out before translation into the functional protein.

Chapter 31

1. Human rhodanese has 296 amino acid residues. Its synthesis would require the involvement of 4 ATP equivalents per residue or 1184 ATP equivalents. Folding of rhodanese by the Hsp60 α_{14} complex consumes another 130 ATP equivalents. The total number of ATP equivalents expended in the synthesis and folding of rhodanese is approximately 1314.
2. Because a single proteolytic nick in a protein can doom it to total degradation, nicked proteins clearly are not tolerated by cells and are degraded quickly. Cells are virtually devoid of partially degraded protein fragments, which would be the obvious intermediates in protein degradation. The absence of such intermediates and the rapid disappearance of nicked proteins from cells indicate that protein degradation is a rigorously selective, efficient cellular process.
3. *Hsp70*: Hsp70 binds to exposed hydrophobic regions of unfolded proteins. The Hsp70 domain involved in this binding is 18 kD in size and therefore would have a diameter of roughly 3 nm (see problem 5 for the math). Assuming the hydrophobic binding site of Hsp70 stretches across its diameter, it would interact with about $3 \text{ nm} / 0.35 \text{ nm} = 8$ or 9 amino acid residues. Multiple Hsp70 monomers could interact with longer hydrophobic stretches. So, for Hsp70 to interact with a polypeptide chain does not necessarily depend on the protein's size, but it does depend on its hydrophobicity (and absence of charged groups).

Hsp70 and Hsp60 chaperonins: Proteins that interact with both of these classes of chaperones not only must fit the description for Hsp70 targets but must also be small enough to access the Hsp60 chaperonin chamber, which has a diameter of about 5 nm. This restriction means that Hsp60 cannot interact with proteins more than roughly 50 kD in mass (see problem 5).

4. Many eukaryotic proteins have a multidomain or modular organization, where each module is composed of a contiguous sequence of amino acid residues that folds independently into a discrete domain of structure (see Figure 6.24 for examples of this type of sequence and structure organization). Such proteins would be ideal for co-translational folding: As each newly synthesized contiguous sequence emerges from the ribosome tunnel, it begins folding into its characteristic domain structure. The final, fully folded state of the complete protein would be achieved when the various domains assumed their proper spatial relationships to one another through hinge motions occurring at intradomain regions of the protein.
5. The maximal diameter for a spherical protein would be 5 nm (radius = 2.5 nm). The volume of this protein is given by $V = \frac{4}{3}\pi r^3 = 4/3(3.14)(2.5 \times 10^{-9} \text{ m})^3 = 65.4 \times 10^{-21} \text{ mL}$. If its density

is 1.25 g/mL, its mass would be $(1.25 \text{ g})(65.4 \times 10^{-21} \text{ mL}) = 81.8 \times 10^{-21} \text{ g/molecule}$, so its molecular weight = $(6.023 \times 10^{23})(81.8 \times 10^{-21} \text{ g}) = 492.5 \times 10^2 \text{ g/mol} = 49,250 \text{ g/mol}$, or about 50 kD.

6. There are $2^7 - 1$, or 127 different phosphorylated forms for a protein having 7 separate phosphorylation sites.
7. 32; one unphosphorylated form and 31 ($2^5 - 1$) phosphorylated forms.
8. GrpE catalyzes nucleotide exchange on DnaK, replacing ADP with ATP, which converts DnaK back to a conformational form having low affinity for its polypeptide substrate. This change leads to release of bound polypeptide, giving it the opportunity to fold, which is an important step in DnaK function. EF-Ts catalyzes nucleotide exchange on EF-Tu, converting it to the conformational form competent in aminoacyl-tRNA binding. Binding of the aminoacyl-tRNA:EF-Tu complex to the ribosome A site triggers the GTPase activity of EF-Tu as codon:anticodon recognition takes place and the aminoacyl-tRNA:EF-Tu complex conformationally adjusts to the A site. DnaJ delivers an unfolded polypeptide chain to DnaK, and its interaction with DnaK also triggers the ATPase activity of DnaK, whereupon the DnaK:ADP complex forms a stable complex with the unfolded polypeptide. In both instances, hydrolysis of bound nucleoside triphosphate is triggered and leads to conformational changes that stabilize the respective complexes.
9. Protein targeting information resides in more generalized features of the leader sequences such as charge distribution,
- 13.

14. A different type of linkage (thioester) joins ubiquitin to E1 and E2 unlike the amide type of linkage between ubiquitin and other proteins. This different linkage does not target E1 and E2 for degradation.
15. E3 ubiquitin protein ligase selects proteins by the nature of the N-terminal amino acid. Proteins with Met, Ser, Ala, Thr, Val, Gly, or Cys at the amino terminus are resistant to its action. Proteins having Arg, Lys, His, Phe, Tyr, Trp, Leu, Ile, Asn, Gln,

relative polarity, and secondary structure, rather than amino acid sequence per se. Proteins destined for secretion have N-terminal amino acid sequence with one or more basic amino acids followed by a run of 6 to 12 hydrophobic amino acids. The sequence MRSLLILVLCFLPAALGK... has a basic residue (Arg) at position 2 and a run of 12 nonpolar residues (...LLILVLPLAALG...); thus, it appears to be a signal sequence for a secretory protein. Cleavage by the signal peptidase would occur between the G and K.

10. Translocation proceeds until a stop transfer signal associated with a hydrophobic transmembrane protein segment is recognized. The stop-transfer signal induces a pause in translocation, and the translocon changes its conformation such that the wall of this closed cylindrical structure either opens or exposes a hydrophobic path, allowing the transmembrane segment to diffuse laterally into the hydrophobic phase of the membrane.
11. The maximal diameter for a spherical protein would be 6 nm (radius = 3 nm). The volume of this protein is given by $V = \frac{4}{3}\pi r^3 = 4/3(3.14)(3 \times 10^{-9} \text{ m})^3 = 113 \times 10^{-21} \text{ mL}$. If its density is 1.25 g/mL, its mass would be $(1.25 \text{ g})(113 \times 10^{-21} \text{ mL}) = 141 \times 10^{-21} \text{ g/molecule}$, so its molecular weight = $(6.023 \times 10^{23})(141 \times 10^{-21} \text{ g}) = 851 \times 10^2 \text{ g/mol} = 85,100 \text{ g/mol}$, or about 85 kD.
12. The thickness of a phospholipid bilayer is 5 nm, so the overall channel formed by a 50S ribosome and the translocon channel is 15 nm; $15 \text{ nm} \div 0.35 \text{ nm per amino acid} = \text{about } 43 \text{ amino acid residues}$.

Asp, or Glu at their N-terminus are susceptible. N-terminal Pro residues lack a free α -amino group, so such proteins are not susceptible.

16. As shown in the figure, a nucleophilic attack by the alcohol functional group of threonine will release the N-terminal portion of the targeted peptide and covalently link the C-terminal portion of the peptide to threonine. Subsequent hydrolysis is needed to release the C-terminal portion of the peptide.

17. The cell cycle relies on the cyclic synthesis and destruction of cell cycle regulatory proteins. Lactacystin inhibits cell cycle progression by interfering with programmed destruction of proteins by proteasomes.
18. The presence of methionine at the N-terminus of a protein prevents degradation by the ubiquitin/proteasome system. Removal of the methionine exposes a new N-terminal amino acid and, depending on the nature of this amino acid, the protein may become more or less susceptible to degradation.
19. The temperature-induced switch could be based on a temperature-dependent conformational change in the HtrA protein that brings the His-Ser-Asp catalytic triad into the proper spatial relationship for protease function.
20. a. EQWERTGHGV**KQ**EGTYPARSTW
c. YQWEFQAASDDF**IKND**PLKIYYN
21. There are many other post-translational modifications, including acylation, alkylation, amidation (at a protein's C-terminus), biotinylation, formylation, glycosylation, isoprenylation, and oxidation. See also Table 5.4.
22. Disulfide bridge formation, modification with carbohydrates, modification with fatty acids or GPI anchor, oxidation of amino acids (proline to hydroxyproline), modification with cofactors like FAD or lipoamide.

23. This exercise is left to the student.
24. A phosphodegron is defined as one or a series of phosphorylated residues on a substrate protein that interact directly with a protein-protein interaction domain in an E3 ubiquitin ligase, thereby linking the substrate to the ubiquitin conjugation machinery. Phosphorylation can affect the affinity of target protein binding; alternatively, phosphorylation can stimulate E2 activity.
25. It depends on which amino acid is penultimate. If Arg, Lys, His, Phe, Tyr, Trp, Leu, Ile, Asn, Gln, Asp, or Glu follow immediately after Met, the protein will have a short half-life after Met removal. If Ser, Ala, Thr, Val, Gly, Cys, Pro, or another Met follow, the protein should have a long half-life after N-terminal Met removal.

Think-Pair-Share Question:

Possible answers:

1. It requires only one type of chemical linkage to create proteins: amide bond formation between different amino acids. The primordial soup of precursors could have contained a multitude of amino acids that could be linked into primordial peptides or proteins by a suitable catalytic surface. It takes more (and different types) of chemical reactions (add base to sugar, add phosphate to sugar, link phosphates together) to generate a nucleic acid structure like RNA molecules.
2. The functionality of a protein is determined in large part by its tertiary structure. A chain of amino acids could fold into a particular 3D structure, either spontaneously or shaped by the boundaries of a cavity of the catalyzing mineral. As the study of biochemistry shows, there appears to be no limit to what can be achieved by (properly folded) proteins. If a diverse range of 3D structures can be generated, a diverse range of chemical reactions could be catalyzed by the proteins. RNA molecules can adopt complex 3D structures and can be catalytically functional. Compared to proteins the catalytic functionality of RNA molecules appears to be less diverse.
3. The "information" related to a particular functionality is determined by the 3D structure of a protein. Thus, "structural fidelity" rather than "chemical fidelity" is sufficient to copy the "information" within a protein. If chemically different polypeptides fold into a similar shape, similar functionality may be achieved. A multitude of examples of this principle can be found throughout the many chapters in the handbook.

Within a primordial catalytic system, chemically different polypeptides could be generated randomly, but shaped similarly (by the boundaries of the cavity of the mineral catalyst) and thus be functionally similar. Hence, the "information" within proteins could be copied. The randomness of the synthesis could provide sufficient opportunities to introduce "errors" or changes in the polypeptide structures to allow for an evolutionary force towards ever increasing efficiency (and specialization) in a protein's functionality.

Chapter 32

1. Polypeptide hormones constitute a larger and structurally more diverse group of hormones than either the steroid or amino acid-derived hormones, and it thus might be concluded that the specificity of polypeptide hormone-receptor interactions, at least in certain cases, should be extremely high. The steroid hormones may act either by binding to receptors in the plasma membrane or by entering the cell and acting directly with proteins

controlling gene expression, whereas polypeptides and amino acid–derived hormones act exclusively at the membrane surface. Amino acid–derived hormones can be rapidly interconverted in enzyme-catalyzed reactions that provide rapid responses to changing environmental stresses and conditions. See *The Student Solutions Manual, Study Guide and Problems Book* for additional information.

2. The cyclic nucleotides are highly specific in their action, because cyclic nucleotides play no metabolic roles in animals. Ca^{2+} ion has an advantage over many second messengers because it can be very rapidly “produced” by simple diffusion processes, with no enzymatic activity required. IP_3 and DAG, both released by the metabolism of phosphatidylinositol, form a novel pair of effectors that can act either separately or synergistically to produce a variety of physiological effects. DAG and phosphatidic acid share the unique property that they can be prepared from several different lipid precursors. Nitric oxide, a gaseous second messenger, requires no transport or translocation mechanisms and can diffuse rapidly to its target sites.
 3. Nitric oxide functions primarily by binding to the heme prosthetic group of soluble guanylyl cyclase, activating the enzyme. An agent that could bind in place of NO—but that does not activate guanylyl cyclase—could reverse the physiological effects of nitric oxide. Interestingly, carbon monoxide, which has long been known to bind effectively to heme groups, appears to function in this way. Solomon Snyder and his colleagues at Johns Hopkins University have shown that administration of CO to cells that have been stimulated with nitric oxide causes attenuation of the NO-induced effects.
 4. Herbimycin, whose structure is shown in the following figure, reverses the transformation of cells by Rous sarcoma virus, presumably as a direct result of its inactivation of the viral tyrosine kinase. The manifestations of transformation (on rat kidney cells, for example) include rounded cell morphology, increased glucose uptake and glycolytic activity, and the ability to grow without being anchored to a physical support (termed *anchorage-independent growth*). Herbimycin reverses all these phenotypic changes. On the basis of these observations, one might predict that herbimycin might also inactivate tyrosine kinases that bear homology to the viral pp60^{v-src} tyrosine kinase. This inactivation has in fact been observed, and herbimycin is used as a diagnostic tool for implicating tyrosine kinases in cell-signaling pathways.
- The chemical structure of Herbimycin is a complex polycyclic molecule. It features a central core with several fused and bridged rings. Key functional groups include multiple methoxy (H₃CO) and methyl (CH₃) groups, as well as amide (H₂NOCO) and carbonyl (C=O) groups. The structure is highly symmetrical and contains several chiral centers.
5. The identification of phosphorylated tyrosine residues on cellular proteins is difficult. Quantities of phosphorylated proteins are generally extremely small, and to distinguish tyrosine phosphorylation from serine/threonine phosphorylation is tedious and laborious. On the other hand, monoclonal antibodies that recognize phosphotyrosine groups on protein provide a sensitive means of detecting and characterizing proteins with phosphorylated tyrosines, using, for example, Western blot methodology.
 6. 1. ATP [γ - ^{32}P] is ATP with the terminal phosphate group radioactively labeled as ^{32}P .
2. Mix the kinase enzyme of interest with its possible substrates and add ATP [γ - ^{32}P]. Using typical protein separation techniques (see Chapter 5) evaluate which proteins carry a radioactive label, indicative of their phosphorylation by the kinase of interest.
 7. Hormones act at extremely low concentrations, but many of the metabolic consequences of hormonal activation (release of cyclic nucleotides, Ca^{2+} ions, DAG, etc., and the subsequent alterations of metabolic pathways) occur at and involve higher concentrations of the affected molecular species. As we have seen in this chapter, most of the known hormone receptors mediate hormonal signals by activating enzymes (adenylyl cyclase, phospholipases, protein kinases, and phosphatases). One activated enzyme can produce many thousands of product molecules before it is inactivated by cellular regulation pathways.
 8. Vesicles with an outside diameter of 40 nm have an inside diameter of approximately 36 nm and an inside radius of 18 nm. The data correspond to a volume of 2.44×10^{-20} L. Then $10,000 \text{ molecules} / 6.02 \times 10^{23} \text{ molecules/mole} = 1.66 \times 10^{-20} \text{ mole}$. The concentration of acetylcholine in the vesicle is thus $1.66/2.44 \text{ M}$ or 0.68 M .
 9. The evidence outlined in this problem points to a role for cAMP in fusion of synaptic vesicles with the presynaptic membrane and the release of neurotransmitters. GTP γ S may activate an inhibitory G protein, releasing $\text{G}_{\alpha i}(\text{GTP}\gamma\text{S})$, which inhibits adenylyl cyclase and prevents the formation of requisite cAMP.
 10. In both cases, the fraction of receptor that is bound with hormone is approximately 50%.
 11. Glucagon signals low blood sugar levels (or low caloric status in general) and will promote the breakdown of glycogen to provide glucose and will promote the release of fatty acids from adipose tissues to raise the caloric status. Epinephrine signals “stress” or a “fight-or-flight” situation. Under “fight-or-flight” circumstances muscle cells will need ATP for muscle contraction and the release of glucose from glycogen or fatty acids from adipose tissues would be promoted by epinephrine in that context.
 12. Statin drugs inhibit the synthesis of new cholesterol in human subjects, but they have no effect on dietary intake of cholesterol. Dietary cholesterol accounts for approximately two-thirds of all body cholesterol. Moreover, synthesis of steroid hormones is not generally dependent on ambient levels of cholesterol in the body. Thus the taking of statin drugs would not be expected to influence the levels and functions of steroid hormones in the body.
 13. β -Strands indeed provide more genetically economical means of traversing a membrane. However, the only significant classes of proteins that employ β -strands for membrane traversal are the porins and toxins such as hemolysin. These β -strand structures provide no easy way to communicate conformational changes across the membrane. On the other hand, bundles of α -helices are more able to convey and transmit conformational changes across a bilayer membrane.
 14. α -helices are more flexible and thus more suitable for cell signaling through conformational changes in proteins. Although not a receptor, the discussions of the structure of calmodulin in Section 32.4k and Figure 32.33 provide a good example of this property of α helices.

15. The formation and breakdown of cAMP:

16. Activation of G-proteins requires and consumes GTP. The GDP produced by the activated G-proteins is converted back to GTP using ATP.

17. Three possible targets could be: inhibition of GTPase activity of $G_{i\alpha}$, inhibition of adenylyl cyclase or inhibition of phosphodiesterase.

The inhibition of GTPase activity in $G_{i\alpha}$ would be more selective. The G_i protein is often selectively activated by a specific receptor itself activated by its specific ligand. Thus, this type of inhibition would affect only one cell signaling pathway and leave cAMP production through other receptors/ligands untouched.

The interventions on adenylyl cyclase or phosphodiesterase would be less selective as they may interfere with the signaling efforts of many different hormones and receptors. These two enzymes are often targeted by multiple different signaling pathways.

18. The point at which no ion flow occurs is the point of equilibrium that balances the chemical and electrical forces across a membrane. The Nernst equation is obtained by setting ΔG to zero in Equation 9.2. Rearrangement yields

$$RT \ln (C_2/C_1) = -ZF\Delta\psi$$

Using the data in Figure 32.49, one can use this equation to yield an equilibrium potential for K^+ of -80 mV and an equilibrium potential for Na^+ of $+55.5$ mV.

19. Using the Goldman equation, one can calculate $\Delta\psi = -60$ mV, in agreement with values measured experimentally in neurons.

20. The resting potential in neurons is -60 mV. Local depolarization of the membrane causes the potential to rise approximately

20 mV to about -40 mV. This change causes the Na^+ channels to open and Na^+ ions begin to flow into the cell. This causes the potential to continue increasing to a value of about $+30$ mV. Because this value is close to the equilibrium potential for Na^+ , the Na^+ channels begin to close and K^+ channels open. K^+ rushes out of the neuron, returning the membrane potential to a very negative value. There is a slight overshoot of the potential, and the K^+ channels close and the resting membrane potential is restored.

21. The binding of hormones, neurotransmitters or other molecules to a specific receptor on the surface of the neuron or the arrival of an action potential from a neighboring neuron.

22. Pathway steps (in Figure 32.4) that involve amplification include the tyrosine kinase of the receptor protein, Raf, MAPKK, and MAPK.

23. If Ras were mutated so as to have no GTPase activity, it would activate Raf indefinitely, and the pathway would run as if hormones were continually activating the receptor tyrosine kinase.

24. There are several possible answers to this problem. One is that the original assays of kinase activities that reflected signaling effects were carried out on whole-cell preparations, in which the G-protein-dependent and G-protein-independent activities would appear as components of the overall activation. The availability of G-protein-uncoupled receptor mutants and ligands that could stimulate arrestin recruitment without G-protein activation made it possible to distinguish the G-protein-dependent and G-protein-independent effects. (See Ahn, S, et al., 2020. Snapshot: β -Arrestin Functions. *Cell* **182**: 1362-13362.e1. for additional discussion of these issues.)

25. Conditions like epilepsy, insomnia, anxiety are caused by the hyperactivity of certain neurons. Using agonists (activators) of an inhibitory neuron makes sense in this context.

26. Malathion has been used for years in the eradication of boll weevils, but it has not presented a serious toxicity problem in this program. Apparently, malathion is very toxic to insects, and relatively less toxic to humans, particularly in the low volume applications used for this purpose.

27. This exercise is left to the student and will presumably be different for every student.

28. This exercise is left to the student and will presumably be different for every student.

29. This exercise is left to the student and will presumably be different for every student.

Think-Pair-Share Question:

1. The concentrations of the hormones present in the circulation.
2. The number or density of receptors on the surface of the target cell.

3. The number of binding sites per receptor molecule or complex.
4. The affinity (K_d constant) of the receptors for their respective ligand. This relates to the "quality" of the receptor (proper folding; proper orientation through membrane).

5. Presence and concentration of the intracellular receptor ligands.

6. Presence and concentration of all the downstream effectors in the signaling pathways.
